Ilmenite, FeTiO3, is a common mineral in nature, existing as an accessory phase in the most basic igneous and metamorphic rocks. For example, FeTiO3 is derived from the upper mantle. Therefore, an understanding of the high-pressure physics of FeTiO3 is of fundamental importance in the study of rock magnetization. Here, we provide experimental evidence of lattice compression of FeTiO3 powder using super-high-energy ball milling, enabling the very high collision energy of 420 times gravitational acceleration. A sample obtained as an ilmenite-hematite 0.5FeTiO3·0.5Fe2O3 solid solution showed a decrease in molar volume of approximately 1.8%. Consequently, the oxidation state in FeTiO3 powder was changed into almost Fe2+Ti3+, corresponding to 87% Fe3+ of the total Fe for FeTiO3, resulting in the emergence of ferromagnetism. This new ferromagnetic behaviour is of crucial importance in the study of rock magnetization which is used to interpret historical fluctuations in geomagnetism. In addition, the super-high-energy ball mill can be used to control a range of charge and spin states in transition metal oxides with high pressure.

Ilmenite, FeTiO3, is a common mineral in nature, existing as an accessory phase in the most basic igneous and metamorphic rocks. For example, FeTiO3 is derived from the upper mantle down to depths of some 400 km and thus pressures of 12–13 GPa. Therefore, an understanding of the high-pressure physics of FeTiO3 is of fundamental importance in the study of rock magnetization. FeTiO3 is a typical transition metal oxide where the partially occupied d shells of the cations allow for a range of charge and spin states. Two types of cation charge ordering exist consistent with O2− anions, namely, Fe2+Ti4+ and Fe3+Ti3+, in which Fe has d-electron configurations of d6 and d5, respectively. The charge transfer excitation between these two oxidation states is known and has been observed in a number of Fe- and Ti-bearing minerals. This results in a rich variation of magnetic, electronics and structural transitions. The Fe3+/Fe2+ ratios in natural FeTiO3 minerals under high pressures, closely representative of the upper mantle pressure condition, have been studied experimentally using a diamond anvil cell in which the rate of Fe3+ formation by charge transfer in FeTiO3 samples showed a rapid increase from ambient up to 2 GPa and saturated at 40% beyond 2–4 GPa to the highest pressure of 14 GPa.

In a previous study, we reported that the lattice for trigonal FeTiO3 powder can be compressed by the high collision energy of 150 gravity using super-high-energy ball milling, whereas little lattice compression was found for FeTiO3 using conventional high-energy ball milling. This lattice compression is to be expected for the charge transfer in FeTiO3 with high pressure. Therefore, we have investigated the oxidation state of Fe cations in a FeTiO3 sample milled at a high-energy collision of 150 G by 57Fe Mössbauer spectroscopy (Fig. S1 and Table S1). Although the raw FeTiO3 powder only showed the oxidation state of Fe2+, i.e., before ball milling the sample, mixed oxygen states of Fe2+ and Fe3+ were confirmed in the FeTiO3 sample after ball milling at 150 G with a Fe3+...
rate of 15%. In this study, we mill the trigonal FeTiO₃ powder at a higher-energy collision of 420 G to increase the oxidation state of Fe³⁺ with high pressure. Consequently, the oxidation state in FeTiO₃ powder was changed into almost Fe³⁺Ti³⁺, resulting in the emergence of ferromagnetism. This magnetic behaviour with high pressure is of crucial importance in the study of rock magnetization which is used to interpret historical fluctuations in geomagnetism. Thus, a super-high-energy ball mill can be used to control a range of charge and spin states in transition metal oxides with high pressure, yielding the emergence of a large spectrum of functionalities such as metal-insulator transitions, superconductivity, thermoelectricity, and multiferroicity as well as magnetism.

Results and Discussion
The raw trigonal FeTiO₃ powder, labelled as raw FeTiO₃, was milled at a very high-energy collision of 420 G (see Methods). The sample was then characterized by measurement of X-ray diffraction (XRD) pattern with synchrotron radiation, as shown in Fig. 1. Notably, the peak position for the as-milled sample was remarkably shifted to a lower d-spacing in comparison with that for the raw powder. This shift in peak position suggests that the trigonal FeTiO₃ lattice can be compressed by the collision shock between the balls using super-high-energy ball milling, leading to charge transfer from Fe²⁺Ti⁴⁺ to Fe³⁺Ti³⁺ in FeTiO₃ with high pressure. Further, the peak position of the as-milled sample was considerably shifted towards a lower d-spacing with increasing collision energy from 150 to 420 G (Fig. S2).

Although metal iron, Fe, was generated from the surface of the steel balls by the super-high-energy ball milling of 150 G (Fig. S2), no peak due to iron was observed in the FeTiO₃ sample as-milled at 420 G, as shown in Fig. 1. This absence of iron is considered to be due to the difference in the experimental setup for the ball milling apparatus. The raw FeTiO₃ powder was milled at 150 G in a closed type steel vial, i.e., under a reduction atmosphere, and at 420 G in an open type steel vial, i.e., under an oxidation atmosphere. Therefore, the formation of haematite, α-Fe₂O₃, is presumed to occur via a reaction between oxygen gas in the air and the metal iron generated from the surface of the steel balls by employing an open type steel vial for the ball milling apparatus operated at 420 G. However, it is difficult to identify the formation from α-Fe₂O₃ by the XRD pattern (Fig. 1) because both FeTiO₃ and α-Fe₂O₃ crystallize in a corundum-derived structure and they usually exist in natural minerals as solid solutions. On the other hand, other iron oxides such as magnetite, Fe₃O₄, and maghemite, γ-Fe₂O₃, did not appear as new peaks in the FeTiO₃ sample as-milled at 420 G. However, one weak impurity peak marked with a cross appeared with an intensity of less than 5% of the main peak intensity, as shown in Fig. 1. The d value for this peak of 2.036 Å did not agree with the first peak for Fe metal (2.027 Å); this remains an unidentified phase.

To clarify the formation of α-Fe₂O₃ in the FeTiO₃ sample as-milled at 420 G, we have investigated the composition of Fe and Ti for the powder sample by an electron dispersion spectroscopy (EDS). The morphological and compositional features of raw FeTiO₃ powder and an as-milled sample are shown in Fig. 2. Notably, the intensity
of Fe in the as-milled sample was stronger than that in the raw powder, although the Fe and Ti elemental distribution was very homogeneous for the as-milled sample as well as the raw powder, as shown in Fig. 2. The compositional ratio for Fe: Ti was approximately 3:1 for the as-milled sample, while the ratio was 1:1 for the raw powder. Similar results were obtained for another as-milled powder sample by additional EDS analyses (Fig. S3). In general, the FeTiO₃ shows a solid solution towards \( \alpha \)-Fe₂O₃ and its chemical composition possesses \( x \text{FeTiO}_3 \cdot (1-x)\text{Fe}_2\text{O}_3 \). Therefore, it is considered that the ilmenite-hematite (IH) solid solution of 0.5FeTiO₃·0.5Fe₂O₃ was formed and the lattice of the IH solid solution powder was compressed by super-high-energy ball milling at 420 G.

The molar volume for the raw powder and obtained IH solid solution sample determined by least-squares refinement of their XRD patterns was 315.9 Å³ and 302.5 Å³, respectively, with the value for the raw FeTiO₃ powder in good agreement with that reported previously. The decrease in molar volume for the IH solid solution powder as-milled at 420 G was approximately 1.8%, which was estimated from the molar volume of 308 Å³ for 0.5FeTiO₃·0.5Fe₂O₃ bulk. This percentage of volume decrease due to the very high-energy collision of 420 G corresponds to that of a single crystal of trigonal FeTiO₃ under a high pressure condition of approximately 5 GPa at 300 K generated using a lever-type diamond anvil cell.

Figure 3 shows the \(^{57}\text{Fe}\) Mössbauer spectra measured at room temperature, with Table 1 listing the corresponding Mössbauer parameters. The spectrum obtained before ball milling showed a quadrupole doublet with an isomer shift, \( \delta \), of 1.08 mm s⁻¹, which is ascribed to Fe²⁺, with the parameters typical for paramagnetic ilmenite. On the other hand, the spectrum consisted of two doublets and three sextets fit lines (Fig. 3b) after super-high-energy ball milling at 420 G. The sextet due to Fe metal was not found, which is in good agreement with the result from the XRD pattern. Two sextets, red with \( \delta \) of 0.39 mm s⁻¹ and orange with \( \delta \) of 0.40 mm s⁻¹ fit lines, are ascribed to Fe³⁺ in the Fe₂O₃ component in IH solid solution because their Mössbauer parameters nearly
agree with those of α-Fe₂O₃. This appearance of two sextets in the Fe₂O₃ component seems to be caused by the R₃ space group of the IH solid solution, whereas the α-Fe₂O₃ has space group R₃c. These two sextets for the Fe₂O₃ component had a total absorption area of 61.2%, which is coherent with the composition of 0.5FeTiO₃·0.5Fe₂O₃ estimated by EDS analysis. Consequently, the residual two doublets and the other sextet are ascribed to the FeTiO₃ component in the IH solid solution.

Two doublets, purple with δ of 0.78 mm s⁻¹ and blue with δ of 0.20 mm s⁻¹ fit lines, are ascribed to Fe²⁺ and Fe³⁺, with an absorption area of 4.6% and 16.0%, respectively. The sextet, green fit line, with δ of 0.32 mm s⁻¹ is ascribed to Fe³⁺, with an absorption area of 18.2%. Therefore, the amount of Fe²⁺ for the FeTiO₃ component in the IH solid solution is only 13%, which seems to be a mixed oxidation state with Fe³⁺ because of its δ value of 0.78 mm s⁻¹. It is found that this large oxidation change from Fe²⁺ to Fe³⁺, corresponding to 87% Fe³⁺ of the total Fe for FeTiO₃, is caused by the lattice compression of FeTiO₃ by the super-high-energy ball milling at 420 G. Such very high-energy collision is effective on the oxidation change in Fe cation because of the slight oxidation rate for Fe³⁺ of 5–8% and 15% (Table S1) for conventional high-energy ball milling and super-high-energy ball milling at 150 G, respectively.

The compression rate for the IH solid solution powder sample obtained by the super-high-energy ball milling at 420 G is approximately 1.8%, which corresponds to that of a single crystal of trigonal FeTiO₃ under a high pressure condition of approximately 5 GPa generated using a diamond anvil cell. The Fe²⁺ to Fe³⁺ ratio in natural FeTiO₃ minerals under high pressures has been studied using a diamond anvil cell in which the oxidation rate for Fe³⁺ was approximately 40% at 5 GPa. It is considered that the higher Fe³⁺ rate of 87% obtained by the very high-energy collision of 420 G is achieved by a characteristic of the ball milling process in which the collision is continuously repeated during milling. The unit-cell compression in FeTiO₃ is quite anisotropic, with the c-axis being more compressible than the a-axis, so that this anisotropic compression seems to take place preferentially for the FeTiO₃ in IH solid solution powder by repeated very high-energy collisions during the super-high-energy ball milling.

**Figure 3.** $^{57}$Fe Mössbauer spectra for raw FeTiO₃ powder and a sample milled at 420 G. (a) Raw powder and (b) as-milled sample measured at room temperature. The coloured solid lines are fits to the data (see text and Table 1 for details).

| Species | A (%) | δ (mm s⁻¹) | Δ (mm s⁻¹) | Γ (mm s⁻¹) | H(T) |
|---------|-------|------------|------------|------------|------|
| a       |       |            |            |            |      |
| Fe²⁺    | 100   | 1.08       | 0.65       | 0.3        | —    |
| b       |       |            |            |            |      |
| Fe²⁺    | 4.6   | 0.78       | 1.55       | 0.43       | —    |

| Fe⁷⁺    | 28.3  | 0.39       | −0.21      | 0.81       | 46.8 |

Table 1. $^{57}$Fe Mössbauer spectra for raw FeTiO₃ powder and a sample milled at 420 G. (a) Raw powder and (b) as-milled sample measured at room temperature. SD is less than 0.03 (mm s⁻¹) and A: ratio (%), δ: isomer shift (mm s⁻¹), Δ: quadrupole splitting (mm s⁻¹), Γ: line width (mm s⁻¹), H: Magnetic field (T).
Notably, the FeTiO₃ component in compressed IH solid solution possessed the sextet, green fit line, as shown in Fig. 3b. This is to be expected for the emergence of ferromagnetism in FeTiO₃. Wilson et al. have reported computation of the magnetic property of FeTiO₃ from first principles²⁰, and according to them, ferromagnetism is stable in the charge transferred Fe³⁺Ti³⁺ state within the Hartree-Fock approximation. Therefore, we have measured the magnetic properties of the powder sample as-milled at 420 G by a superconducting quantum interference device (SQUID) magnetometer. Figure 4a shows magnetization M as a function of the applied magnetic field H at 300 and 100 K. The as-milled sample showed a mixed magnetic behaviour between ferromagnetism and paramagnetism, whereas the raw trigonal FeTiO₃ powder showed a paramagnetic state at 300 K. These results are consistent with the Mössbauer spectra (Fig. 3). It is found that the FeTiO₃ in compressed IH solid solution was weakly ferromagnetic and that its dependence on temperature was negligible. This magnetic behaviour is coherent with the temperature dependence of magnetization, as shown in Fig. 4b.

It is known that IH solid solution exhibiting R₃̅ symmetry shows large ferrimagnetism in thin films²¹–²³ and bulk samples¹⁴,²⁴. In this case, the cation charge orderings in FeTiO₃ is Fe²⁺Ti⁴⁺ without charge transfer and the slope in magnetization versus temperature is quite steep in comparison with that for the powder sample as-milled at 420 G (Fig. 4b). Therefore, it is considered that the ferromagnetism in compressed IH solid solution is not related to the conventional ferrimagnetism in the IH solid solution and that it emerges from the cation charge orderings of Fe³⁺Ti³⁺ by charge transfer in the compressed FeTiO₃. This ferromagnetic behaviour is of crucial importance to studies in which rock magnetization under high pressure is used to interpret historical fluctuations in the earth’s magnetic field²⁶. It is now an open question as to the reason why the compressed FeTiO₃ sample can be quenched by super-high-energy ball milling. It may be due to the charge transfer in FeTiO₃ because the irreversible nature of charge transfer in natural FeTiO₃ minerals has been shown in experimental study using a diamond anvil cell⁷.

**Conclusion**

In conclusion, we milled trigonal FeTiO₃ powder using super-high-energy ball milling at 420 G and succeeded in lattice compression of FeTiO₃ powder. A sample obtained as an IH solid solution showed a decrease in molar volume of approximately 1.8%. Consequently, charge transfer from Fe²⁺Ti⁴⁺ to Fe³⁺Ti³⁺ took place in FeTiO₃ with high pressure, resulting in the emergence of ferromagnetism. This finding enables us to infer that such simple and intense collisions induced by super-high-energy ball milling can be used to control the range of charge and spin states in transition metal oxides with high pressure. We believe that property tuning for many functional materials such as graphite²⁵ and graphene²⁶ with high pressure will be realized and that various high pressure materials²⁷ including silica²⁸ and titania²⁹ with α-PbO₂ structures will be synthesized based on the super-high-energy ball milling process.

**Methods**

**Materials.** The raw material was commercially available FeTiO₃ powder (99.9%, Mitsuwa Chemicals Co., Ltd) with a mean particle size of 149 µm.

**Super-high-energy ball milling.** One gram of FeTiO₃ powder was loaded into a 200 cm³ cylindrical steel vial along with 35 g of milling balls. The milling balls were commercial stainless steel balls such as SUS440C, which is a solid solution of iron (Fe, 83 wt.%), chromium (Cr, 16 wt.%), and carbon (C, 1 wt.%) with a diameter of 3 mm. The powder was super-high-energy ball milled using a Thinky Nano Pulverizer (NP-100, Thinky Corporation). The ball milling apparatus operated for 10 min in air atmosphere using an open type steel vial under 420 centrifugal forces, with the ball milling treatment repeated 3 times. It is considered that this short milling time of 30 min is suitable for maintaining the crystallinity of the powder sample. In this experiment, the open type vial was used in order to release the heat in the vial generated by the high collision energy of 420 G.

---

**Figure 4.** Magnetic properties of raw FeTiO₃ powder and a sample milled at 420 G. (a) Magnetization measured at 300 and 100 K. (b) Temperature dependence of the magnetization at 60 kOe.
XRD measurement. Powder x-ray diffraction patterns were measured for the samples filled inside a capillary with an inner diameter of 200 µm using a synchrotron x-ray source (λ = 0.65296 Å) in the BL15XU beam line at SPring-8, Harima, Japan.

SEM-EDS measurements. A small piece of the produced powder was suspended in ethanol by ultrasonication until a homogeneous suspension was obtained. The suspension was dropped onto an aluminium sample holder, dried, and examined by scanning electron microscopy (SEM) with electron dispersion spectroscopy (EDS) operated at 15 kV (JSM-7600F, JEOL).

Mössbauer measurements. We measured the $^{57}$Fe Mössbauer spectra using the constant acceleration method, using a $^{57}$Co(Rh) source and an α-Fe as a reference. γ-Ray radiation was monitored with a multi-channel analyser (MCA-7700, Seiko EG&G) using 512 channels for each spectrum. The obtained spectra were analysed by Lorentzian fitting using Mösswin 3.0i XP.

Magnetic measurements. We measured the magnetic properties using a conventional superconducting quantum interference device (SQUID) magnetometer (MPMS-XL, Quantum Design) under a magnetic field of up to 50 kOe in the temperature range from 5 to 300 K for dc-magnetization.
