Gene therapy using adeno-associated viral (AAV) vectors for the treatment of retinal degenerations has shown safety and efficacy in clinical trials. However, very high levels of vector expression may be necessary for the treatment of conditions such as Stargardt disease where a dual vector approach is potentially needed, or in optogenetic strategies for end-stage degeneration in order to achieve maximal light sensitivity. In this study, we assessed two vectors with single capsid mutations, rAAV2/2(Y444F) and rAAV2/8 (Y733F) in their ability to transduce retina in the Abca4<sup>−/−</sup> and rdl1 mouse models of retinal degeneration. We noted significantly increased photoreceptor transduction using rAAV2/8(Y733F) in the Abca4<sup>−/−</sup> mouse, in contrast to previous work where vectors tested in this model have shown low levels of photoreceptor transduction. Bipolar cell transduction was achieved following subretinal delivery of both vectors in the rdl1 mouse, and via intravitreal delivery of rAAV2/2(Y444F). The successful use of rAAV2/8 (Y733F) to target bipolar cells was further validated on human tissue using an <em>ex vivo</em> culture system of retinal explants. Capsid mutant AAV vectors transduce human retinal cells and may be particularly suited to treat retinal degenerations in which high levels of transgene expression are required.

INTRODUCTION

Inherited retinal degenerations are in general a group of single gene diseases, which would potentially be amenable to gene therapy. Recent retinal gene therapy clinical trials using subretinally delivered serotype 2 adeno-associated viral (AAV2) vectors have shown safety and efficacy. Based on these studies together with data regarding safety of second eye administration and long-term gene expression, AAV2 remains the mainstay vector of choice for ocular use. However in order to optimize photoreceptor transduction, and possibly to administer vectors via intravitreal injection, efforts are ongoing to improve AAV transduction efficacy and alter cell tropism.

Early work concentrated on the use of natural variation in AAV biology and explored pseudotyped recombinant (r)AAV vectors, whereby vector expression cassettes containing the terminal repeats sequences of AAV2 were packaged into virions composed of capsid protein from other AAV serotypes. Using this principle, studies have shown improved primate photoreceptor transduction with the use of rAAV2/8 over rAAV2/2.

More recently, mutation of the AAV capsid has been undertaken. Once internalized in the cell, AAV may be degraded by phosphorylation of exposed capsid tyrosine (Y) residues leading to ubiquitination and subsequent breakdown via the proteasome-mediated pathway. Phenylenalanine (F) is less amenable to phosphorylation compared with tyrosine as it lacks a para-hydroxyl group. Tyrosine to phenylalanine mutation on the VP3 capsid protein of AAV2 has been demonstrated to increase transduction in vitro and in vivo, possibly by bypassing ubiquitin-mediated degradation of the virion shortly after intracellular entry.

Previous work examining retinal transduction by capsid mutant AAV examined multiple (two to seven) capsid mutations in rAAV2/2. However, minimizing the number of capsid mutations may be advantageous as these may alter antibody binding and therefore the immune response. Further work compared single tyrosine mutations in self-complementary (sc) rAAV2/2, rAAV2/8 and rAAV2/9, and also sc rAAV2/8(Y733F) in isolation. AAV has a single-stranded genome; and therefore, a rate-limiting step in AAV transduction is the generation of double-stranded DNA. Self-complementary rAAV was designed to bypass this step since their single-stranded genome contains both forward and reverse copies of the transgene of interest with one wild-type (WT) inverted terminal repeat and one mutated inverted terminal repeat. This enables the viral DNA to fold into a double-stranded molecule after uncoating. These vectors have shown increased transduction efficacy in the eye, however, their effective coding capacity is limited since both forward and reverse copies of the transgene must be included.

The purpose of our study was to examine the effect on retinal transduction of a single tyrosine mutation in non self-complementary rAAV2/2(Y444F) and rAAV2/8(Y733F) due to the larger coding capacity of these vectors compared with their self-complementary counterparts.

All vectors expressed green fluorescent protein (GFP) as a reporter protein. We examined cellular tropism of the mutant capsid rAAV vectors following subretinal delivery in WT mice (C57BL/6 strain) in comparison with the Abca4<sup>−/−</sup> mouse model. Mutations in the gene coding for the ATP-binding cassette A4 (ABCA4) transmembrane transporter are among the commonest causes for inherited retinal dystrophies including Stargardt disease, with a key feature being accumulation of the bisretinoid N-retinylidene-N-retinylethanolamine (A2E) in the retinal pigment epithelium (RPE). ABCA4 is a large transgene (6.7 kb) and potential gene therapy for ABCA4 mutations would require gene packaging in two AAV particles with the split gene recombining after infection of the cell. For this to occur successfully, high transduction levels would be essential. We have previously shown that GFP expression following subretinal delivery of various AAV serotypes to Abca4<sup>−/−</sup> mice is significantly less than in WT mice, suggesting that the molecular changes in Abca4-associated retinopathy may inhibit AAV transduction in some way. We therefore assessed whether retinal transduction in this disease model would be more successful with capsid mutant AAV.

We also examined retinal transduction following subretinal and intravitreal delivery of capsid mutant AAV in Pde6b<sup>rd1/rd1</sup> mice. The Pde6b gene encodes the rod-specific cGMP phosphodiesterase β6 subunit (Pde6b<sup>β6</sup>), and in this model there is rapid and severe rod photoreceptor degeneration followed by cone degeneration. This is therefore a model of end-stage retinitis pigmentosa where very few photoreceptors remain. A strategy for vision restoration in patients with end-stage retinitis pigmentosa is to use the technique of optogenetics, whereby a light sensitive protein is made them light sensitive; however, the tropism of unmodified rAAV vectors for bipolar cells is poor. Few previous studies have obtained adequate transduction to show functional improvement in this model, either using a self-complementary AAV vector with a single capsid mutation, a synthetic AAV capsid, or one derived from a directed evolution approach. Therefore we therefore sought to assess whether capsid mutation of only a single residue in non self-complementary rAAV could improve retinal transduction in the Pde6b<sup>rd1/rd1</sup> model.

Recent studies have also demonstrated that retinal transduction using AAV may also differ between species, possibly due to differences in retinal morphology. To assess whether capsid mutant AAV would be suitable for use in future human clinical trials, we subsequently went on to test these vectors on human retinal tissue cultured ex vivo.

**RESULTS**

Retinal transduction in the Abca4<sup>−/−</sup> mouse following subretinal delivery of capsid mutant vectors

We have previously demonstrated that rAAV2/2 transduction is reduced in the Abca4<sup>−/−</sup> mouse model of retinal degeneration compared with WT mice. We therefore delivered single tyrosine mutant rAAV2/2(Y444F) and rAAV2/8(Y733F) by subretinal injection in both WT and Abca4<sup>−/−</sup> mice to assess transduction efficiency by these vectors.

**In vivo measurement of fluorescence intensity.** Three weeks after subretinal injection, vector expression was assessed by measuring in vivo GFP fluorescence using in vivo confocal scanning laser ophthalmoscopy (cSLO) imaging. Ocular GFP fluorescence was present in Abca4<sup>−/−</sup> and WT mice after injection of both of the test vectors, rAAV2/2(Y444F) and rAAV2/8(Y733F), and was confined to the area of subretinal vector injection (Figure 1a). By assessing mean pixel grey level as previously described, significant differences in GFP fluorescence intensity were found between capsid mutant AAV types. Subretinal delivery of rAAV2/8 (Y733F) resulted in 4-fold higher expression in WT mice and 13-fold higher expression in Abca4<sup>−/−</sup> mice, than rAAV2/2(Y444F) (n = 5–6 eyes per group, two-way ANOVA, P < 0.001; Bonferroni post hoc test, both P < 0.001, Figure 1b). No difference was seen in the expression of either vector between mouse strains.

**Retinal cell tropism of capsid mutant AAV.** In vivo fluorescence intensity measurements using cSLO images represent the combined fluorescence intensity of cells contained in multiple retinal layers. Therefore, histological sections were examined to evaluate differences in transduction efficiency in specific retinal cell types. rAAV2/2-injected eyes were assessed as a reference to compare any difference in transduction pattern between vectors or mouse strain. RPE cell, photoreceptor, horizontal cell, bipolar cell, Müller cell and ganglion cell identity was determined on the basis of immunocytochemistry staining and cellular morphology.

Following subretinal vector delivery in both mouse strains, all vectors transduced RPE and photoreceptors to some degree (Figures 2a–f). Photoreceptor transduction, however, appeared to be most efficient using rAAV2/8(Y733F), with the highest levels of
GFP expression. In the Abca4−/− mouse in particular, rAAV2/8 (Y733F) was highly effective at transducing photoreceptors with levels of GFP expression being higher than both other vectors tested and also higher than in WT mice injected with the same vector (n = 5–6 eyes per group).

Fewer RPE cells were transduced by rAAV2/2(Y444F) in the Abca4−/− mouse compared with injection of the same vector in WT mice (Figures 2b and e, 3a). The tropism of rAAV2/2(Y444F) was markedly different from that of rAAV2/2 in both mouse strains, with more photoreceptor transduction, and less Müller cell and ganglion cell transduction using the capsid mutant vector (Figure 2).

**Histological analysis of fluorescence intensity.** To quantify transduction differences between the capsid mutant vectors, the quantification of GFP fluorescence was used as an indicator of transgene expression and therefore transduction efficiency. GFP fluorescence was determined by separately measuring the mean grey level in the RPE and outer nuclear layer (ONL) in standardized histological preparations, which was then compared between rAAV serotypes and mouse strains.

There was a trend for RPE to be transduced more efficiently by rAAV2/2(Y733F) than rAAV2/2(Y444F) (P = 0.09), especially in the Abca4−/− mouse. However, neither viral type nor mouse strain had a statistically significant effect on RPE transduction (Figure 3a; two-way ANOVA). There was a significant difference in ONL transduction between rAAV serotypes (P < 0.01) but not between mouse strains (P = 0.22), and no significant interaction between the two factors (P = 0.17) (Figure 3b; two-way ANOVA). The most striking finding was significantly increased ONL transduction in the Abca4−/− mouse using rAAV2/2(Y733F) compared with rAAV2/2(Y444F) (P < 0.05, Bonferroni post hoc analysis). This difference in ONL transduction between vectors did not reach statistical significance in WT mice.

Tropism of capsid mutant vectors in the Pde6brd1/rd1 mouse

The Pde6brd1/rd1 mouse is a model of end-stage retinal degeneration, and targeting a light sensitive protein to bipolar cells in this model may restore visual function. However, these cells are difficult to transduce using rAAV, and we therefore aimed to assess whether single capsid mutant rAAV vectors would be effective in transducing the retina in this model of degeneration.

Three weeks, after subretinal injection of rAAV2/2(Y444F) and rAAV2/8(Y733F) to Pde6brd1/rd1 mice with rAAV2/2 used for comparison, histological sections of the retina were examined to evaluate transduction and retinal cell tropism by these vectors (Figures 4a–c). All vectors tested were able to transduce RPE, horizontal cells and ganglion cells (Supplementary Figure 1). Similar to transduction in the WT retina, there was reduced Müller cell transduction with the use of rAAV2/2(Y444F) compared with rAAV2/2. Of note, both rAAV2/2(Y444F) and rAAV2/8(Y733F) capsid mutant vectors transduced bipolar cells effectively as shown by co-labelling for PKCalpha (Figure 4b, i–iii). No bipolar cell transduction was observed with rAAV2/2.

The transduction efficiency of these vectors was also assessed following intravitreal delivery, to ascertain whether bipolar cells could also be transduced via this route. WT mice were used for comparison, to assess whether any differences between vectors were consistent between strains. Following intravitreal vector delivery, all vectors were able to transduce ganglion cells (Figures 5a–f), although transduction with rAAV2/2(Y733F) was sparse in both WT and Pde6brd1/rd1 mice (Figures 5c and f). Examining morphology of transduced cells, there was some evidence of Müller cell and horizontal cell transduction by rAAV2/2 and rAAV2/2(Y444F). Significantly, rAAV2/2(Y444F) successfully transduced bipolar cells in both WT and Pde6brd1/rd1 mice as shown by co-labelling for PKCalpha (Figure 5b, i–iii). As with subretinal delivery, no bipolar cell transduction was seen with intravitreal delivery of rAAV2/2.

Tropism of capsid mutant vectors in ex vivo human retinal culture

To assess whether the capsid mutant rAAV types tested in mice would be able to transduce human retina successfully, samples of human retina were obtained from patients undergoing complex surgery for retinal detachment in which a retinectomy procedure was performed as part of the operation. The retinal fragments obtained were maintained in an ex vivo culture system, as described previously. Since successful human retinal

**Figure 2.** GFP fluorescence patterns of different rAAV serotypes following subretinal injection in WT C57BL/6 and Abca4−/− mice. Images (a–f) are confocal stacks illustrating overall GFP expression patterns (green). GCL, ganglion cell layer; INL, inner nuclear layer. Scale bar 50 μm.
Figure 3. Quantitative analysis of GFP fluorescence intensity on histological sections in eyes that underwent subretinal injection of rAAV2/2 Y444F and rAAV2/8 Y733F capsid mutant AAV serotypes expressing GFP (mean ± s.e.m.). The grey level analysis of the retinal pigment epithelium (RPE, a) and the outer nuclear layer (ONL, b) represents an estimate for the level of transgene expression within the individual cell layers. Four to six eyes were analysed per group. *P < 0.05.

Figure 4. GFP fluorescence patterns of different rAAV serotypes following subretinal injection in Pde6brd1/rd1 mice. The main images (a–c) are confocal stacks illustrating overall GFP expression patterns (green). The boxed regions are enlarged and shown as confocal slices in panels (b–iii and c–iii). Images show GFP expression (green), nuclear labelling (blue) and immunostaining with anti-PKCalpha antibody, identifying bipolar cells (red). Colocalization of red and green signals therefore indicates instances of viral transduction of bipolar cells. GCL, ganglion cell layer; INL, inner nuclear layer. Scale bar 30 μm.

Figure 5. GFP fluorescence patterns of different rAAV serotypes following intravitreal injection in WT C57BL/6 and Pde6brd1/rd1 (rd1) mice. The main images (a–f) are confocal stacks illustrating overall GFP expression patterns (green). The boxed regions are enlarged and shown as confocal slices in panels (b–iii and e–iii). Images show GFP expression (green), nuclear labelling (blue) and immunostaining with anti-PKCalpha antibody identifying bipolar cells (red). Colocalization of red and green signals therefore indicates instances of viral transduction of bipolar cells. GCL, ganglion cell layer; INL, inner nuclear layer. Scale bar 50 μm for images (a–c), 30 μm for images (d–f).
transduction using rAAV2/2 has been demonstrated using this culture system,\(^\text{12}\) this was used for comparison.

Successful human retinal transduction was seen with all rAAV types tested (Figure 6). Using rAAV2/2 and rAAV2/2(Y444F), GFP was predominantly seen in the ONL, consistent with photoreceptor transduction (Figures 6a and b). Sparse inner retinal transduction was also seen with rAAV2/2 (Y444F). Using rAAV2/8(Y733F), the transduction pattern appeared to be different, with less GFP expression in the ONL compared with the other two vectors, but markedly more expression in the inner nuclear layer (Figure 6c). On the basis of cell morphology, Müller cell transduction is apparent with multiple characteristic branching cells that span the entire retina. Immunocytochemistry confirmed that rAAV2/8 (Y733F) can transduce human bipolar cells effectively (Figure 6d).

**DISCUSSION**

In this study, we have assessed the retinal cell tropism and transduction efficiency of two recombinant AAV vectors with capsid mutations of a single tyrosine to phenylalanine residue, rAAV2/2(Y444F) and rAAV2/8(Y733F). The tropism of both vectors was evaluated in vivo in WT mice and two mouse models of retinal disease, Abca4\(^{-/-}\) and the totally degenerate retina, since successful clinical strategies for these conditions would most likely require very high levels of AAV transduction. We also assessed our findings from both vectors with ex vivo testing on the human retina. In both the WT and the Abca4\(^{-/-}\) mice, the rAAV2/8 (Y733F) vector was highly effective at targeting photoreceptors when delivered subretinally. Our novel observation that transduction is highly efficient in the Abca4\(^{-/-}\) mouse is important because vectors tested in this model in previous work have shown low levels of photoreceptor transduction.\(^\text{24}\) This raised the possibility that biochemical alterations induced by abnormal dimerization of vitamin A molecules might interfere with AAV transduction.

In these models, we provide data showing that a single capsid mutation significantly alters the tropism of rAAV2/2, enhancing photoreceptor transduction and reducing Müller cell tropism when delivered subretinally. In the Pde6b\(^{fl/fl}\) model, the same AAV2 capsid mutation enabled bipolar cell transduction in the degenerate retina when delivered via both subretinal and intravitreal routes. We also show bipolar cell transduction in human retinal explants using rAAV2/8 (Y733F).

While the rAAV2/8(Y733F) vector showed increased transduction efficiency in the Abca4\(^{-/-}\) mouse compared with WT, there was no such effect of the AAV2 capsid mutation. However, previous assessments using rAAV2/2, rAAV2/5, as well as two novel hybrid recombinant AAV serotypes showed lower transduction in Abca4\(^{-/-}\) compared with WT mice,\(^\text{24}\) whereas rAAV2/2 (Y444F) showed similar efficiency in both strains. Thus, there might be enhanced photoreceptor transduction using both single residue AAV capsid mutant vectors in Abca4\(^{-/-}\) mice. This is likely to be mediated by altered ubiquitination and proteasome-mediated breakdown, since our in vitro studies demonstrated increased rAAV2/2 transduction in the presence of proteasome inhibitors, but no such effect is seen with rAAV2/2(Y444F) (Supplementary Figure 2), consistent with previous reports.\(^\text{13}\)

The low transduction efficiency seen with some vectors in the Abca4\(^{-/-}\) mouse may be caused by the disease process induced by this mutation; however, strain background effects may also be a contributing factor as WT mice were C57BL/6 and Abca4\(^{-/-}\) were on a 129S background (these WT controls were chosen to due to differences in background autofluorescence between mouse strains).\(^\text{24}\) It remains to be investigated to what extent the superior efficiency of rAAV2/8(Y733F) is explained by the mutated capsid or rather due to a more general improved receptor-mediated uptake of AAV8 virions compared with other serotypes.

We also demonstrate that rAAV2/2(Y444F) can transduce WT retina effectively; however, tropism was altered by this single capsid mutation with greater photoreceptor transduction and reduced Müller cell transduction compared with rAAV2/2. It has previously been proposed that AAV capsid mutations may alter retinal penetration;\(^\text{24}\) however, this is unlikely to explain the reduced Müller cell tropism as these span the entire width of the retina. Other work has also demonstrated that mutations of the
AAV capsid may affect heparan sulphate proteoglycan binding capacity and this could contribute to the altered Müller cell tropism seen.

Inducing light sensitivity in bipolar cells in the degenerate retina may be an important optogenetic strategy for restoring vision, and therefore identifying a vector that can successfully target bipolar cells is essential. RAAV2/2 vectors with quadruple and pentuple capsid mutations have been shown to transduce bipolar cells when delivered by both the subretinal and intravitreal route in WT mice. Our findings indicate a vector with a single capsid mutation, rAAV2/2(Y444F), can be used to transduce bipolar cells when delivered by both the subretinal and intravitreal route in the Pde6b +/- rd1 model of degeneration. Therefore for future clinical trials in optogenetic strategies, rAAV2/2(Y444F) could be administered intravitreally to transduce bipolar cells, which might avoid the need for intraoperative retinal detachment in patients with advanced retinal degeneration. The ability to do so with a single capsid mutant rAAV2/2 vector may be advantageous as although capsid mutation increases infectivity, this may be at the expense of altering antibody binding and therefore immune responses. Thus for clinical trial applications it may be prudent to limit capsid mutation as much as possible in order to limit deviation from the presumed optimally evolved AAV structure.

A previous study in the rd10 mouse model of retinal degeneration identified bipolar cell transduction using a self-complementary rAAV2/8(Y733F) with transgene expression driven by a bipolar cell-specific promoter. We also show that a single-stranded rAAV2/2(Y733F) vector is able to target bipolar cells in another mouse model (Pde6b +/- rd1) and using a ubiquitous and different promoter to that which has been previously reported. Significantly, this vector was also successful at targeting bipolar cells in ex vivo human retinal explants. Retinectomy tissue from patients who had chronic retinal detachment was used, which was placed in culture immediately after removal from the eye, making it more likely to be viable for transduction by AAV than post-mortem tissue used in previous studies. However, there may have been a variation in the baseline severity and nature of pathologic retinal changes among the retinal samples thus obtained, as the duration of preoperative retinal detachment and amount of proliferative vitreoretinopathy were different between tissue samples. Therefore, the human retinal transduction patterns reported here may be affected by these factors, which may explain the limited photoreceptor transduction seen by AAV2/2(Y733F). The high level of Müller cell transduction seen in the human retinal explants when transduced with rAAV2/2(Y733F) may be related to the extensive glial cell proliferation is known to be a feature of retinal detachment. Nevertheless, some glial cell activation is also likely to occur in end-stage retinal degenerations and the observation of efficient AAV transduction in the degenerate human retina may therefore be relevant.

In summary, we report effective retinal transduction with two single-stranded capsid mutant vectors in WT mice and in two mouse models of human retinal disease in which high levels of AAV transduction would most likely be required. In addition, we demonstrated human bipolar cell transduction in an ex vivo culture system using rAAV2/2(Y733F).

MATERIALS AND METHODS

Viral vectors
rAAV2/2, rAAV2/2(Y444F) and rAAV2/8(Y733F) used in our study were designed by REM based on published observations from other groups. Capsid mutant vectors were generated by site-directed mutagenesis of surface-exposed tyrosine residues on AAV capsid VP3 as previously described and custom cloned by Genedetect (Auckland, New Zealand). All vectors expressed GFP under the control of the same CMV-enhanced chicken beta-actin (CAG) promoter and included an X-antigen deleted Woodchuck hepatitis virus post-transcriptional regulatory element and bovine growth hormone polyadenylation signal, similar to the sequences used in an ongoing choroideremia gene therapy clinical trial. Vectors were purified by iodixanol gradient centrifugation and titres were confirmed by PCR to the promoter region.

Mice
WT C57BL/6 mice were provided by the Biomedical Sciences division, University of Oxford. C3H/HeNrd-Pde6b +/- mice were purchased from Harlan Laboratories (Hillcrest, UK). Founder Abcam knockout mice (129SVJ-Joe-Abcamer+/+G9117g1Jrmi1m2Dc1) were generously provided by Gabriel Travis, David Geffen School of Medicine, University of California, Los Angeles, USA; and bred locally at the University of Oxford.

Animals were housed under a 12-h light (,<100 lux)/dark cycle, with food and water available ad libitum. All procedures were performed under the approval of local and national ethical and legal authorities and in accordance with the Association for Research in Vision and Ophthalmology statements on the care and use of animals in ophthalmic research.

At the time of intraocular injection, mice were between 6 and 8 weeks old. For surgery and in vivo imaging procedures, animals were anaesthetized by intraperitoneal injection of 1 mg kg-1 medetomidine (Dormitor 1 mg ml-1, Pfizer, Sandwich, UK) and 60 mg kg-1 ketamine (Ketaset 100 mg ml-1, Fort Dodge, Southampton, UK) and pupils fully dilated with tropicamide 1% eye drops (Bausch & Lomb), Kingston-Up-Thames, UK) and, for the imaging procedure, phenylephrine 2.5% eye drops (Bausch & Lomb).

Intraocular injections
Intraocular injections were performed tangentially through the sclera with a 10 mm 34-gauge needle (Hamilton AG, Bonaduz, Switzerland) mounted on a 5 μl syringe (65 RN, Hamilton AG) under direct visual control using a surgical microscope (M620 F20, Leica, Wetzlar, Germany). A circular cover glass (06 mm, WVR International, Lutterworth, UK) was applied onto the cornea with a carbomer coupling gel (Viscoatex, Novartis, Frimley, UK) to ensure good visualization of the fundus. The eye position was controlled and stabilized by holding the superior or inferior rectus muscle with notched forceps. In all, 1 μl viral vector solution (1.0 × 10^12 vg ml^-1) was injected into each eye, and complete subretinal or intravitreal delivery was confirmed by direct visualization. After injection, the needle was left in position for an additional 20–30 s and then withdrawn quickly to minimize reflux and to allow self-sealing of the scleral tunnel. Each animal received a different viral type in each eye, with different syringes and needles used for the different viruses. Between individual injections, the needle and syringe was flushed with sterile water. For WT (C57BL/6) mice and C3H/HeNnd-Pde6b +/- mice, five eyes were injected for each virus tested (the same virus was not tested in both eyes of a mouse). For ABCA44-/ mice, six eyes were injected per virus tested.

Fundus imaging using a confocal scanning laser ophthalmoscope
Three weeks after intraocular injection, confocal scanning laser ophthalmoscope (cSLO; Spectralis HRA, Heidelberg Engineering, Heidelberg, Germany) imaging was performed under general anaesthesia (as above) according to a modified protocol that has been described in detail previously. In brief, the pupils were fully dilated and a custom-made mouse contact lens (Cantor-Nissel) placed on the cornea. The near-infrared reflectance mode (820 nm laser) was used for camera alignment. For recordings from the outer or inner retina, the plane of highest near-infrared reflectivity or the plane of the nerve fibre layer was identified, respectively. After switching to the autofluorescence mode (excitation wavelength: 488 nm, emission collection 500–700 nm) and slight focus adjustments (due to the dioptic shift between the different wavelengths), images were recorded with a standardized detector sensitivity of 70 using the automated real-time mode, without image normalization. All images were recorded in the high-resolution mode (1536 × 1536 pixels) using a 55 degree lens.

Tissue collection and processing
After the imaging procedure, mice were perfusion fixed using 4% paraformaldehyde (Thermo Fisher, Loughborough, UK) in phosphate-buffered saline (PBS). After enucleation, the cornea and lens were removed under direct visualization with an operating microscope in 4% paraformaldehyde in PBS. After fixation overnight, the eyecups were
Human retinal explant culture

Ethical approval was previously obtained to culture samples of retina ex vivo from patients undergoing retinectomy for complex retinal detachment surgery (REC reference no. 10/H0505). Samples were obtained from three patients with their written consent. A routine 23-gauge (23G) pars plana vitrectomy was done for retinal detachment surgery. Discs of scarred retina were cut with a 23G vitrectomy system (Ocutome; Alcon Surgical, Irvine, TX, USA), refixed into the eye, aspirated with a flute needle and placed in balanced salt solution.

Within 1 h of removal from the eye, retinectomy samples were transferred using a 5 ml pipette into organotypic culture inserts (BD Falcon, Bedford, MA, USA) and placed in a 24-well plate. In all, 700 μl culture media was added per well consisting of Neurobasal A, l-glutamine (0.08 mM), penicillin (100 U ml⁻¹), streptomycin (100 U ml⁻¹), B27 supplement (2%) and N2 supplement (1%), all obtained from Invitrogen (Paisley, UK). Explants were maintained at 34 °C in a humidified, 5% CO₂ environment.

After 24 h, media was changed and 10 μl of one of rAAV2/2, rAAV2/8 Y444F or rAAV8/8 Y733F (titre 1 × 10⁻¹² vg ml⁻¹) was added to each well, with two wells tested per virus. Media was changed every 48 h, and explants were imaged daily on an inverted epifluorescence microscope (Leica DM IL; Leica).

Fourteen days post transfection, explants were fixed overnight in 4% paraformaldehyde, cryoprotected in 20% sucrose for 1 h, embedded in optimal cutting temperature compound (Tissue-Tek, Sakura Finetek, Loughborough, UK). The sections were air-dried and then stored at −20 °C until further histological processing.

Histology and immunohistochemistry

After hydration and 3 × 5 min washes in 0.01x PBS, retinal sections were blocked for 1 h at room temperature in PBS+0.1% Triton X-100+10% donkey serum. After 3 × 5 min washes, the sections were incubated at 4 °C overnight with the primary antibody (PKCα, 1:1000, Epitomics, CA, USA) and virus were added. In all, 1 μl of virus (1.0 × 10¹² vg ml⁻¹) all from Sigma-Aldrich (Dorset, UK), and 10% fetal calf serum (GIBCO, Invitrogen). Cells were maintained at 37 °C in a 5% CO₂ environment.

After 24 h, media was changed and 10 μl of one of rAAV2/2, rAAV2/8 Y444F or rAAV8/8 Y733F (titre 1 × 10⁻¹² vg ml⁻¹) was added to each well, with two wells tested per virus. Media was changed every 48 h, and explants were imaged daily on an inverted epifluorescence microscope (Leica DM IL; Leica).

Fourteen days post transfection, explants were fixed overnight in 4% paraformaldehyde, cryoprotected in 20% sucrose for 1 h, embedded in optimal cutting temperature compound and frozen on dry ice. Each explant was cut into 16 μm sections using a cryostat as above.

Confocal microscopy

Retinal sections were viewed on a confocal microscope (LSM710; Zeiss, Munich, Germany). GFP-positive cells were located using epifluorescence illumination before taking a series of overlapping XY optical sections of ~0.5 μm thickness. Representitive images were taken within the region of vector delivery, avoiding the needle entry site where associated retinal damage often led to localized increased transduction.

Light microscopy

For the purpose of quantitative analysis of GFP expression, images were taken using the Leica DM IL inverted epifluorescence microscope (Leica). Images were obtained at ×20 magnification using identical acquisition settings including exposure time, and were saved at a resolution of 1200 × 1600 pixels.

Image analysis

Image analysis was performed on 8-bit images using ImageJ. Mean pixel grey levels on cSLO images were measured within a circle of 300 pixel diameter. This area was placed within the region of vector delivery, avoiding the needle entry site where associated retinal damage often led to localized increased transduction.

Green levels on histological fluorescence images were analysed separately for the RPE, the photoreceptor layer, and the inner retina (including the outer plexiform layer and the inner nuclear layer). This allowed a quantitative analysis of GFP expression within individual retinal layers and thus to assess vector tropism. Regions of defined sizes (RPE: 20 × 200 pixels; ONL: 50 × 250 pixels; inner retina: 100 × 250 pixels) were analysed within areas of highest GFP expression, and the mean pixel grey level was calculated from a plot profile.

Fluorescence images of fixed cells were analysed by calculating mean grey value for each image using ImageJ software, and background levels of fluorescence were subtracted by determining mean grey level of images of untransfected cells.

Statistical analysis

Mean grey levels on cSLO and histological fluorescence images were compared using a two-way analysis of variance (ANOVA) test with mouse strain and rAAV vector type as factors. The Bonferroni post hoc test was applied in all instances to correct for multiple testing, and the significance level was set at 0.05. Mean ± s.e.m. values are shown in all figures. All statistical analysis was done using Prism 6 for Mac OS X (San Diego, CA, USA).

CONFLICT OF INTEREST

REM is a Founder and Director of Nightstar Ltd (Gibbs Building, 215 Euston Road, London NW1 2BE), a choroideremia gene therapy company established by the University of Oxford and funded by the Wellcome Trust through Syncona Partners.

ACKNOWLEDGEMENTS

This study was supported by Wellcome Trust, NIHR Biomedical Research Centres of Oxford and Moorfields, MRC, Fight for Sight, Royal College of Surgeons ProRetina.
