(Dated: March 30, 2020)

We study the behavior of the magnetization and the magnetic susceptibility of molecular magnets with complex bridging structure. Our computations are based on a post-Hartree-Fock method accounting for the intricate network of interatomic bonds and an effective spin-like Hamiltonian that captures the essential magnetic features of magnetic molecules. The devised method and the constructed Hamiltonian are further employed to characterize the magnetic properties of the molecular magnet Ni₄Mo₁₂. The obtained results reproduce both quantitatively and qualitatively the main features of the magnetic spectrum. Furthermore, the computations for the magnetization and the low-field susceptibility are in very good agreement with their experimental counterparts. In this respect, they improve upon the results obtained with conventional Heisenberg models.

I. INTRODUCTION

Molecular magnets are some of the most prominent examples of physical systems that unveil the quantum origin of magnetism. Due to their plain chemical structure and small number of constituent ions, nanomagnets demonstrate peculiar magnetic and related properties that underpin future applications and challenge scientists working in different fields.

The effects observed in Ni₁₂-acetate, Fe₉ based molecular magnets and in the Ni₄ clusters, strongly emphasize the unique role of nanomagnets in determining the relation between electrons' correlations and magnetism. On the molecular level the existing magnetic exchange processes uniquely characterize the nanomagnets' properties. The number and type of constituting elements, their bonding and thus the resulting geometric symmetry lies in the footprints of each nanomagnet, such as the lightly distorted octahedral magnetic molecules with a central Cr ion, the high spin molecular complex Fe₁₉, the molecular wheel Fe₁₈ with eighteen antiferromagnetically coupled spin-½ ions and the heterometalic Cr₃Ni antiferromagnet. Despite the fact that in addition to the above mentioned compounds a huge variety of molecular magnets (see e.g. and references therein) were synthesized and extensively studied during the last decade, one could still be fascinated by the richness of their magnetic properties and the challenges they pose to scientists.

The intricate magnetic features of the molecule [Mo₁₂O₃₆(μ₂-OH)₁₀H₂(Ni(H₂O)₃)₄] (Ni₄Mo₁₂), with four Ni magnetic centers occupying the vertices of a slightly distorted tetrahedron, has been the subject of many investigations. In Ref. 19, a very general Heisenberg model involving different sorts of magnetic interactions among localized spins and the Hubbard model with localized electrons were used to analyze INS data. Both studied models were proven unable to appropriately explain the magnetism in the named molecular magnets. Further analysis of the magnetic spectra of Ni₄Mo₁₂, formulated as [Mo₁₂O₃₆(μ₂-OH)₉(μ₃-OH)H₃Ni(H₂O)₃]₄, was performed in Ref. 20, where in terms of the Heisenberg model a "naive" spin coupling scheme with two arbitrary coupling parameters of the isotropic Heisenberg model was used. The physical reason lying behind this parametrization was not discussed. A shortcoming of the proposed model is that it provides a single intensity curve for all three low-temperature magnetic peaks. Moreover, even after including a single ion anisotropy with yet another running parameter, the magnetic features of Ni₄Mo₁₂ could not be fully determined. A more recent study showed that electron correlations are the driving mechanisms behind magnetism of four-center transition-metal clusters. Thus, despite the efforts an overall theoretical description and deep understanding of the magnetic spectrum obtained via inelastic neutron scattering (INS) experiments is still an open question.

In an attempt to elucidate the mechanisms underpinning the magnetic properties of this molecule we revisited

![FIG. 1. Inelastic neutron scattered intensities for the magnetic molecule Ni₄Mo₁₂ as a function of the temperature and neutrons' energy transfer. The experimental data are taken from Ref. 19. The curves represent the calculated intensities Iₙₙ', with n and n' denoting the number of initial and final states in the transition processes, where n = 0 is the ground state.](image-url)
the reported experimental data and proposed an alternative approach that helped explaining the details of the magnetic spectrum obtained via INS, see Fig. 1. Within our approach the four magnetic excitations, I, II, III and IV, with energies $\Delta_1 = 0.4$, $\Delta_{II} = 0.6$, $\Delta_{III} = 1.7$ and $\Delta_{IV} = 1.15$ meV, and INS intensities $I_{10}$, $I_{30}$, $I_{90}$ and $I_{64}$, respectively, are uniquely characterized. All features in the magnetic spectrum, such as splitting and broadened, were revealed. For further details the reader may consult Ref.12.

In order to interpret the experimental measurements of the magnetization and the susceptibility obtained for Ni$_4$Mo$_{12}$ reported in Ref.17, the authors relied on electron paramagnetic resonance experiments and explored the relevant magneto-optical properties. They combined the isotropic Heisenberg Hamiltonian with a biquadratic and a single-ion anisotropy terms in addition to field dependent coupling parameters. This allowed them to qualitatively reproduce the magnetization and susceptibility measurements data but failed to explain the inelastic neutron scattering experiments. Another study of the magnetization and the susceptibility proposed a non-negligible contribution of the three-body spin interaction term. To reproduce the behavior of the field dependent magnetization and the associated susceptibility of the compound under consideration, it was suggested to account for single-ion anisotropy, as well. However, no firm physical grounds were reported in support of the pure technical procedure leading to the parametrization of Ref.20. Furthermore it does not account for the background emanating from delocalized electrons.

In this article we report theoretical results on the magnetization and the magnetic susceptibility results for the tetramer Ni$_4$Mo$_{12}$ based on the proposed spin-like Hamiltonian taking into account the Zeeman term. From the physical point of view the present model opens a new perspective on the theoretical studies of the magnetic properties of Ni$_4$Mo$_{12}$. Notice that in contrast to the introduced in Ref.20 picture of strongly localized electrons, the model considered in this paper views the electrons as delocalized and hence assures the role of the bridging structure in the exchange processes. This is in concert with other investigations on clusters with four Ni centers. We would like to anticipate that the obtained results are in good qualitative and fairly quantitative agreement with the corresponding experimental measurements data. The analysis suggests that the observed shifting in magnetization steps is associated to variations in the correlations between delocalized electrons due to the presence of externally applied magnetic field. The influence of the field is indirect and differs by a contribution emanating from the Zeeman term. It originates from the interaction between the molecules intrinsic magnetic vector potential and the magnetic vector potential of the external field, and it is especially underlined due to the electrons’ delocalization. The resulting interaction terms contribute to the correlation functions derived from a post-Hartree-Fock method and thus enters into the spin-like Hamiltonian. Moreover, the approach proposed here leads to improvements upon that based on the conventional isotropic Heisenberg model. For the sake of comparison we computed the magnetization and magnetic susceptibility with the aid of the isotropic Heisenberg model, as well as the Hamiltonian involving anisotropic in space spin-spin interaction and an axial single-ion anisotropy proposed in Ref.20.

The rest of this paper is organized as follows: In Section II A we write down the Hamiltonian and the model parameters relevant to the present study. In Sections III we obtain the explicit expression of the energy spectrum as a function of all running parameters used to study the magnetization and the magnetic susceptibility of the Ni$_4$Mo$_{12}$. In Section III C we determine the values of the model parameters fitted to the experimental results. A summary of the results obtained throughout this paper is presented in Section IV.

II. THE EFFECTIVE MODEL

A. The spin-like Hamiltonian

In order to investigate the magnetic properties of the tetramer we apply the formulism presented in Ref.42 by accounting for the action of the externally applied magnetic field. Thus, we consider the following spin-like Hamiltonian

$$\mathcal{H} = \sum_{i \neq j} J_{ij} \hat{\sigma}_i \cdot \hat{\sigma}_j - \mu_B B \sum_{i} g_{\alpha i} \hat{s}_{\alpha i}^z, \quad (2.1)$$

where $J_{ij} = J_{ji}$ are effective constants, the operator $\hat{\sigma}_i = (\hat{\sigma}_i^x, \hat{\sigma}_i^y, \hat{\sigma}_i^z)$ indirectly accounts for the differences in electrons’ distribution with respect to the $i$-th magnetic center with spin operator $\hat{s}_i$, $\mu_B$ is the Bohr magneton, $g_{\alpha i}$ is the $\alpha$ component of the corresponding effective $g$-factor and $B$ is the magnitude of the external magnetic field oriented along a preselected magnetic easy axis $\alpha \in \{x, y, z\}$. Moreover, for each total spin multiplet the $\sigma$ operators will also account for the rate at which the electrons’ correlations alter due to the presence of an externally applied magnetic field.

We would like to point out that the effective $g$-factor differs from the $g$-tensor known in the theory of magnetism. Thus, in contrast to the widely applied $g$-tensor, derived via the quantum perturbation theory, the effective $g$-factor resulting from the post-Hartree-Fock method is a three component vector $\mathbf{g}_i = (g_{i}^x, g_{i}^y, g_{i}^z)$. The reason is that we use a variational method and the electrons are regarded as delocalized to a large extent, occupying molecular orbitals. The technical details behind the derivation of $\mathbf{g}$ vector lies bend the objective of the present article and will be a subject of separate paper. However, following the short review in Ref.42 explaining the main steps leading to the construction of the spin-sigma bilinear form in (2.1) we can give an explicit representation of the effective $g$-factor.

It is worth mentioning that the applied formulism is based on a multi-configuration self consistent field method that in turn relies on the molecular orbital theory as the main approach in describing the interatomic bonding. The initial canonical Hamiltonian that
leads to (2.1) takes into account the electrons’ kinetic energy, the electron-electron and electron-nuclei interactions in addition to the influence of externally applied magnetic field on the electrons’ motion. In addition to the action of the external magnetic field, each electron is viewed as interacting with an intrinsic local magnetic field that originates from the orbital and spin angular momenta of all remaining electrons. All electrons in the system are considered as delocalized in terms of the molecular orbital theory. Thus, they occupy molecular orbitals

$$\psi^\alpha_{\mu_i,m_i}(r_i),$$

with $n \in \mathbb{N}$, represented as a linear combinations of atomic orbitals

$$\psi^\alpha_{\mu_i,m_i}(r_i),$$

where $r_i$ are the coordinates of the $i$-th electron, $\mu_{ij}$ denotes the electronic shell and subshell with respect to the $\eta$ nucleus and $i$-th electron, $m_i$ is the spin magnetic quantum number of the $i$-th electron. In the considered method, different exchange bridges may favor different electrons’ distributions and thus configurations. Therefore, the corresponding state functions are given by a linear combination of Slater determinants with elements $\phi_{n,m_i}(r_i)$ and are symmetrized in accordance to the spin quantum numbers $s_{ij}$ of all electron pairs and with respect to all probable electrons’ distributions along all exchange bridges.

Within the assumption of delocalized electrons the effective $g$-factor may be derived from the interaction between the magnetic vector potential of the externally applied field and the magnetic vector potentials associated to the orbital and spin magnetic moments of the constituent electrons. These interactions result from the relevant electrons’ generalized momenta. In terms of $N$ electrons with $N \geq 2$ pairs, the effective $g$-factor associated with the $(N-1)$-th and $N$-th unpaired by orbitals electrons is given by

$$g_\alpha = \frac{1}{2} \sum \left| c_i \right|^2 \left( g_{N-1}^a + g_{N}^a \right),$$

where the coefficient $c_i$ accounts for the probability of observing both electrons in one of the three possible triplet configurations associated with a set of molecular orbitals $\tau = (n_1, \ldots, n_i)$, with $n$ denoting the orbital’s number. Further, for all $\alpha \in \{x, y, z\}$ we have

$$g_{N}^{a,\alpha} = g_e \mu_0 \epsilon \frac{\eta}{8\pi^2 m_e} \sum_{j=1}^{N-1} \left( a_j \left( n \cdot r_{Nj} \right) - n_a \left( r_j \cdot r_{Nj} \right) \right),$$

where $g_e$ is the electron’s spin $g$-factor, $\epsilon$ is the elementary charge, $\mu_0$ is the magnetic permeability, $m_e$ is the electron’s rest mass, $n = (n_x, n_y, n_z)$ is a unit vector such that $B = n \cdot \mathbf{B}$, $r_j = (x_j, y_j, z_j)$ are the coordinates of the $j$-th electron and $r_{Nj}$ is the distance separating the $N$-th and the $j$-th electrons.

**B. Properties of the $\sigma$ operators**

For the sake of completeness, we present the properties of $\sigma$ operators relevant to the present study. Additional details can be found in Refs. 40, 42.

The components of $\sigma$ operator are such that for all $i$ and $\alpha \in \{x, y, z\}$, we have

$$\hat{\sigma}_i^\alpha |\ldots, s_i, m_i, \ldots, m_j, \ldots\rangle = a_i^{s_i,m_i} a_i^{s_i,m_i} |\ldots, s_i, m_i, \ldots, m_j, \ldots\rangle,$$

where $a_i^{s_i,m_i} \in \mathbb{R}$.

When the $i$-th and $j$-th spin centers are coupled, with total spin operator $\hat{s}_i = s_i + s_j$, one has the corresponding total $\sigma$-operator $\hat{\sigma}_{ij}$. Hence, similar to Eqs. (2.2), for all $i \neq j$ and $\alpha \in \{x, y, z\}$, we have

$$\hat{\sigma}_{ij}^\alpha |\ldots, s_{ij}, s, m\rangle = a_{ij}^{s_{ij},m_{ij}} a_{ij}^{s_{ij},m_{ij}} |\ldots, s_{ij}, s, m\rangle,$$

where $a_{ij}^{s_{ij},m_{ij}} \in \mathbb{R}$. The individual $\sigma$-operators from the $(i, j)$-th spin pair share the same coefficient. Thus, for any $i \neq j$ and $\alpha \in \{x, y, z\}$ one gets

$$\hat{\sigma}_{ij}^\alpha |\ldots, s_{ij}, s, m\rangle = a_{ij}^{s_{ij},m_{ij}} a_{ij}^{s_{ij},m_{ij}} |\ldots, s_{ij}, s, m\rangle.$$ (2.4)

In the presence of an external magnetic field the constraints in Ref. 42, obtained without magnetic field need to be modified. Since according to the underlying post-Hartree-Fock method the electrons’ correlations are field dependent, in the considered case these constraints enter a more general form. The equations relating $\sigma$ and spin operators read

$$\hat{\sigma}_{ij}^\alpha |\ldots, s_{ij}, s, m\rangle = h_{ij}^{\alpha} s_{ij}^\alpha |\ldots, s_{ij}, s, m\rangle,$$ (2.5a)

$$\hat{\sigma}_{ij}^\alpha |\ldots, s_{ij}, s, m\rangle = \left( h_{ij}^{\alpha} s_{ij}^\alpha |\ldots, s_{ij}, s, m\rangle \right),$$ (2.5b)

where the parameter $h_{ij}^{\alpha} \in \mathbb{R}$ accounts for the changes in electrons’ correlations due to the indirect action of the externally applied magnetic field. Such an influence alter the energy spectrum obtained for $B = 0$ and differ from the contribution associated to the Zeeman term. Notice that in the absence of external magnetic field, for all $s_{ij}$ one has $h_{ij}^{\alpha} = 1$.

Using Eqs. (2.3) and the constraints (2.5) we distinguish four cases:

1. For $s_{ij} \neq 0$ and $m_{ij} \neq 0$, or when the value of $m_{ij}$ cannot be determined, we have $a_{ij}^{s_{ij},m_{ij}} = h_{ij}^{s_{ij}}$.

2. When $s_{ij} \neq 0$ and $m_{ij} = 0$, then from Eq. (2.5b) it follows that

$$\hat{\sigma}_{ij}^{s_{ij},0} = \pm h_{ij}^{s_{ij}}.$$ (2.6)

3. In the presence of a singlet bond, $s_{ij} = 0$, one has unconstrained parameters such that for the set of coefficients $c_i^{n} \in \mathbb{R}$,

$$a_{ij}^{0,0} \in \{ h_{ij}^{c_i^{n}} \}_{n \in \mathbb{N}}.$$ (2.7)

4. In the case of a total singlet $s = 0$ and $s_{ij} = 0$ the system resemble a closed shell system with unique electron configuration. As a result, the effective parameter will have a unique value

$$a_{ij}^{0,0,0} = h_{ij}^{0}.$$ (2.8)
For more details on the quantities $c_{ij}^n$, see Ref. 42. In general, within Hamiltonian (2.1) one relies on two classes of parameters. The spectroscopic parameters $c_{ij}^n$ that can be fitted according to performed spectroscopic measurements and the parameters $h_{ij}^n$, that account for the effect of externally applied magnetic filed. The latter can be fixed with respect to the magnetization and magnetic susceptibility measurements.

III. Ni$_4$Mo$_{12}$

A. The Hamiltonian

The spin-sigma bilinear form in (2.1) is derived in a such a way to be valid for arbitrary magnetic field. Therefore, for calculating the energy spectrum for $B \neq 0$, we take into account the applied spin coupling scheme discussed in Ref. 42. In other words we have Ni1-Ni2 and Ni3-Ni4 spin bonds and the eigenstates $|s_{12}, s_{34}, s, m\rangle$. Since the four Ni spin centers are indistinguishable for $i, j = 1, \ldots, 4$ we set $J_{ij} = J$. Furthermore, we distinguish two $\sigma$ bond operators, $\hat{\sigma}_{12}$ and $\hat{\sigma}_{34}$, corresponding to Ni1-Ni2 and Ni3-Ni4 spin pairs, respectively. According to (2.3) and (2.4) one has the spin bond operators $a_{ij}^{s_{12},m_{12}}$ and $a_{ij}^{s_{34},m_{34}}$, associated with Ni1-Ni2 and Ni3-Ni4 spin pairs, respectively. In our previous work 42, we were able to unveil the driving exchange mechanism behind the magnetic spectrum of Ni$_4$Mo$_{12}$. Now, taking in to account the field parameters $h_{12}^n$ and $h_{34}^n$, we can shed more light on the way the external magnetic field affects the electrons' correlations in this magnetic molecule.

Using (2.1) and selecting the z-axis as the magnetic easy axis we end up with the Hamiltonian

$$\hat{H} = J \left( \hat{\sigma}_1 \cdot \hat{\sigma}_2 + \hat{\sigma}_2 \cdot \hat{\sigma}_3 + \hat{\sigma}_3 \cdot \hat{\sigma}_4 + \hat{\sigma}_4 \cdot \hat{\sigma}_1 \right) + J \left( \hat{\sigma}_{12} \cdot \hat{\sigma}_{34} + \hat{\sigma}_{34} \cdot \hat{\sigma}_{12} \right) - g \mu_B B \hat{S}_z^2, \quad (3.1)$$

where $\hat{S}_z^2$ is the total spin $z$ component and since all Ni centers are indistinguishable for $i = 1, \ldots, 4$ we may set $g = g_0^z$.

With the aid of Hamiltonian (3.1) the total spin $s$ remains a good quantum number and hence the magnetic molecule is fully described by a total of eighty one eigenstates.

B. Energy spectrum

Bearing in mind that the model parameters $a_{ij}^{s_{12},m_{12}}$ and $a_{ij}^{s_{34},m_{34}}$ take discrete values, the energy spectrum of Hamiltonian (3.1) can be generalized by the expression

$$E_{s_{12},s_{34},z}^{m_{12},m_{34}} = J a_{12}^{s_{12},m_{12}} s_{12}(s_{12} + 1) - 2 s_0 s_{0} + 1 \right)$$

$$+ J a_{34}^{s_{34},m_{34}} s_{34}(s_{34} + 1) - 2 s_0 s_{0} + 1 \right)$$

$$+ \frac{1}{2} J \left( a_{12}^{s_{12},m_{12}} a_{34}^{s_{34},m_{34}} s(s + 1) - s_{12} s_{12} + 1 \right)$$

$$- s_{34}(s_{34} + 1) - g \mu_B Bm. \quad (3.2)$$

The eigenvalues in (3.2) are not explicit functions of the scalars in (2.7). However, for convenience their dependence on the number $n$ will be explicitly underlined only in the case when $n > 1$.

According to Ref. 42 and the analysis based on the inelastic neutron scattering experiments reported in19,20 the ground state of this nanomagnet appears to be the singlet $|1, 1, 0\rangle$. Taking into account (2.5) for the ground state energy, we obtain

$$E_{1,1,0}^0 = E_{2,2,0}^0 = E_{0,0,0}^0 = -4J(h_{12}^0 + h_{34}^0).$$

The triplet level is determined by eighteen eigenstates, where $|1, 1, 1, m\rangle$ and $|2, 2, 1, m\rangle$, with $m = 0, \pm 1$, are characterized by the energy

$$E_{2,2,1}^m = E_{1,1,1}^m = -3J(h_{12}^1 + h_{34}^1) - g \mu_B Bm.$$

Further, the respective triplets $|1, 2, 1, m\rangle$ and $|2, 1, 1, m\rangle$ energies are

$$E_{2,1,1}^m = -3J(h_{12}^1 + h_{34}^1) - 2J(h_{12}^1 - h_{34}^1) - g \mu_B Bm, \quad E_{2,1,1}^m = -3J(h_{12}^1 + h_{34}^1) + 2J(h_{12}^1 - h_{34}^1) - g \mu_B Bm.$$

With $|0, 1, 1, m\rangle$ the Ni1-Ni2 coupled spin pair form a singlet. The set of constants $c_{ij}^n$ in (2.7) then can be determined in the limit of zero external magnetic field, corresponding to $h_{12}^1 = 1$. According to the estimations for the low-lying
The graphical representation of the energy sequence for $B = 0$ is shown on Fig. 2.

The quintet level is represented by thirty eigenstates and for $|1,1,2, m⟩$ and $|2,2,2, m⟩$, where $m = 0, ±1, ±2$ we obtain

$$E_{1,1,2}^m = E_{2,2,2}^m = E_{3,3,2}^m = -J (h_{12}^2 + h_{34}^2) - g\mu_B B.$$  

When the cluster exhibits the structure of a local triplet and quintet spin bonds with eigenstates $|1,2,2, m⟩$ and $|2,1,2, m⟩$ one obtains the following eigenvalues

$$E_{1,2,2}^m = -J (h_{12}^2 + h_{34}^2) - 2J (h_{12}^2 - h_{34}^2) - g\mu_B B,$$

$$E_{2,1,2}^m = -J (h_{12}^2 + h_{34}^2) + 2J (h_{12}^2 - h_{34}^2) - g\mu_B B.$$  

Similarly to (3.3) and (3.4) when the spins of Ni1-Ni2 ions are paired in a singlet $|0,2,2, m⟩$, for the “+” sign in (2.6) one gets

$$E_{0,2,2}^m = -4J c_{12}^n h_{12}^2 + 2J h_{34}^2 - g\mu_B B$$

and for the “-” sign

$$E_{0,2,2}^m = -4J c_{12}^n h_{12}^2 - 2J h_{34}^2.$$  

For the Ni3-Ni4 singlet the eigenvalues are

$$E_{2,0,2}^m = -4J c_{34}^n h_{34}^2 + 2J h_{12}^2 - g\mu_B B$$

and

$$E_{2,0,2}^m = -4J c_{34}^n h_{34}^2 - 2J h_{12}^2.$$
The septet level consists of twenty one eigenstates and in the presence of two quintet spin bonds, \([2, 2, 3, m]\), one gets the energy
\[
E_{2,2,3}^m = 2J(h_{12}^3 + h_{34}^3) - g\mu_B B m.
\]
The eigenvalues of the remaining fourteen eigenstates \([1, 2, 3, m]\) and \([2, 1, 3, m]\) are given by
\[
\begin{align*}
E_{1,2,3}^m &= 2J(h_{12}^3 + h_{34}^3) - 2J(h_{12}^3 - h_{34}^3) - g\mu_B B m, \\
E_{2,1,3}^m &= 2J(h_{12}^3 + h_{34}^3) + 2J(h_{12}^3 - h_{34}^3) - g\mu_B B m,
\end{align*}
\]
respectively. The indirect splitting of the septet level related with the inequality \(h_{12}^3 \neq h_{34}^3\) is depicted on Fig. 2.

All nonet eigenstates \([2, 2, 4, m]\), with total magnetic quantum numbers \(m = 0, \pm 1, \pm 2, \pm 3, \pm 4\), correspond to the eigenvalue
\[
E_{2,2,4}^m = 6J(h_{12}^4 + h_{34}^4) - g\mu_B B m.
\]

### C. Model parameters

The overall description of the magnetic properties of \(\text{Ni}_4\text{Mo}_{12}\) obtained with the aid of (3.1) requires fourteen parameters. Four field-independent parameters, i.e. \(J, c_{12}^1, c_{12}^2\) and \(c_{34}\), are determined via the neutron spectroscopic analysis, see e.g. Ref. 42. The other ten parameters, denoted commonly by “\(h\)”, account for the indirect influence of the externally applied magnetic field onto the correlation functions. Their values can be determined from the magnetization and the magnetic susceptibility measurements. Thus, one could expect that for small magnitudes of the external magnetic field the proposed parameters will tend to one.

We would like to point out that the parameters in (2.1) are intended to capture a particular degeneracy of the initial energy spectrum obtained within the framework of the applied variational method briefly discussed in Sec. II A and in more detail in Ref. 42. This degeneracy arises from the probability of observing different distributions of all electrons involved in the exchange processes. It is influenced by the presence of an externally applied magnetic field and it decreases exponentially with increasing temperature. Thus, the Hamiltonian in (2.1) is an effective model for studying low-temperature properties when \(T \rightarrow 0\) and any attempt of tuning the “\(h\)” parameters to high temperature measurements would lead to erroneous results. Thereby the low-temperature and high-field magnetization measurements play a crucial role in extracting precise information on the values of the aforementioned parameters.

Using the Hamiltonian (3.1) we have computed the magnetization, differential magnetization and low-field susceptibility shown on Figs. 3, 4 and 5, respectively. The values of the parameters \(J, c_{12}^1, c_{12}^2\) and \(c_{34}\) are determined according to the neutron spectroscopy analysis reported in Ref. 42 and are listed in Table I along with the values for the field parameters discussed in Sec. III B.

These values allow us to reproduce the experimentally observed four magnetization steps found at 4.5, 8.9, 20.1 and 32 T of Ref. 17. The values of both parameters \(h_{ij}^0\) and \(h_{ij}^1\) indicate the low field dependence of \(\text{Ni}_4\text{Mo}_{12}\) molecule. On the other hand, the values of quintet and septet field parameters, corresponding to the domain \(10 \leq B \leq 30\), significantly differ form \(h_{ij}^0\) and \(h_{ij}^1\). Moreover, a pronounced jump is exhibited between \(h_{ij}^2\) and \(h_{ij}^3\). According to the used formalism such results are a signal for relatively important electrons orbital contributions. As a result, indepen-
FIG. 5. Low-field susceptibility. The experimental points from Ref.17 are in yellow and black. The blue and red lines represent the theoretical calculations, where the respective Hamiltonians are the isotropic Heisenberg and Hamiltonian (2.1) with \( J = 0.325 \) meV. The results obtained with the aid of model (3.5) constructed in Ref.20 are depicted by a green line. All calculations are performed with respect to the values \( B = 0.5 \) T and \( g = 2.25 \). The values of all field parameters for (2.1) are given in Table I.

D. Comparison to model \( H_{2d} \) of Ref.20

To describe the magnetic spectrum of the compound Ni₄Mo₁₂, in Ref.20 several models based on the conventional Heisenberg interaction among localized spins were proposed. One of them tried to accommodate at the best the distorted crystalline structure of the considered molecular magnet. Taking into account our convention, the named model involving anisotropic in space spin-spin interaction and an axial single-ion anisotropy, reads

\[
H_{2d} = J (\mathbf{s}_1 \cdot \mathbf{s}_2 + \mathbf{s}_1 \cdot \mathbf{s}_3 + \mathbf{s}_1 \cdot \mathbf{s}_4) + J' (\mathbf{s}_1 \cdot \mathbf{s}_3 + \mathbf{s}_1 \cdot \mathbf{s}_4) + D \sum_{i=1}^{4} (\mathbf{s}_i^z)^2.
\]

Here, the parameters \( J = 0.2517 \) meV, \( J' = 0.5723 \) meV and \( D = 0.2025 \) meV are determined by fitting to the relevant experimental data.

To compare our results, we computed the magnetization and the susceptibility with the aid of Hamiltonian (3.5). The results for the associated physical quantities are depicted with a green line on Figs. 3, 4 and 5. Notice that at weak external magnetic field, Hamiltonians (2.1) and (3.5) lead to slightly different results, while at strong fields \( (B > 25 \) T) the corresponding curves are indiscernible, see Figs. 3 and 4. On Fig. 5, we show the temperature dependence of the low-field susceptibility at \( B = 0.5 \). We see clearly that at low temperatures our model (2.1) fits better to experimental results than the Heisenberg Hamiltonian (3.5) with single ion anisotropy.

IV. CONCLUSION

In order to study the magnetization and magnetic susceptibility of the magnetic molecule Ni₄Mo₁₂, we extended the introduced in Ref.42 post-Hartree-Fock method, based on the molecular orbital theory, by accounting for the orbital contributions of the electrons to the intrinsic magnetic field and found all electrons’ correlations as a field dependent43. We calculated the effect of externally applied magnetic field on the electrons’ correlations with the aid of the effective spin-sigma bilinear form (2.1) via the field parameters described in Sec. II B. This allowed us to reproduce the behavior of the magnetization, differential magnetization and low-field susceptibility data reported in Ref.17. As it is shown on Figs. 3, 4 and 5 the obtained results are consistent with the available experimental data.

The values of all parameters entering the theory are presented in Table I. The role of the “h” parameters is to detect any variations in the zero-field energy spectrum induced from the externally applied magnetic field. Thus, as the magnitude of the external magnetic field increases, the energy sequence alters making the molecule more resistive to the applied external action. Consequently, one needs to input more magnetic energy in order to magnetize the molecule, Fig. 3. This process is also visible from the susceptibility measurements, see Fig. 4. The gaps become wider increasing the magnitude of the external magnetic field and hence making the Ni tetramer less susceptible. On both Figs. 3 and 4 the described effect is pronounced in the interval 10 – 30 T.

This process is also imprinted in the diagram shown on Fig. 2. The triplet and quintet energy levels are very close to each other and almost indistinguishable. As a consequence the triplet step, i.e. after 5 and 8 T, is not as wide as the upper steps. On the other hand, the quintet and septet energy levels are separated by a larger energy gap, which explains the extent of the quintet step. The same principle defines the width of septet plateau.

The approach used of the present study is applicable to any isolated nanomagnetic unit with a set of magnetic centers interacting by one or more complex intermediate bridges. The microscopic model in (2.1) rests on the multi-configuration self consistent field method based on the molecular orbital theory. Therefore, it is aimed to capture all magnetic features originating from the electrons’ delocalization and their distribution along the exchange bridges of a finite sized magnetic complex. It may be of great value since a nontrivial bridging structure favors a multitude of electrons’ distributions leading to a number of magnetic excitations that don’t result from spin-orbit coupling processes nor from the existence of conducting bands. Furthermore, such bridging structure also favors strong field dependent electrons’ correlations arising form the orbital contribution of each delocalized electron included in the exchange processes. In that respect neither of the known
conventional effective spin models possess an adequate parametrization scheme. Moreover, any attempt to tune the exchange parameters from any such model lead to an incomplete energy spectrum making the former inconvenient and thus inadequate. To conclude, for a nanomagnets with trivial bonding bridges and localized electrons the Hamiltonian in (2.1) naturally reduces to the Heisenberg model.

ACKNOWLEDGMENTS

The authors are indebted to Prof. N.S. Tonchev, Prof. N. Ivanov for very helpful discussions, and to Prof. J. Schnack for providing us with the experimental data used in Figs. 3, 4 and 5. This work was supported by the Bulgarian National Science Fund under Grant No. DN08/18 and the National program “Young scientists and postdoctoral researchers” approved by DCM 577, 17.08.2018.
