Two point configurations \(\{p_1,\ldots,p_n\}\) and \(\{q_1,\ldots,q_n\}\) are of the same order type if, for every \(i,j,k\), the triples \((p_i,p_j,p_k)\) and \((q_i,q_j,q_k)\) have the same orientation. In the 1980’s, Goodman, Pollack and Sturmfels showed that (i) the number of order types on \(n\) points is of order \(4^n+o(n)\), (ii) all order types can be realized with double-exponential integer coordinates, and that (iii) certain order types indeed require double-exponential integer coordinates. In 2018, Caraballo, Díaz-Báñez, Fabila-Monroy, Hidalgo-Toscano, Leanos, Montejano showed that \(n^{3n-o(n)}\) order types can be realized on an integer grid of polynomial size. In this article, we show that \(n^{4n-o(n)}\) order types can be realized on an integer grid of polynomial size, which is essentially best-possible.

1 Introduction

A set of \(n\) labeled points \(\{p_1,\ldots,p_n\}\) in the plane with \(p_i = (x_i, y_i)\) induces a chirotope, that is, a mapping \(\chi : [n]^3 \to \{+,-,0\}\) which assigns an orientation \(\chi(a,b,c)\) to each triple of points \((p_a,p_b,p_c)\) with

\[
\chi(a,b,c) = \text{sgn det} \begin{pmatrix} 1 & 1 & 1 \\ x_a & x_b & x_c \\ y_a & y_b & y_c \end{pmatrix}.
\]

Geometrically this means \(\chi(a,b,c)\) is positive (negative) if the point \(p_c\) lies to the left (right) of the directed line \(\overrightarrow{p_a p_b}\) through \(p_a\) directed towards \(p_b\). Figure 1 gives an illustration. We say that two point sets are equivalent if they induce the same chirotope and denote the equivalence classes as order types. An order type in which three or more points lie on a common line is called degenerate.
Goodman and Pollack [11] (cf. [16] Section 6.2) showed the number of order types on $n$ points is of order $\exp(4n \log n + O(n)) = n^{4n+o(n)}$. While the lower bound follows from a simple recursive construction of non-degenerate order types, the proof of the upper bound uses the Milnor–Thom theorem [17, 21] (cf. [19, 22]) - a powerful tool from real algebraic geometry. The precise number of non-degenerate order types has been determined for up to 11 points by Aichholzer, Aurenhammer, and Krasser [1, 2] (cf. [15]). For their investigations, they used computer-assistance to enumerate all “abstract” order types and heuristics to either find a point set representation or to decide non-realizability. Similar approaches have been taken by Fukuda, Miyata, and Moriyama [10] (cf. [9]) to investigate order types with degeneracies for up to 8 points. It is interesting to note that deciding realizability is an ETR-hard problem [18] and, since there are $\exp(\Theta(n^2))$ abstract order types (cf. [6] and [8]), most of them are non-realizable. For more details, we refer the interested reader to the handbook article by Felsner and Goodman [7].

Grünaum and Perles [13, pp. 93–94] (cf. [4, pp. 355]) showed that there exist degenerate order types that are only realizable with irrational coordinates. Since we are mainly interested in order type representations with integer coordinates in this article, we will restrict our attention in the following to the non-degenerate setting.

Goodman, Pollack, and Sturmfels [12] showed that all non-degenerate order types can be realized with double-exponential integer coordinates and that certain order types indeed require double-exponential integer coordinates. Moreover, from their construction one can also conclude that $n^{4n-o(n)}$ order types on $n$ points require integer coordinates of almost doubly-exponential size as outlined: For a slowly growing function $f: \mathbb{N} \to \mathbb{R}$ with $f(n) \to \infty$ as $n \to \infty$ and $m = \lfloor n/f(n) \rfloor \ll n$, we can combine each of the $(n-m)^4(n-m-o(n-m)) = n^{4n-o(n)}$ order types of $n-m$ points with the $m$-point construction from [12], which requires integer coordinates of size $\exp(\exp(\Omega(m)))$. Another infinite family that requires integer coordinates of super-polynomial size are the so-called Horton sets [3] (cf. [14]), which play a central role in the study of Erdős–Szekeres–type problems.

In 2018, Caraballo et al. [5] showed that at least $n^{3n-o(n)}$ non-degenerate order types can be realized on an integer grid of size $\Theta(n^{2.5}) \times \Theta(n^{2.5})$. In this article, we improve their result by showing that $n^{4n-o(n)}$ order types can be realized on a grid of size $\Theta(n^4) \times \Theta(n^4)$, which is essentially best-possible up to a lower order error term.

**Theorem 1** The number of non-degenerate order types which can be realized on an integer grid of size $(3n^4) \times (3n^4)$ is of order $\exp(4n \log n - O(n \log \log n))$.

2 Proof of Theorem 1

Let $n$ be a sufficiently large positive integer. According to Bertrand’s postulate, we can find a prime number $p$ satisfying $\frac{n}{\lfloor \log n \rfloor} < p < \frac{n}{\lceil \log n \rceil}$. As an auxiliary point set, we let

$$Q_p = \{(x, y) \in \{1, \ldots, p\}^2 : y = x^2 \mod p\}.$$

The point set $Q_p$ contains $p$ points from the $p \times p$ integer grid, and each two points have distinct $x$-coordinates. Moreover, $Q_p$ is non-degenerate because, by the Vandermonde determinant, we have

$$\det \begin{pmatrix} 1 & 1 & 1 \\ a & b & c \\ a^2 & b^2 & c^2 \end{pmatrix} = (b - a)(c - a)(c - b) \neq 0 \mod p,$$

and hence $\chi(a, b, c) \neq 0$ for any pairwise distinct $a, b, c \in \{1, \ldots, p\}$ (cf. [20]). In the following, we denote by $R(Q_p) = \{(y, x) : (x, y) \in Q_p\}$ the reflection of $Q_p$ with respect to the line $x = y$.

Let $\alpha = 2n$ and $m = \alpha \cdot (2n^2 + n^3)$. For sufficiently large $n$, we have $2n^2 + n^3 \leq 2n^3$ and $m + 2p \leq 3n^4$. Our goal is to construct $4^{n-o(n)}$ different $n$-point order types on the integer grid

$$G = \{-p, \ldots, m + p\} \times \{-p, \ldots, m + p\}.$$

We start with placing four scaled and translated copies of $Q_p$, which we denote by $D, U, L, R$, as follows:

- To obtain $D$, we scale $Q_p$ in $x$-direction by a factor $\alpha n \lceil \log n \rceil$ and translate by $(\alpha n^2, -p)$. All points from $D$ have $x$-coordinates between $\alpha n^2$ and $2\alpha n^2$ and $y$-coordinates between $-p$ and $0$;

- To obtain $U$, we scale $Q_p$ in $x$-direction by a factor $\alpha n \lfloor \log n \rfloor$ and translate by $(\alpha n^2, m)$. All points from $U$ have $x$-coordinates between $\alpha n^2$ and $2\alpha n^2$ and $y$-coordinates between $m$ and $m + p$;

- To obtain $L$, we scale $R(Q_p)$ in $y$-direction by a factor $\alpha n \lceil \log n \rceil$ and translate by $(-p, \alpha n^2)$. All points from $L$ have $y$-coordinates between $\alpha n^2$ and $2\alpha n^2$ and $x$-coordinates between $-p$ and $0$;

- To obtain $R$, we scale $R(Q_p)$ in $y$-direction by a factor $\alpha n \lfloor \log n \rfloor$ and translate by $(m, \alpha n^2)$. All points from $R$ have $y$-coordinates between $\alpha n^2$ and $2\alpha n^2$ and $x$-coordinates between $m$ and $m + p$.

Each pair of points $(l, r) \in L \times R$ spans an almost-horizontal line-segment with absolute slope less than $\frac{1}{n}$. Similarly, each pair of points from $D \times U$ spans an almost-vertical line-segment with absolute reciprocal slope less than $\frac{1}{n}$. As depicted in Figure 2 these line-segments bound $(p^2 - p)^2$ almost-square regions. Later, we will distribute the remaining
Figure 2: An illustration of the construction. The four copies $D, U, L, R$ of $Q_p$ are highlighted gray and the $(p^2-p)^2$ almost-square regions are highlighted green.

$n - 4p$ points among these almost-square regions in all possible way to obtain many different order types.

For every pair of distinct points $d_1, d_2$ from $D$, the $x$-distance between them is at least $\alpha n \lfloor \log n \rfloor$ and their $y$-distance is less than $p$. Since both points $d_1, d_2$ have $x$-coordinates from $\{\alpha n^2, \ldots, 2\alpha n^2\}$ and non-positive $y$-coordinates, the line $l_1l_2$ can only pass through points of $G$ with $y$-coordinate less than $p \cdot \frac{m}{\alpha n \lfloor \log n \rfloor} < 2n^3 \leq \alpha n^2$. (Recall that $m = \alpha \cdot (2n^2 + n^3) \leq 2\alpha n^3$ and $p \leq \frac{n}{\lfloor \log n \rfloor}$.) We conclude that every point from $U \cup L \cup R$ or from the almost-square regions lies strictly above the line $l_1l_2$. Similar arguments apply to lines spanned by pairs of points from $U$, $L$, and $R$, respectively. Note that, in particular, our construction has the property that for any point $q$ from an almost-square region, the point set $D \cup U \cup L \cup R \cup \{q\}$ is non-degenerate.
Almost-square regions Consider an almost-square region $A$ with top-left vertex $a$, bottom-left vertex $b$, top-right vertex $c$, and bottom-right vertex $d$, as depicted in Figure 3. The two almost-horizontal line-segments $\ell_1, \ell_2$ bounding $A$ meet in a common end-point $l \in L$. Let $r_1, r_2 \in R$ denote the other end-points of $\ell_1$ and $\ell_2$, respectively, which have y-distance $\alpha n \lfloor \log n \rfloor$.

Since we assumed $n$ to be sufficiently large, the points $l$ and $r_i$ (for $i = 1, 2$) have $x$-distance between $\alpha n^3$ and $2\alpha n^3$, and $a$ and $b$ have $x$-distance between $\alpha n^2$ and $2\alpha n^2$. Hence, we can bound the $y$-distance $\delta$ between $a$ and $b$ by

$$\frac{1}{2} \alpha \lfloor \log n \rfloor = \alpha n \lfloor \log n \rfloor \cdot \frac{\alpha n^2}{2\alpha n^3} \leq \delta \leq \alpha n \lfloor \log n \rfloor \cdot \frac{\alpha 2n^2}{\alpha n^3} = 2\alpha \lfloor \log n \rfloor.$$

Moreover, since $a$ and $b$ lie on an almost-vertical line (i.e., absolute reciprocal slope less than $\frac{1}{n}$), the $x$-distance between $a$ and $b$ is less than $\frac{2\alpha \lfloor \log n \rfloor}{n}$. An analogous argument applies to the pairs $(a, c), (a, c),$ and $(a, c)$, and hence we can conclude that the almost-square region $A$ contains at least

$$\left(\frac{1}{2} \alpha \lfloor \log n \rfloor - \frac{2\alpha \lfloor \log n \rfloor}{n}\right)^2 \geq \frac{1}{5} \left(\alpha \lfloor \log n \rfloor\right)^2$$

points from the integer grid $G$, provided that $n$ is sufficiently large.

Placing the remaining points We have already placed $p$ points in each of the four sets $D, U, L, R$. For each of the remaining $n - 4p$ points, we can iteratively choose one of the
(p^2 - p)^2 almost-square regions and place it, unless our point set becomes degenerate. To deal with these degeneracy-issue, we denote an almost-square region \( A \) alive if there is at least one point from \( A \) which we can add to our current point configuration while preserving non-degeneracy. Otherwise we call \( A \) dead.

Having \( k \) points placed (\( 4p \leq k \leq n - 1 \)), these \( k \) points determine \( \binom{k}{2} \) lines which might kill points from our integer grid and some almost-square regions become dead. That is, if we add another point that lies on one of these \( \binom{k}{2} \) lines to our point configuration, we clearly have a degenerate order type.

To obtain a lower bound the number of alive almost-square regions, note that all almost-square regions lie in an \( (\alpha n^2) \times (\alpha n^2) \) square and that each of the \( \binom{k}{2} \) lines kills at most \( \alpha n^2 \) grid points from almost-square regions. Moreover, since each almost-square region contains at least \( \frac{1}{15} (\alpha \lfloor \log n \rfloor)^2 \) grid points, we conclude that the number of alive almost-square regions is at least

\[
(p^2 - p)^2 - \binom{n}{2} \cdot \frac{\alpha n^2}{\frac{1}{5} (\alpha \lfloor \log n \rfloor)^2} \geq \frac{1}{17} \left( \frac{n}{\lfloor \log n \rfloor} \right)^4
\]

for sufficiently large \( n \), since \( \frac{n}{2 \lfloor \log n \rfloor} \leq p \leq \frac{n}{\lfloor \log n \rfloor} \) and \( \alpha = 2n \).

Altogether, we have at least

\[
\left( \frac{1}{17} \left( \frac{n}{\lfloor \log n \rfloor} \right)^4 \right)^{n-4p} = n^{4n-O(n \frac{\log \log n}{\log n})}
\]

possibilities to place the remaining \( n - 4p \) points. Each of these possibilities clearly gives us a different order type because, when we move a point \( q \) from one almost-square region into another, this point \( q \) moves over a line spanned by a pair \((l, r) \in L \times R \) or \((d, u) \in D \times U \), and this affects \( \chi(l, r, q) \) or \( \chi(d, u, q) \), respectively. This completes the proof of Theorem 1.
