Abstract

In this paper, we are concerned with improving the forecast capabilities of the Global approach to Time Series. We assume that the normal techniques of Global mapping are applied, the noise reduction is performed, etc. Then, using the mathematical foundations behind such approaches, we propose a method that, without a great computational cost, greatly increase the accuracy of the corresponding forecasting.

I. INTRODUCTION

For any observed system, physical or otherwise, one generally wishes to make predictions on its future evolution. Sometimes, very little is known about the system. Possibly, the dynamics behind the phenomenon being studied is unknown, and one is given just a time series of one (or a few) of its parameters. Therefore, performing a time-series analysis is the best one can do in order to learn the properties of the phenomenon. Its relevance may be gauged by the existence of extensive studies in a great diversity of branches of knowledge, in physics as well as in economics and the stock exchange, meteorology, oceanography, medicine, etc.

A time series is normally taken as a set of numbers that are the possible outcome of measurements of a given quantity, taken at regular intervals. In reality, however, the assumption that the time series reflects in some way the underlying dynamics of the systems is worsened by the fact that the measured data usually contain irregularities. These
may be due to a random external influence on a linear system, a noise (induced possibly by the measuring apparatus or other sources of contamination) which gets mixed with the desired information, thereby hiding it. But it may well be that they appear as a manifestation of low-dimensional deterministic chaos resulting from an intrinsic nonlinear dynamics governing the quantity under study (over which a random noise may also be superimposed), with the characteristic sensitivity to initial conditions.

If the time series is the only source of information on the system, prediction of the future values of the series requires a modelling of the system’s (perhaps nonlinear) dynamical law through a set of differential equations or through discrete maps. However, it is even possible that we do not know whether the measured quantity is the only relevant degree of freedom (frequently it is not) of the dynamical problem, nor how many of them there are.

Both noise-contaminated linear and nonlinear systems have nevertheless been studied with success employing statistical tools, chaos-theory concepts, together with time-series analysis [1, 2]. Given a time series, one should ask first whether it represents a causal process or whether it is stochastic. Tools have been developed to decide upon this fundamental question (the most common ones are spectral analysis, Lyapunov characteristic exponents and correlation functions, see [3, 4]). In the case of a series originated from a low-dimensionality chaotic dynamics, traditional linear methods of analysis are not adequate, but an analysis apparatus was devised for applications to such nonlinear systems [3, 4] and we will not be concerned with stochastic processes in this paper.

Methods for dealing with nonlinear time series fall mainly into two categories: local or global methods. Local methods are based on the assumption that, while in the long run nearby trajectories on the phase space diverge considerably, they stay within the same neighborhood for a while. One may conjecture that to predict the next step in a time series, a good indication should come from the previous visits the system had made to the phase space neighborhood containing the “last point” of the series. An average of the behavior of the system for neighboring points, with a minimization of the distance in the phase space between them, gives good results for the next-step forecasting.

Global methods, on the other hand, postulate a functional form for the dynamics to be valid for any time. Usually one considers polynomials of a suitable degree and one should devise a convenient way to estimate its coefficients. In this paper, we are going to concentrate in the global approach and, ac-
tually, we will start from the global mapping itself, i.e., we are not going to be concerned with how the global mapping was generated (there are many standard approaches to do it) and we will not deal with noise reduction either (such considerations are important when determining the mappings, etc.). We will focus on a new method to, from any standard mapping one might have, improve the forecasting using it, without having to pay a very high computational price.

Nonlinear analysis of Time Series relies not on the original maps of the dynamic system, but on its time-delay reconstruction. All discussions on the nonlinear treatment of Time Series make use of this reconstruction scheme. There are already classical references dealing with the subject [1, 3, 4, 5, 6, 7, 8]. This method allows one to reconstruct the phase space of the system with reasonable accuracy, using the information contained in the series only.

Lorenz [9] showed that dynamic systems of low dimensionality could present strange attractors on their phase spaces. Takens [10] proposed a method to reconstruct such phase spaces from the knowledge of a Time Series obtained from the system. He demonstrated that the original attractor and the reconstructed one are characterized by the same asymptotic properties and topological characteristics [11]. So, if we want to analyze the properties of the corresponding attractor of the system we have to reconstruct it.

In [10], Takens used a method to reconstruct the phase space. Vectors \( \xi_i \) (with dimension “m”) are reconstructed from the Time Series \( x_i = x(t_i), i = 1, ..., N \) as follows:

\[
\xi_i = \{x(t_i), x(t_i+p), ..., x(t_i+(m-1)p)\} \quad (1)
\]

where \( m \) is the embedding dimension and \( p \) is the time lag (for definitions, see [12]). Based on the trajectories of the reconstructed attractor, we can study various topological invariants of the system such as the Lyapunov exponents, the generalized entropies [11], etc. We can also extract the underlying dynamics via a global modelling of the system. For example, one can try to obtain a low order Taylor series expansion for the system, thus obtaining a global mapping representing the system. We can use this mapping to perform a forecast of entries we ignore, i.e., in the future\(^1\).

\(^1\) One can also do forecasting in a local version via analyzing the behavior of close vectors (to the one just before the one to be predicted) in order to estimate the next (unknown) entry (see [1]).
II. AN ALGORITHM TO IMPROVE THE GLOBAL FORECASTING

A. Stating the problem

Suppose that the system can be modelled by a set of differential equations of low dimensionality. What we would like to obtain is some kind of global map that, given any point of the phase space, could calculate a subsequent point of the trajectory. If we have known the set of differential equations (SDE) that models the system, we could find a solution (starting from an initial condition) by making a numerical integration through some map obtained from the SED (probably a Runge-Kutta map, a Taylor series one or an expansion in some function basis). For practical purposes (computers can not work with the infinity) a truncation must occur at some order of the series expansion. However, if the truncation order is low, we can run away from the real solution in a few time steps (even if each time step is very small). For chaotic systems it is not used (in general) a Runge-Kutta expansion of degree less than four. This implies that the map generated present polynomials of high degree. Let’s exemplify using one of the simplest chaotic system that exists, the Lorenz system:

$$\dot{x}_1 = \sigma (x_2 - x_1),$$

$$\dot{x}_2 = -x_2 - x_1 x_3 + R x_1,$$

$$\dot{x}_3 = x_1 x_2 - b x_3,$$

where $\sigma$, $R$ and $b$ are parameters and the system presents chaotic behavior for $R > 24.74$.

Why one of the simplest? Notice that this system possesses the minimum number of autonomous\(^2\) differential equations permeating chaos: three\(^3\). Besides that, chaos is a phenomenon that only takes place in non-linear systems, and the smallest piece of non-linearity that we can add to a linear system in order to turn it non-linear is a quadratic term.

Observe that the Lorenz system presents only two non-linear quadratic terms. Even in this simple case, as we will show, a Taylor series expansion of fourth order, will lead to a map of fifth degree in three variables.

Consider the following initial condition: $x_1(0) = x_{10}$, $x_2(0) = x_{20}$, $x_3(0) = x_{30}$. We can expand the corresponding solution as:

$$x_i = \phi_i(t) = \phi_i(0) + \frac{d\phi_i}{dt}(0) t + \frac{d^2\phi_i}{dt^2}(0) \frac{t^2}{2!} + \cdots.$$  \[3\]  

Since the system is defined by the equations $\frac{dx_i}{dt} = f_i(\vec{x})$, we have that $\dot{x}_i = \phi_i = f_i$ \(^4\).

\(^2\) The time does not appear explicitly.
\(^3\) In two dimensions we can not have chaos because the trajectories can not cross.
\(^4\) Where $\dot{u}$ represents $\frac{du}{dt}$. 

4
implying that:

\[
\frac{d}{dt} \left( \frac{d\phi_i}{dt} \right) = \frac{df_i}{dt} = \sum_{j=1}^{3} \frac{\partial f_i}{\partial x_j} \frac{dx_j}{dt} = \sum_{j=1}^{3} \frac{\partial f_i}{\partial x_j} f_j.
\]

We can notice that, for the case of the Lorenz system, this process will increase the degree of the polynomials forming the mapping by one for each order\(^5\). So, the mapping corresponding to the forth order Taylor expansion is, at maximum, formed by fifth degree terms. A polynomial mapping of fifth degree implies a total of 168 coefficients. Please remember that, as mentioned, this is for one of the simplest chaotic dynamic system cases (i.e., three-dimensional and only two non-linear (quadratic) terms).

It is important to notice that, in Time Series analysis, we do not have the dynamic system to begin with. We, of course, will consider that there is such a system behind the series and we will look for determining it. With the explanations above, we hope to have made it clear that, even if the underlying system is as simple as the Lorenz’s one, we will already have to face a great computational task (if one wants to use forth order expansions - generally the minimum accuracy necessary for practical purposes) of determining the 168 coefficients. With more detail, using the Lorenz system as a model for the Global Fitting scheme, let us suppose that we have a Time Series produced from this system (for instance, take one of the coordinates of the system). After the usual phase space reconstruction \([4]\), say we want to have a fourth order mapping (for the reconstructed system) with the same accuracy that could be found on the fourth order Taylor expansion for the Lorenz system. We would have to employ some minimization technique to determine 168 coefficients. In practice, this is a very high number making the whole procedure computationally expensive.

So, we are left with the hard choice of: either pay the computational price mentioned above and be very patient or try and decrease the degree of the mapping. Of course, there is no such thing as a free meal. The price for the latter choice would be that the accuracy would decrease (the corresponding Taylor expansion would be of lower order).

Therefore, despite the fact that the global approach has many attractive features, such as the fact that, once it is determined it is applicable to the whole series\(^6\), one sees that the effective use of it can be difficult to achieve in practice. So, there is a clear demand for procedures that can, without increasing the\(^5\) Since the highest degree present in the functions \(f, g\) and \(h\) is quadratic, the derivatives (present on \([\Pi]\) are, at maximum, first degree polynomials.

\(^6\) In the case of Local mappings, we have to determine a mapping for each entry of the series.
degree of the global mapping, enhance the accuracy of such mappings. In the next subsection, before introducing one such attempt, we will talk about mappings.

**B. Regarding Mappings**

In order to clarify the central idea of our proposed algorithm, let us make some comments and present some results concerning mappings representing the solutions for SDEs.

Consider the transformation group in \( n \) variables:

\[
x_i^* = F_i(\vec{x}, t),
\]

where \( t \) is the group parameter. From Lie’s theory [13, 14, 15], we know that this group is the solution to a SDE defined by:

\[
\dot{x}_i = f_i(\vec{x}),
\]

where \( f_i(\vec{x}) \equiv \frac{\partial F_i}{\partial t} \bigg|_{t=0} \) and \( \dot{x}_i \equiv \frac{dx_i}{dt} \). Therefore, the transformation group (5) (i.e., the solution to the dynamic system (6)) can be obtained from the group generator defined as the operator \( X \equiv \sum_{i=1}^{n} f_i \frac{\partial}{\partial x_i} \), as follows:

\[
x_i^* = F_i(\vec{x}, t) = x_i + tX[x_i] + \frac{t^2}{2!}X^2[x_i] + \cdots = \sum_{k=0}^{\infty} \frac{t^k}{k!}X^k[x_i].
\]

In practice, the process of numerically solving the SDE can be summarized by choosing a small time interval (\( \delta t \ll 1 \)) and truncating the series (8) at some order \( N \), thus obtaining a mapping \( M \) given by:

\[
\vec{x}_{i(P+1)} = \vec{F}_i(\vec{x}_{(P)}, \delta t) = \sum_{k=0}^{N} \frac{\delta t^k}{k!}X^k[x_{i(P)}],
\]

where \( \vec{x}_{i(P+1)} \) approaches \( x_{i(P+1)} \) when \( \delta t \rightarrow 0 \). Defining the functions \( \delta^k \varepsilon_i \) as
\[
\begin{align*}
(\varepsilon_i(\vec{x}(P)) &= \delta^0 \varepsilon_i(\vec{x}(P))) \equiv x_{i(P+1)} - \vec{x}_{i(P+1)} = \sum_{k=N+1}^{\infty} \frac{t^k}{k!} X^k[x_i(P)] \\
(\delta \varepsilon_i(\vec{x}(P)) &= \delta^1 \varepsilon_i(\vec{x}(P))) \equiv \varepsilon_i(\vec{x}(P+1)) - \varepsilon_i(\vec{x}(P)) \\
\delta^k \varepsilon_i(\vec{x}(P)) &\equiv \delta^{k-1} \varepsilon_i(\vec{x}(P+1)) - \delta^{k-1} \varepsilon_i(\vec{x}(P)) 
\end{align*}
\]

(10)

where \((k=2, \ldots)\), one can notice that

\[
\delta \varepsilon_i(\vec{x}(P)) = \sum_{j=1}^{n} \frac{\partial \varepsilon_i(\vec{x}(P))}{\partial x_j} \delta x_i + O(\delta x_i^2) \tag{11}
\]

and, generally,

\[
\delta^{k+1} \varepsilon_i(\vec{x}(P)) = \delta \delta^k \varepsilon_i(\vec{x}(P)) = \sum_{j=1}^{n} \frac{\partial \delta^k \varepsilon_i(\vec{x}(P))}{\partial x_j} \delta x_i + O(\delta x_i^2). \tag{12}
\]

Since \(\delta t \to 0\) implies that \(\delta x_i \to 0\), we can, using (12), enunciate the following result:

\[
\lim_{\delta t \to 0} \frac{\delta^{k+1} \varepsilon_i}{\delta^k \varepsilon} = 0, \tag{13}
\]

where \(k\) is a positive integer.

In the next subsection, based on this important result, we will present an algorithm that enhances the predictive power of global mappings for Time Series.

**C. Mathematical Basis for the Algorithm**

Based on the above result (13), we have produced an algorithm that allows for improving the forecasting for the global fitting of a Time Series.

As mentioned, we will suppose that the given Time Series is originated from phenomena that can be described by a low dimension dynamic system \((S_0)\). After the phase space reconstruction \([10]\), we have a set of vectors defining a set of points along a single trajectory of the reconstructed systems \((S_r)\). As usual, what we would like to determine is a global mapping \(M\) that would (with infinite precision) represent the solutions of the system \(S_r\). But, of course, in practice, what we can do is to produce a global mapping \(M\) through a procedure involving a minimization process\(^8\). If the Mapping \(M\) produces good forecasting for the series, that means that the coefficients present on \(M\) are close to the analogous ones present on the mapping \(M\) which can be represented by the infinite series \([8]\) (and, ideally, it would describe \(S_r\) with absolute precision). In that situation, we would be in a similar position to the

\(^7\) Takens [10] has demonstrated that the system \(S_0\) and \(S_r\) are topologically equivalent.

\(^8\) In layman terms, what is done is to adjust the coefficients of the polynomial mapping (of a certain degree) to better reproduce the phase space points.
one presented on the last subsection (where we had just a truncated series because we knew the underlying SDE and could determine the Taylor expansion). Why similar? In the “real” case we are dealing with now, we only have the series and have to determine the mapping through a finite process and, therefore, the coefficients would not be exactly the same as in the truncated expansion of $S_r$. So, defining functions $\varepsilon_i$ and $\delta^k \varepsilon_i$ analogously to how we did in the last subsection, we would expect that (13) would be valid. Actually, in the real world, the inequality $\delta^k \varepsilon_i \ll \delta^k \varepsilon$ is not valid for any positive integer $k$. The point is that, in actual calculations, $\delta t$ would be a finite value (not infinitesimal) $\Delta t$. So, at some integer value $K$, the inequality (14) would become

$$\Delta^{K+1} \varepsilon_i \approx \Delta^K \varepsilon_i.$$  

The above reasoning allows us to build an easily applicable algorithm: Consider that we want to forecast the coordinate $x_i$ (where $i$ can take any value from 1 to the dimensionality of the reconstructed system) of a point $P + 1$ that immediately follows a given point $P$. In order to produce the mapping $\overrightarrow{M}$, we use a certain number $a + 1$ of points that precede the point $P + 1$ (the points $P, P - 1, P - 2, \ldots, P - a$). Using this mapping, we can forecast the $x_i$ coordinates for these $a + 1$ points. Let us call these $a + 1$ values $\overrightarrow{x}_i$. From these, we can define the functions $\Delta^k \varepsilon_i$ (analogously to the functions (10) in subsection II B).

$$\Delta^0 \varepsilon_i(\overrightarrow{x}(J)) \equiv x_i(J) - \overrightarrow{x}_i(J)$$
$$\Delta^1 \varepsilon_i(\overrightarrow{x}(J)) \equiv \Delta^0 \varepsilon_i(\overrightarrow{x}(J)) - \Delta^0 \varepsilon_i(\overrightarrow{x}(J-1))$$
$$\vdots \quad \vdots$$
$$\Delta^k \varepsilon_i(\overrightarrow{x}(J)) \equiv \Delta^{k-1} \varepsilon_i(\overrightarrow{x}(J)) - \Delta^{k-1} \varepsilon_i(\overrightarrow{x}(J-1)), \quad \vdots \quad \vdots$$  

(16)

where $(k = 0, \ldots)$ and $(J = P - a + k, \ldots, P)$. Using these definitions, we can determine the values for $k$ where we have $\Delta^{k+1} \varepsilon_i \approx \Delta^k \varepsilon^9$ and, using this knowledge, we will see that we can improve the forecasting generated by the mapping $\overrightarrow{M}$. Let us clarify what we mean: if we want to forecast the value for the coordinate $x_i$ of the point $P + 1$, we may use the global mapping $\overrightarrow{M}$ that would produce the forecast $\overrightarrow{x}_i(P+1)$. We know that $x_i(P+1) - \overrightarrow{x}_i(P+1) = \Delta^0 \varepsilon_i(\overrightarrow{x}(P+1))$ and, therefore,

$$x_i(P+1) = \overrightarrow{x}_i(P+1) + \Delta^0 \varepsilon_i(\overrightarrow{x}(P+1)).$$  

(17)

Notice that we do not know the value for $\Delta^0 \varepsilon_i(\overrightarrow{x}(P+1))$. But we know that $\Delta^1 \varepsilon_i(\overrightarrow{x}(P+1)) = \Delta^0 \varepsilon_i(\overrightarrow{x}(P+1)) - \Delta^0 \varepsilon_i(\overrightarrow{x}(P))$, im-

9 There is a finite range for the values for $k$ in which that happens. After a certain value, the $\Delta^{k-1} \varepsilon_i$ start to diverge.
plying that
\[ \Delta^0 \varepsilon_i(\bar{x}_{(P+1)}) = \Delta^0 \varepsilon_i(\bar{x}_P) + \Delta^1 \varepsilon_i(\bar{x}_{(P+1)}). \] (18)

Let us examine this: we know the value for \( \Delta^0 \varepsilon_i(\bar{x}_P) \) (i.e., \( x_i(P) = \bar{x}_i(P) \)) but we do not know \( \Delta^1 \varepsilon_i(\bar{x}_{(P+1)}) \). However, if \( P \) and \( P+1 \) are sufficiently close (such that \( \Delta^1 \varepsilon_i \ll \Delta^0 \varepsilon_i \)), we can expect that we will gain information when substituting (18) into (17) obtaining
\[ x_i(P+1) = \bar{x}_i(P+1) + \Delta^0 \varepsilon_i(\bar{x}_P) + \Delta^1 \varepsilon_i(\bar{x}_{(P+1)}). \] (19)

Why do we gain information? If we compare (17) to (19), we can observe that

the unknown term in (17) is \( \Delta^0 \varepsilon_i(\bar{x}_{(P+1)}) \) which is (by hypothesis) much bigger than the unknown term in (19): \( \Delta^1 \varepsilon_i(\bar{x}_{(P+1)}) \). So, the term \( \Delta^0 \varepsilon_i(\bar{x}_P) \) is a correction to \( \bar{x}_i(P+1) \). Analogously, we have \( \Delta^2 \varepsilon_i(\bar{x}_{(P+1)}) = \Delta^1 \varepsilon_i(\bar{x}_{(P+1)}) - \Delta^1 \varepsilon_i(\bar{x}_P) \), implying that:
\[ \Delta^1 \varepsilon_i(\bar{x}_{(P+1)}) = \Delta^1 \varepsilon_i(\bar{x}_P) + \Delta^2 \varepsilon_i(\bar{x}_{(P+1)}), \] (20)

substituting this into (19), if \( P \) and \( P+1 \) are sufficiently close such that \( \Delta^2 \varepsilon_i \ll \Delta^1 \varepsilon_i \), we would have a second order correction to \( \bar{x}_i(P+1) \). Actually, when the relation \( \Delta^{k+1} \varepsilon_i \ll \Delta^k \varepsilon_i \) applies, we can further correct \( \bar{x}_i(P+1) \), i.e.,
\[ x_i(P+1) = \bar{x}_i(P+1) + \Delta^0 \varepsilon_i(\bar{x}_P) + \Delta^1 \varepsilon_i(\bar{x}_P) + \cdots + \Delta^k \varepsilon_i(\bar{x}_P) + \Delta^{k+1} \varepsilon_i(\bar{x}_{(P+1)}). \] (21)

Therefore, we can build a simple algorithm to improve the prediction \( \bar{x}_i(P+1) \), obtained with mapping \( \bar{M} \): we determine the integer \( k \) for which the approximation starts to fail, i.e., \( \Delta^{k+1} \varepsilon_i \approx \Delta^k \varepsilon_i \), then we neglect the term \( \Delta^{k+1} \varepsilon_i(\bar{x}_{(P+1)}) \) and end up with
\[ x_i(P+1) \approx \bar{x}_i(P+1) + \Delta^0 \varepsilon_i(\bar{x}_P) + \Delta^1 \varepsilon_i(\bar{x}_P) + \cdots + \Delta^k \varepsilon_i(\bar{x}_P). \] (22)

The remaining question is: How to define \( \Delta^{k+1} \varepsilon_i \approx \Delta^k \varepsilon_i \)? Let us elaborate the analysis just made above. We are interested in using an approximation, a kind of Taylor series expansion, when trying to forecast the Time Series, what one might expect from such a situation? In a perfect world, the terms in the series would, gradually, become smaller in an infinite fashion. Of course, as already mentioned above, we are dealing with a real series, where each entry is not infinitesimally apart the previous one and is, actually, finitely separated. How “finitely separated” depends on the particular series under study and, being more rigorous, on the particular
section of the series we are considering. This translates to the fact that, if one considers the absolute values of the differences $\Delta^k \varepsilon_i$, they will decrease with increasing values for $k$ until this value reaches the magnitude defined by the “non-infinitesimal” character of the Time Series we have just emphasized, where this character will then make the values for the differences oscillate (for a while) around this magnitude (since this magnitude would dominate over the initial tendency of the differences to decrease). With the increasing values for $k$, this initial tendency of the differences to decrease will cease as our approximation (Taylor like) starts to diverge from the actual value for the series. We will then see the absolute values for the following differences start to increase and rapidly diverge. That clearly, if one thinks in plotting the (absolute) values for the differences, defines a plateau where $\Delta^{k+1} \varepsilon_i \approx \Delta^k \varepsilon_i$ and our above introduced method will work at its best.

D. The steps of the algorithm

Consider that we have already reconstructed the phase space from the Time Series under study and that we want to forecast the $P+1$ entry ($P$ is the last known value of the series). This entry corresponds to a coordinate of a reconstructed vector on the phase space (as usual). Using a global mapping $\mathcal{M}$, obtained via standard k-fold validation procedures [16], we do the following:

1. Set $n = 10$.

2. We calculate the absolute value for the functions $\Delta^k \varepsilon_i$ (see eq. (16)) up to $k = n$ for the point $P$.

3. We check to see if we have already found the plateau, i.e., we look for the value of $k$ for which $|\Delta^k \varepsilon_i| < |\Delta^{k+1} \varepsilon_i|$. Please note that this checking can be very easily automatized.

4. If the checking returns false we set $n = n+10$ and return to step 2. Otherwise we would have found the corrected value for $x_i(P+1)$ as:

$$x_i(P+1) \approx x_i(P) + \Delta^0 \varepsilon_i(x_i(P)) + \Delta^1 \varepsilon_i(x_i(P)) + \cdots + \Delta^k \varepsilon_i(x_i(P)). \quad (23)$$

III. APPLICATIONS

In this section, we are going to present two applications of the above introduced improved forecast method. We will start by introducing the Time Series in question, present the reconstruction parameters and the associated Global Mapping. We then will proceed to the algorithm, following the steps just introduced and compare the average performance for the “usual” and the improved approaches.
A. Application 1: Lorenz

1. The Time Series

This is an “academic” application in the sense that it is, certainly, originated from a dynamic system and we actually even know which one. But it is important in order for us to see the ideas of the improved method working on an arena that suits it very nicely.

The Time Series was generated taking the consecutive values for the $x_1$ coordinate of the Lorenz system (see eq. (2)), starting from the initial condition $x_{10} = -0.3336666667, x_{20} = -0.3336666667, x_{30} = 21.9996666667$, using an eighth order Runge-Kutta numerical integration [17]. The Series presents 600 entries (please see figure (1) for a plotting of this Time Series).

Now, in order to apply the Global Analysis ([1, 4]) to this Time Series, we have to reconstruct the phase space. To do that, we need to determine the relevant parameters, namely the time-lag and the embedding dimension (please see [12]). For this present case, the reconstruction parameters are time-lag = 6 and embedding dimension = 3. So, in the remaining of this subsection, we will call these three dimensions of the reconstructed phase space for the Lorenz system ($x, y, z$).

In real life, we use the whole Time Series we know/measure to produce the Global Mapping and use it to predict future (unknown) entries. Here, in order to evaluate the accuracy of the predictions we obtain using a regular Global Fitting and our Improved one, we are going to use an initial portion of the Series to generate the Mapping and the other (remaining) portion of the Series as our testing ground, i.e., we will apply our mappings to entries in that region and compare it to the actual values to see how the mappings fared. In the present case, the first 140 entries constitute our portion of the Series used to build the Mapping up. Basically, we use all the vector reconstructed from these entries and produce a quadratic fitting minimizing the distances from this fitting (when applied to each vector) to the actual values via, for instance, a least mean square procedure. Actually, we also have used an improvement (a very standard one) called a k-validation. In layman’s language, basically what this k-validation does is to average up several mappings. Doing all this, the global mapping we have derived (and to be used on this application henceforth) is:

$$\widetilde{M} = 1.317833301 x - 0.005266089766 x^2$$
$$+ 0.07580676400 x y - 0.1245478927 x z - 0.01839588238 y^2 + 0.06578287850 y z - 0.01025562766 z^2 - 0.4700554502 y + 0.1415056465 z.$$  

(24)
2. The inner works of the improved forecast algorithm

Let us now, using two generic points from the Series, exemplify the workings of our improved method.

Consider the entries \( P = 316 \) and \( P = 533 \), with respective values of \(-1.370578116\) and \(6.860383245\). The values for the entries \( P = 317 \) and \( P = 534 \), the “next” entry for each case considered here, are \(-1.041455029\) and \(7.225654731\). Let us see how the “usual” Global Fitting fares in these entries. Using the mapping presented on (24), we get the following forecasting for the entries \( P = 317 \) and \( P = 534 \):

\[
-1.041455029 \quad \text{and} \quad 7.225654731.
\]

These present a “percentage error” (given by \(|(\text{value} - \text{forecast})/\text{value}|\)) of \(24.85090309\) and \(2.259732482\) respectively.

3. Performance Comparison

The reader may ask: why these two entries above? Fair enough, they are not special at all. So, in order to confirm the fact that our new approach may be an advantage, let us make a general survey of the entries on the Time Series. We take 21 entries, equally distributed, on the last part (not used when producing the Global Mapping) of the Time Series, we see that happens for \(k = 5\). Using this into equation (23), we find (see table (1)) that the “percentage error” for our method is \(0.0004798095\).

- \(P=533\) Again, what we have to do is, by looking at table (II), second column, determine to which value of \(k\) \(\Delta^k \varepsilon(\vec{x}(P))\) stops decreasing for the first time (and begin the oscillations we have mentioned in section II C). From table (II), we see that happens for \(k = 3\). Using this into equation (23), we find (see table (II)) that the “percentage error” for our method is \(0.001986533\).

As we have mentioned in section II C, we expect the absolute values of \(\Delta^k \varepsilon(\vec{x}(P))\) to oscillate when \(|\Delta^k \varepsilon_i| \approx |\Delta^{k+1} \varepsilon_i|\). That fact is illustrated, for the entries \(P = 316\) and \(P = 533\) respectively, on figures (2) and (3).
Series. The results are presented on table (III).

The idea behind of presenting the results for points equally spaced on the entire Time Series (meaning the entire testing ground defined above) was to provide the information on all the Time Series, i.e., it is very important (for many Series) the section in which the analysis is carried out. So, we have decided to present the results for many points, evenly distributed along every section of the Time Series. But, for completeness, we will present the average percentage error (for the improved Global fitting) for the whole testing ground for the Time Series and for the 21 entries used on table (III). The percentage error for the whole series is $1601961683e^{-1}$ and for the 21 entries on the table is $3385849199e^{-1}$. Both are compatible, showing that the chosen 21 are representative of the totality of the possibilities. The percentage error for the “regular” global fitting is (for the whole series) $10.58939930$.

As can be seen, our method is a great improvement of accuracy when compared with the “plain” Global Fitting. To help in this analysis we present figure [1] where we plot $\ln(\Delta_{GF}/\Delta_{IGF})$, where $\Delta_{GF}$ and $\Delta_{IGF}$ are, respectively the percentage errors in the Global Fitting and the Improved Global Fitting. As can be seen from the figure, most of the IGF errors are smaller than $e^{-4}$ times the GF errors.

**B. Application 2: Heart beat**

1. **The Time Series**

Let us now deal with a more “real” example, where we deal with data extracted from Nature, we do not know the system behind the phenomenon, etc. The following Time Series was obtained\(^\text{10}\) from measurements of the heart beat rate in a person performing many different activities. The Series presents 1744 entries (please see figure [5] for a plotting of this Time Series).

In order to produce the Global Mapping for this case, we have proceeded in the same fashion as we did in the Lorenz System Time Series application. So, we will not repeat the whole explanation of the procedures involved here. Please refer to section IV-A above. For this application, the reconstruction parameters are time-lag = 10 and embedding dimension = 3. So, in the remaining of this subsection, we will call these three dimensions of the reconstructed phase space for the Heart beat data $(x, y, z)$. The global mapping we have derived (and to be used on this application

\[^{10}\text{http://ecg.mit.edu/time-series/}\]
henceforth) is:

\[ M = -1.172534275 x - 0.2617292220 z^2 + 0.4661889468 y z - 0.3426537822 y^2 - 0.1107944588 x z + 0.3574412776 x y - 0.1136908621 x^2 + 15.65933419 z - 12.98866231 y. \]

(25)

2. The inner works of the improved forecast algorithm

Let us now, using two generic points from the Series, exemplify the workings of our improved method.

As in the previous application, consider the entries \( P = 737 \) and \( P = 1016 \), with respective values of 89.18875624 and 94.25098125. The values for the entries \( P = 738 \) and \( P = 1017 \), the “next” entry for each case considered here, are 89.16743126 and 94.28981563. Let us see how the “usual” Global Fitting fares in these entries. Using the mapping presented on (25), we get the following forecasting for the entries \( P = 738 \) and \( P = 1017 \):

\[ 90.996977 \text{ and } 82.611004. \]

These present a “percentage error” (defined above) of 2.051809404 and 12.38607961 respectively.

How about the improved method? In order to apply our method we have to find the plateau by finding the value for \( k \) to which \( |\Delta^k \varepsilon| < |\Delta^{k+1} \varepsilon| \). Let us do that for the couple of points chosen above:

- \( P=737 \)

As “prescribed” above, what we have to do is, by looking at table (IV), second column, determine to which value of \( k \) \( \Delta^k \varepsilon(\bar{x}(P)) \) stops decreasing for the first time (and begin the oscillations we have mentioned in section [II]C). From table (IV), we see that happens for \( k = 1 \). Using this into equation (23), we find (see table (IV)) that the “percentage error” for our method is 0.3970473916.

- \( P=1016 \)

Again, what we have to do is, by looking at table (V), second column, determine to which value of \( k \) \( \Delta^k \varepsilon(\bar{x}(P)) \) stops decreasing for the first time (and begin the oscillations we have mentioned in section [II]C). From table (V), we see that happens for \( k = 3 \). Using this into equation (23), we find (see table (V)) that the “percentage error” for our method is 1.524959626.

As in the previous application, we expect the absolute values of \( \Delta^k \varepsilon(\bar{x}(P)) \) to oscillate when \( |\Delta^k \varepsilon| \approx |\Delta^{k+1} \varepsilon| \). That fact is illustrated, for the entries \( P = 737 \) and \( P = 1016 \) respectively, on figures (6) and (7).
3. Performance Comparison

Let us make the general survey of the entries on this Time Series. We take 26 entries, equally distributed, on the last part (not used when producing the Global Mapping) of the Time Series. The results are presented on table (VI).

The idea behind of presenting the results for points equally spaced on the entire Time Series (meaning the entire testing ground defined above) is the same one explained on the section regarding the Lorenz System. The percentage error for the whole series is 1.877994467 and for the 26 entries on the table is 1.429515613. Both are compatible, showing that the chosen 26 are representative of the totality of the possibilities. The percentage error for the “regular” global fitting (for the whole series) is 5.971546764.

As can be seen, in the majority of cases, our method is, for this more “realistic” case, also a great improvement of accuracy when compared with the “plain” Global Fitting. To help in this analysis we present figure [S] where we plot \( \ln(\Delta_{GF}/\Delta_{IGF}) \), where \( \Delta_{GF} \) and \( \Delta_{IGF} \) are, respectively the percentage errors in the Global Fitting and the Improved Global Fitting. As can be seen from the figure, most of the IGF errors are more than five times smaller than the GF errors.

IV. CONCLUSION

There is a huge demand for improving methods that do not cost too high a computational price to achieve desired levels of accuracy in Time Series Analysis.

Here, we have presented one such method. The basic rational behind it is that we can make use, as explained in section [II] of the underlying (assumed) low-dimensionality dynamics to correct our forecast. It is important to mention that, in order to apply the method, one does not have to quantify the hyperbolicity (or the low-dimensionality, for that matter) of the Time Series. The steps of the procedure will take (automatically) care of stopping when this hyperbolicity “spoils” the correcting power of the method. So, the algorithm is secure. It is also useful to remember that our efforts here are aimed to avoid the computational cost of the fitting/minimizing procedures. So, our method is not equivalent to fittings, with the same computational cost, in any shape or form.

We have presented two applications of our method: The first one is a (we are going to call it) pure low dimensional known system, from where we generated a Time Series. The reason for this application is to use the method on a controlled arena, i.e., we can see the method working at its best. What do we mean by its best? Could not have we...
gotten better results than the ones presented in section IIIA? Of course we could have, for instance, if we have made the Time Series more “dense”, i.e. if we have used smaller values for $\Delta t$, of course, the results would be better. Indeed, we can do the same indefinitely up to infinite precision. What we mean by “its best” is the fact that there is not, for sure, any high dimensional behavior. We have then demonstrated that the ideas behind our method work quite nicely.

The second application corresponds to a Time Series obtained from measurements, i.e., we do not have any prior knowledge about the (possible) dynamic system underlying it. We have found that, after the usual techniques have been used to produce the Global mapping, we could improve the forecast capabilities of the fitting quite a bit (see section IIIB), thus demonstrating the practicality of our approach on a uncontrolled situation.

Our method has, of course, its limitations. Perhaps the most obvious one is the fact that it won’t help much in the case where the Time Series is “sparse”, i.e., as we have mentioned just above, as $\Delta t$ becomes large, the method won’t work. The limitation so far is that we do not have a criteria, as yet, to, just by quickly inspecting the Time Series, determine if our method applies well or not. One has to have a go and, in a testing arena, verify if the method is improving things.

That leads to future work: produce a fast algorithm to test the time series for applicability (or not) of the method. One other possible line of research to be pursued is to improve our algorithm in the sense of using more information contained on the plateau than we are using now. So far, we are taking the first piece of data on the plateau but, as we have explained in section IIIB the values for the corrections will oscillate from that point on. It is reasonable to look for an algorithm to extract information from this oscillation.

TABLE VI: Comparison between the Global Fitting and the Improved Global Fitting for the Time Series with Heart Beat data
FIG. 2: The plot shows the values of the $|\Delta^k \varepsilon|$ against the number $k$, for the entry 316, for the Lorenz System Time Series. In the x-axis, marked with the letter $K$, is the value of $k$ that our procedure defines as the beginning of the plateau.
FIG. 3: The plot shows the values of the $|\Delta^k \varepsilon|$ against the value of $k$, for the entry 533, for the Lorenz System Time Series. In the x-axis, marked with the letter $K$, is the value of $k$ that our procedure defines as the beginning of the plateau.

FIG. 4: The plot is for $\ln(\Delta GF / \Delta IGF)$ against the position in the Time Series ($i$). The line marks the threshold where, above it, $\Delta IGF$ starts to be smaller than $e^{-4}$ times $\Delta GF$. 

\[ 2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20 \]
FIG. 5: Heartbeat data. The horizontal axis marks the position of the entry (i) and the vertical on the value for the entry (X(i)).

FIG. 6: The plot shows the values of the $|\Delta^k \varepsilon|$ against the value of $k$, for the entry 737, for the Heartbeat Time Series. In the x-axis, marked with the letter $K$, is the value of $k$ that our procedure defines as the beginning of the plateau.
FIG. 7: The plot shows the values of the $|\Delta^k \varepsilon|$ against the vale for $k$, for the entry 1016, for the Heartbeat Time Series. In the x-axis, marked with the letter $K$, is the value of $k$ that our procedure defines as the beginning of the plateau.
FIG. 8: The plot is for $\ln(\Delta_{GF}/\Delta_{IGF})$ against the position in the Time Series ($i$). The solid line marks the threshold where, above it, $\Delta_{IGF}$ starts to be the half of $\Delta_{GF}$ and the dotted line the threshold where, above it, $\Delta_{IGF}$ starts to be the fifth of $\Delta_{GF}$.
