ABSTRACT
Within its observational band the Laser Interferometer Space Antenna, LISA, will simultaneously observe orbital modulated waveforms from Galactic white dwarf binaries, a binary black hole produced gravitational-wave background, and potentially a cosmologically created stochastic gravitational-wave background (SGWB). The overwhelming majority of stars end their lives as white dwarfs, making them very numerous in the Milky Way. We simulate Galactic white dwarf binary gravitational-wave emission based on distributions from various mock catalogs and determine a complex waveform from the Galactic foreground with 3.5 × 10⁷ binaries. We describe the effects from the Galactic binary distribution population across mass, position within the Galaxy, core type, and orbital frequency distribution. We generate the modulated Galactic white dwarf signal detected by LISA due to its orbital motion, and present a data analysis strategy to address it. The Fisher Information and Markov Chain Monte Carlo methods give an estimation of the LISA noise and the parameters for the different signal classes. We estimate the detectable limits for the future LISA observation of the SGWB in the spectral domain with the three LISA channels A, E, and T. We simultaneously estimate the Galactic foreground, the astrophysical and cosmological backgrounds. Assuming the expected astrophysical background and a Galactic foreground, a cosmological background energy density of around Ω_{GW,cosmo} ≈ 8 × 10^{-13} could be detected by LISA. LISA will either detect a cosmologically produced SGWB, or set a limit that will have important consequences.

Key words: Gravitational waves – stars: White dwarfs – Cosmology: early Universe – Stars: binaries

1 INTRODUCTION
The latest Gaia data release, the Early Data Release 3 (EDR3), was recently presented (Gaia Collaboration et al. 2020). Gaia is an astrometry mission, it measures with great precision the position, parallax, and movement of millions of stars in our Galaxy. Moreover, with its spectrometer, it is possible to know the type of most of the stars observed. This is the most accurate stellar map to date giving the position, the luminosity, and the spectrum of more than 1.8 × 10⁹ stars. Among these, 10⁵ white dwarfs (WDs) have been observed and well separated from other stars in the Hertzsprung–Russell diagram (Gentile Fusillo et al. 2019). Stars with an initial mass between 0.9 and 80 solar mass (M☉) will become a WD within a Hubble time. This implies that 97% of stars in the Galaxy will finish as a WD (Napiwotzki 2009; Fontaine et al. 2001), resulting in 10 to 50 billion WDs in the Milky Way. For 50 billion WDs, we use the density of 5 × 10⁻³ pc⁻³. In Ledrew (2001), the distribution of the star class differences in our galaxy is given. The calculation is based on the number stars of each type in a volume of 10⁴ pc³ around the Sun.

WDs are stellar core remnants, have typical radii around 10,000 km and masses between 0.25M☉ for the He WDs and up to the Chandrasekhar mass 1.4M☉, which makes them compact objects (Chandrasekhar & Milne 1931). There are a significant number of WDs that form double WDs (DWD) (Nelemans et al. 2001a). Ultra-compact WD binaries with a short orbital period, from a few hours down to a few minutes, can have a significant electromagnetic (EM) signal, making them observable. Among these are cataclysmic variable (CV) systems (Kupfer et al. 2020) made of a WD and a companion star, which transfers part of its mass after having filled its Roche lobe. When matter falls towards the WD, there is a strong periodic emission of UV and sometimes X-rays (Warner 1995). Such interacting binaries are possible progenitors of Type Ia supernova (Webbink 1984; Hillebrandt & Niemeyer 2000).

DWDs in our Galaxy are sources of gravitational waves

(GW) that will be detectable with LISA (Amaro-Seoane et al. 2017), the future space mission of the European Space Agency (ESA) whose objective is to detect low frequency GW from space. Its observational band is a great source for understanding the astrophysical properties of our Galaxy and the DWD population.

*Gaia* DR2 provided astrometry for some WDs. We cannot yet distinguish individual DWDs binaries, but for some known binaries the estimate of their GW emission could be refined. *Gaia* DR4 will identify many sources that will be detectable by LISA with a signal-to-noise ratio (SNR) larger than five (Kupfer et al. 2018); note also that many systems which can be found by *Gaia* will not have a larger SNR for LISA (Korol et al. 2017; Gentile Fusillo et al. 2019). From the light curves, it will be possible to extract an estimate of the DWD population that is detectable by LISA (Hollands et al. 2018). The GW emission will be at frequencies less than one $10^{-3}$ Hz. The study and measurement of these systems are some of the key science goals of the *LISA* mission. In addition, there are binary systems known as ‘verification binaries’ (Kupfer et al. 2018). For example, recently the Zwicky Transient Facility (ZTF) has measured a DWD with an orbital period measured at 7 minutes (Burdge et al. 2019), which corresponds to a GW emission of $3 \times 10^{-2}$ Hz. Well studied systems like this can be used to verify the *LISA* performance, acting as a way to confirm the sensitivity of LISA.

The band $10^{-5}$ to $10^{-3}$ Hz, if usable with *LISA* data, would be important for the detection and separation of the stochastic gravitational wave backgrounds (SGWBs). The high frequency (up to 0.1 Hz) is dominated by the LISA noise, so it is difficult to separate a SGWB from this noise. However, the high frequency data does provide some important information about the *LISA* noise. The goal of the *LISA* mission (Amaro-Seoane et al. 2017) is to detect GWs in the $[10^{-5}, 0.1]$ Hz frequency band, possibly extendable to $[10^{-5}, 1]$ Hz. This corresponds to orbital periods between 12 seconds and 15 days.

The study of the population of DWDs is an important goal for the *LISA* mission. *LISA* is being led by the ESA, with participation from NASA. The launch is currently planned for 2034, with at least 4 years of observations, possibly extended to 10 years. The *LISA* constellation will consist of three spacecrafts separated from one another by $L = 2.5 \times 10^9$ m. There are many GW signals expected to be detected in the *LISA* band. Galactic sources will be significant for *LISA*, for example from DWD systems (Nelemans et al. 2001b; Cornish & Littenberg 2007; Ruiter et al. 2010; Adams & Cornish 2014; Lamberts et al. 2019; Eldridge et al. 2017; Hernandez et al. 2020). The stochastic GW signal from the DWDs, or the Galactic foreground, is anisotropic and the representation of its energy density is not a simple power law (Ungarelli & Vecchio 2001). Many studies have addressed populations of DWDs in our Galaxy and their detectability in the *LISA* band. Nissanke et al. (2012) computes the stochastic signal of Galactic origin according to different DWD models. Breivik et al. (2020) presents a method of calculating the Galactic foreground and discusses the power distribution and resolvability by *LISA* as a function of distance to the source. Adams & Cornish introduce the calculation of the orbitally induced modulation of the Galactic foreground in the context of detecting a stochastic GW background (SGWB) of cosmological origin (Cornish 2002; Adams & Cornish 2014, 2010). Korol et al. (2020) and Roebber et al. (2020) explore the possibility of observing DWDs in satellite Galaxies.

The SGWB is the superposition of the large number of independent GW sources (Romano & Cornish 2017; Christensen 2019). We can distinguish three types of SGWB in the *LISA* band, depending on their origin. The most important by its amplitude is the Galactic foreground produced by the DWDs in our Galaxy. We note that it mainly consists of DWDs, but there are other types of galactic sources which contribute to the Galactic foreground, CVs, Stripped stars or WD+M-dwarfs for example. We simulate this foreground with mock catalogs of DWDs. The second source is the background from extragalactic binary black holes (BBH) and binary neutron stars (BNS) throughout the universe which we call the astrophysical background. This background is also present in the LIGO and Virgo band (roughly between 20 and 1000 Hz) and by considering this background as a power law, it is possible to extrapolate this background in the *LISA* band (Chen et al. 2019; Abbott et al. 2016).

It is also possible to use binary population synthesis models to construct an astrophysical population of BBH and BNS and to predict the associated SGWB (Péroux et al. 2021). Finally, the cosmological background (Caprini & Figueroa 2018a) denotes the stochastic background coming from the primordial processes such as inflation, phase transitions or cosmic strings (Sakellariadou 2009; Chang & Cui 2020). The cosmological SGWB originates in the early universe (Mendes et al. 1995; Garcia-Bellido & Figueroa 2007), and its measurement may allow for the estimation of parameters related to the physical processes at this initial period (Campeti et al. 2020).

The cosmic string study of Auclair et al. (2020) describes the possibility for *LISA* of detecting a minimum string tension around $G_U \leq 10^{-17}$, which corresponds to a plateau around $\Omega_{GW}^{\text{plateau}} \approx 5 \times 10^{-12}$. The review of Caprini & Figueroa (2018b) states that it will be possible with *LISA* to measure a SGWB from a phase transition with $\Omega_{GW} \approx 10^{-12}$; there is much uncertainty as to the existence of a phase transition SGWB source in the *LISA* observation band, let alone its signal strength. The review by Christensen (2019) describes a limit of detectability with *LISA* of $\Omega_{GW} (f \approx 10^{-3} \text{ Hz}) \approx 5 \times 10^{-13}$ for a standard inflation produced SGWB. The SGWB level from inflation is probably $\Omega_{GW} (f \approx 10^{-3} \text{ Hz}) \approx 10^{-15}$ or lower. See these reviews (Caprini & Figueroa 2018b; Christensen 2019) for descriptions of other possible cosmologically produced SGWBs. These studies cited above correspond to an ideal case of a cosmological source and *LISA* noise, and have not included the effects of a galactic foreground nor an astrophysical background (as we do in this paper). Many recent studies explore avenues to detect a cosmological SGWB in the presence of an astrophysical SGWB, and a brief review is presented in our previous study (Boileau et al. 2021). The goal of this present paper is to address the possibility for *LISA* to observe a SGWB of cosmological origin in the presence of other stochastic signals. Our previous study (Boileau et al. 2021) addressed the detectability by *LISA* of a cosmologically produced SGWB in the presence of different levels of a BBH produced astrophysical background. This study did not consider the Galactic foreground, but did demonstrate the utility of using Bayesian parameter estimation methods for spectral separability. Adding the Galactic foreground is the goal of the study given in this paper. We
present an algorithm to calculate the parameters associated with the Galactic foreground seen by LISA. The calculation is aided by the fact that the Galactic foreground experiences a modulation over a year as the LISA constellation orbits the sun and changes its orientation with respect to the Galactic center. We use a mock Galactic DWD catalog as the input for calculating the GW foreground. We highlight the quantities which introduce the most variation in the energy spectrum of the Galactic foreground and use that knowledge to predict its form. We also present a strategy to separate the three stochastic signals (Galactic, astrophysical, and cosmological), as well as the inherent LISA detector noise, using a Bayesian strategy (Christensen & Meyer 1998; Cornish & Littenberg 2007) based on an Adaptive Markov chain Monte-Carlo (A-MCMC) algorithm.

The remainder of this paper is organized as follows. In Section 2, we present the DWD catalog and the production of GWs from binary systems. In Section 3 we calculate the waveform for each binary, and how LISA responds to this Galactic foreground. The spectrum of the Galactic DWD foreground is calculated and presented in Section 4, as well as a brief summary of the A-MCMC methods. Section 5 gives a description of the LISA data channels and methods used to describe the LISA detector noise. Section 6 presents the strategy to identify the Galactic foreground using the information from the orbital modulation of the LISA signal. The limits for LISA to observe a cosmological SGWB are presented in Section 7. The conclusions for our study are given in Section 8.

2 DESCRIPTION OF THE CATALOGS OF DOUBLE WHITE DWARFS (DWDs)

2.1 Simulation of the DWDs

Lamberts et al. (2019) provide a catalog of short-period WD binaries producing GWs in LISA’s observational frequency band. We refer the reader to this publication for a detailed description of the catalog. This simulation of the large population of binaries ($\sim 3.5 \times 10^7$) is based on the “Latte” (Hopkins et al. 2014; Wetzel et al. 2016) model of a Milky-Way-like Galaxy from a cosmological simulation in the FIRE project (Hopkins et al. 2018). The simulation provides a realistic model for the star formation history, metallicity evolution and morphology of the Milky Way, including statistical properties of its satellite population.

It is of course possible to calculate the galactic foreground from other catalogs and compare the effects of different populations. Here, we also use the MLDC catalog. The Galaxy model is combined with a distribution of DWDs based on a binary population synthesis model (Hurley et al. 2002) which naturally produces DWDs with different core compositions depending on initial conditions. Each core composition has a different mass distribution; the He cores are less massive than CO and NeO cores. The formation of CO-CO DWDs typically occurs on timescales shorter than 2 Gyr while He-He DWDs form on timescales of at least 3 Gyr. These different delay times result in a distinct distribution of He-He DWDs dominating in the older regions of the Galaxy (thick disk, bulge and halo) and the CO-CO DWDs dominating in regions of more recent star formation (thin disk).

The LISA LDC 1-4 catalog is a Galactic white dwarf binaries population comprising about 30 million systems (Babak et al. 2008). The catalog contains for each binary the binary mass, the mass ratio, the orbital frequency of the binary $f_{\text{orb}}$; and the Cartesian position in the Galaxy $X,Y,Z$.

It is straightforward to derive the quantities necessary to describe GW emission from these parameters. The chirp mass is given by:

$$M_c = \frac{(M_1M_2)^{3/5}}{(M_1 + M_2)^{1/5}}. \quad (1)$$

The frequency of the GW emitted by each binary is

$$f_{\text{GW}} = 2f_{\text{orb}}. \quad (2)$$

with $f_{\text{orb}}$ the orbital frequency; we assume that the orbits are circular.

The GW frequency derivative is given by

$$f_{\text{GW}}\dot{\Omega} = \frac{GM_c}{c^3} \left( \frac{96}{5} \pi^8 \right)^{1/3} \frac{11^{1/3}}{f_{\text{GW}}} \cdot (3)$$

The distance between the binary and LISA (approximating the LISA constellation position at the Sun):

$$R = \sqrt{(X - X_\odot)^2 + (Y - Y_\odot)^2 + (Z - Z_\odot)^2} \quad (4)$$

with $(X_\odot,Y_\odot,Z_\odot) = (8.178, 0, 0.659)$ kpc the position of the Sun in the Galactic Cartesian coordinates.

For a DWD, according to Cornish & Littenberg (2007) we can compute the GW amplitude for an optimally polarized and aligned binary at a distance $R$ as,

$$h_{\text{opt}} = 4(\pi)^{2/3} \frac{G^{5/3} M_c^{5/3}}{c^4} \frac{1}{R}. \quad (5)$$

This is sufficient for mapping the amplitude. We use the healpix (Górski et al. 2005) view in Fig. 1, with $N_{\text{side}} = 256$ (see definition $N_{\text{side}}$ in Górski et al. 2005). For each pixel on the map we stack the amplitudes of binaries present; Fig. 1 and Fig. 3 are the logarithm of the sky GW amplitude background of Lamberts et al. (2019) and Nelemans et al. (2001b),
The distribution of the inclination will be uniform for the Galactic WD binaries for \( f_{GW} \geq 1 \times 10^{-5} \) Hz. The DWD distribution in position \((X,Y,Z)\) is from the simulation of Lamberts et al. (2019). This map is made with the Galactic coordinates \( GLON, GLAT \) with \( N_{side} = 256 \).

This model gives a binary rich Galactic center and the arms. However, there are few binaries in the rest of the sky. In comparison, the population of Lamberts et al. (2019) (see Fig. 1) has a distribution closer to our Galaxy. Indeed the simulated Galaxy contains a disk, a bulge, a halo and satellite Galaxies. In addition, there is the presence of DWDs all over the sky but with an anisotropy.

### 2.3 Amplitude calculation

The GW amplitudes for the two polarisations from a binary are given by:

\[
A_x(M_1, M_2, R, f, i) = \frac{2G^2M_1M_2}{c^4R} \left( \frac{(\pi f)^2}{G(M_1 + M_2)} \right)^{1/3} \left(1 + \cos^2(i)\right),
\]

\[
(6)
\]

\[
A_y(M_1, M_2, R, f, i) = -\frac{4G^2M_1M_2}{c^4R} \left( \frac{(\pi f)^2}{G(M_1 + M_2)} \right)^{1/3} \cos(i).
\]

\[
(7)
\]

In the calculation of Lamberts et al. (2019) there is no inclination for the orbital plane of the binary, \( i \). We assume the distribution of the inclination will be uniform for \( \cos(i) \). We integrate the two amplitudes over \( \cos(i) \):

\[
\Delta = \int_{-1}^{1} (A_x(i)^2 + A_y(i)^2) d(\cos(i))
\]

\[
= \frac{4G^2M_1M_2}{c^4R} \left( \frac{(\pi f)^2}{G(M_1 + M_2)} \right)^{1/3} \int_{-1}^{1} d(\cos(i))
\]

\[
= \frac{4\pi^2}{3} \frac{f_{GW}^2}{c^3} G^{5/3} M_1^{2/3} M_2^{2/3} \Delta_t.
\]

\[
(8)
\]

\[
\Delta_t = \sqrt{\int_{-1}^{1} \left(1 + y^2\right)^{2/4} + y^2} dy = \sqrt{\frac{8}{5}},
\]

which gives

\[
\Delta = 4(\pi)^{2/3} f_{GW}^2 G^{5/3} M_1^{2/3} M_2^{2/3} \Delta_t.
\]

Below, Sec. 3, we give the response of LISA to both gravitational-wave polarisations, and in deriving the final results for our study we average over \( \cos(i) \).

For the DWD population we can compute the polarisation-averaged \( h \). We use Eq. 5 for a binary located at 1 kpc from the LISA constellation with an orbital period of one hour and with a chirp mass of 1 solar mass:

\[
h = 1.08 \times 10^{-21} \left( \frac{M_*}{1 \, M_\odot} \right)^{5/3} \left( \frac{P_{orb}}{1 \, \text{hr}} \right)^{-2/3} \left( \frac{R}{1 \, \text{kpc}} \right)^{-1}
\]

\[
(10)
\]

where \( R \) is the distance between LISA and the binary in kpc and the orbital period \( P_{orb} = \frac{1}{f_{orb}} \). An orbital period of 1
hour corresponds to an orbital frequency $f_{orb} = 2.8 \times 10^{-4}$ Hz. We define the amplitude spectral density (ASD) as:

$$\sqrt{S_h(f)} = ASD(f) = \frac{h}{\sqrt{2f_{\text{obs}}}}$$  \hspace{1cm} (11)

with $T_{\text{obs}} = 4$ years and $S_h(f)$ is the power spectral density of the binary signal (see Robson et al. 2019, Eq. 19). We can predict the amplitude spectral density for each binary, and compare the population with the LISA sensitivity $S_n(f)$ (Robson et al. 2019):

$$S_n(f) = \left[\frac{1}{\sqrt{2}} \left(1 + \frac{2 \times 10^{-3} \text{ Hz}^{-1}}{f}\right)^4 + 9.6 \times 10^{-48} \text{ s}^{-3} \text{ Hz}^{-1} \cdot \left(1 + \cos^2 \frac{f}{f_{\text{ref}}} \right) \left(1 + 4 \times 10^{-4} \text{ Hz}^2 \right) \left(2\pi f \right)^4 \right]^{1/2}.$$  \hspace{1cm} (12)

In Fig. 4, the black scatter plot shows the amplitude spectral density (ASD) of all the binaries from Lamberts et al. (2019); the red dots are the identifiable binaries, and the blue dots are resolved binaries. In the LISA band $f_{GW} \geq 10^{-5}$ Hz, we expect signals from $\approx 35$ million binaries. We restrict our study to binaries with a GW frequency greater than $10^{-5}$ Hz. Approximately one in a thousand binaries will be resolvable, leaving the major part of the Galactic binaries unresolved in a stochastic signal. A DWD is resolved if it is uniquely identified in its frequency bin and has $\text{SNR} > 7$ (Timpano et al. 2006). The presence of a signal from a DWD can be identified for $\text{SNR} > 7$, but if there is more than one signal per bin it will not be possible to resolve it individually; we refer such binaries as identifiable. A resolved source has a frequency difference with any other binary larger than the LISA bin $1/\text{f}_{\text{ref}}$. The frequency derivative of the gravitational wave is $f_{GW} \approx \mathcal{M} c^3/11^3$. Considering the example at low frequency of $f_{GW} = 0.06$ Hz and $\mathcal{M} = 1 M_\odot$; this implies $f_{GW} = 2.48 \times 10^{-11}$ Hz s$^{-1}$.

For a 4 year duration, we have a maximum frequency shift $f_{GW} \Delta t_{\text{obs}}$ of 0.0003 Hz; the maximum relative frequency shift $f_{GW} \Delta t_{\text{obs}} \Delta f$ in the catalog is 0.5%. Hence the orbital GW emission can be considered as monochromatic. We can also calculate the coalescence time

$$\tau_c = 5 \times 10^{-4} \frac{G^3 M_1 M_2 (M_1 + M_2)^4}{256},$$  \hspace{1cm} (13)

with $a$ the initial separation between the two WDs, given by Kepler’s 3rd law, $f_{orb} \approx G (M_1 + M_2)$. The smallest coalescence time of the population is 23 500 years and the biggest is 26 600 times the age of the Universe. Resolved binaries are separated in two populations (see Fig. 4). The blue (identifiable binaries for a LISA bin $\Delta f = \frac{1}{\text{f}_{\text{ref}}} \Delta t_{\text{obs}}$) left population $f_{GW} \in [1 \times 10^{-4}, 2 \times 10^{-4}]$ Hz consists of small binaries (less mass); there is a large number of sources at low frequencies. The LISA noise is relatively high, so a large number of these binaries are not identifiable. However, there are some resolved binaries because they are located close to LISA. In Fig. 4, the blue right population $f_{GW} \in [7 \times 10^{-4}, 5 \times 10^{-2}]$ Hz is produced by the largest objects in terms of mass, but with a small number of them and a dispersion of amplitudes. The middle part $f_{GW} \in [2 \times 10^{-4}, 7 \times 10^{-4}]$ Hz is where there are many observable binaries, a region where the LISA noise is low. Because of a large number of sources, separation in frequency is smaller than the frequency bin size $1/\text{f}_{\text{ref}}$. When LISA will be observing galactic binaries there will be only a few of these sources per frequency bin, namely the real and imaginary parts in the $A$ and $E$ channels. As such, when there are more than one binary per two frequency bins, there will be more parameters than data points, and resolution of an individual binary will be challenging. However, recent studies have made progress in characterizing the galactic foreground coming from an astrophysical population of binaries, as in Karnesis et al. (2021).

Fig. 5 shows the GW amplitude spectral density for the different cores of DWD. We have evidence of the domination of the type He-CO and He-CO for the resolved binaries. The distributions for all binary types from the catalog, and the resolved binaries are presented in five plots. The black line corresponds to the LISA strain sensitivity $S_n(f)$. The figure at the bottom right is the total distribution of binaries for the different core compositions. We cannot estimate the distribution of the resolved binaries with the help of the distribution type of the resolved DWD. The gaps (black scatter) seen in the plots below $10^{-3}$ Hz correspond to the large number of sources close in terms of frequency. Indeed, this part of the spectrum comprises a large number of sources, that to be resolvable, must have a frequency difference greater than the frequency resolution of LISA.

### 2.4 Galactic confusion noise

In Fig. 4 the sensitivity curve can be further updated with the contribution from the Galactic confusion noise $S_c(f)$ (Cornish & Robson 2017), which corresponds to the unresolved binaries of the galactic population. This has been modeled with the catalog from Nelemans & Tout (2005) as a kind of power spectrum. This model depends on the measurement duration, and for a duration of 4 years the model gives $\alpha = 0.138, \beta = -221, \kappa = 521, \gamma = 1680$ and $f_k = 0.00113$.

$$S_c(f) = Af^{-7/3} e^{-\pi \sin^2(\kappa f)} \left[1 + \tanh \left(\gamma (f_k - f)\right)\right].$$  \hspace{1cm} (14)

$A$ is the amplitude of the Galactic confusion noise in the low-frequency limit from the power spectrum of a quasi-circular binary population. This noise can be seen as adding further noise to the LISA sensitivity.

In our calculation we introduce for each binary the amplitude gap from the other binaries in the local frequency band of the binary considered. We generate a catalog of resolved binaries; see Fig. 5. We note that the distribution of resolved binaries depends on the catalog used and the number of sources considered. Our study here is firstly an estimation of the ability to observe a cosmologically produced SGWB in the presence of a galactic foreground. These estimates of resolved and unresolved binaries depend on the catalog, but we find no evidence of any significant influence of the galactic foreground with the presence or not of resolved binaries in the foreground, or how they are defined (see Fig. 11).
Figure 4. Amplitude spectral density for the GW from the Galactic WD binaries for four years of duration of science time with the \textit{LISA} strain sensitivity \( S_n(f) \) (black line). The black scatterplot displays the totality of binaries from the \textit{Lamberts et al.} (2019) catalog of DWD. We calculate for each DWD the amplitude spectral density (ASD); see Eq. 11. In red, we calculate the "identifiable" binaries; these are binaries of \( SNR > 7 \) (\textit{Timpano et al.} 2006). The blue population corresponds to "resolved" binaries, namely no more than one per \textit{LISA} bin; we calculate for each binary a spectral separation from all the other binaries in comparison to the \textit{LISA} frequency bin size of \( \frac{1}{T_{\text{Obs}}} \).

Figure 5. The GW amplitude spectral density for the different core compositions from the resolved Galactic DWD for four years of science time duration with the \textit{LISA} strain sensitivity \( S_n(f) \).
3 CALCULATION OF THE WAVEFORM

In this section we present the calculation of the waveform of the Galactic foreground.

3.1 Amplitude of the waveform

The GW strain \( h(t) \) is given by the polarisation decompositon of the waveform,

\[
h(t) = h_x(t)e_x + h_\beta(t)e_\beta
\]

where the two polarisation tensors \( e_x \) and \( e_\beta \) are given by:

\[
e_x = E\begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}^T \\
e_\beta = E\begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}^T
\]

with the polarisation coordinate matrix \( E \); \( \beta, \lambda \) are the ecliptic latitude and longitude, while \( \psi \) is the rotation around the direction of gravitational-wave propagation (see Fig. 6),

\[
E = \begin{pmatrix}
\lambda_x \psi_c - \lambda_c \psi_x & -\lambda_y \psi_x - \lambda_x \psi_y & -\lambda_c \psi_y \\
-\lambda_y \psi_x - \lambda_x \psi_y & \lambda_x \psi_c - \lambda_c \psi_x & -\lambda_y \psi_x \\
\beta_c \psi_s & \beta_c \psi_c & -\beta_s
\end{pmatrix}
\]

The \( s \) and \( c \) subscripts refer to the sinus and cosinus operators, respectively.

In Fig. 6 we define the elliptical coordinates. For a DWD, the GW is a plane wave, quasi-monochromatic (there is a frequency drift over time). The frequency changes slightly for each orbit of the binary, the reason for this is energy loss from the emission of GW. For a DWD the drift is very small. The binary can be just considered as essentially monochromatic, and the polarisations given by:

\[
\begin{pmatrix}
h_x(t) \\
h_\beta(t)
\end{pmatrix} = \begin{pmatrix} A_x(t) \cos(2\pi f t + \phi_0) \\ A_\beta(t) \sin(2\pi f t + \phi_0) \end{pmatrix}
\]

with \( \phi_0 \) an initial phase. In the calculation we have a uniform distribution between 0 and 2\( \pi \). The parameter \( f \) characterizes the frequency change from the loss of orbital energy. To calculate the response of the detector arms, \( \mathcal{H}_x(t) \) and \( \mathcal{H}_\beta(t) \), we need to calculate the one arm detector tensor \( \mathbf{D} \):

\[
\mathbf{D} = \frac{1}{2} \mathbf{u} \otimes \mathbf{u} - \mathbf{v} \otimes \mathbf{v}
\]

Figure 6. Generic plane waveform reference for a binary localised at ecliptic latitude \( \beta \) and longitude \( \lambda \). The LISA constellation is in the center of the coordinate system. We use the conventional definition from Królak et al. (2004) for the GW polarisations: + (in red) and \( \times \) (in blue). The coordinate \( \Psi \) is the rotation around the direction of wave propagation.

Figure 7. \((\hat{u}, \hat{v})\) coordinate system where the LISA constellation is the red hexagons.

where \( u = \begin{pmatrix} 1/2 \\ 0 \end{pmatrix} \) and \( v = \begin{pmatrix} -1/2 \\ \sqrt{3}/2 \end{pmatrix} \). Finally we have:

\[
\mathcal{H}_x(t) = A_x(t) \cos(2\pi f t + \phi_0) e_x : D \\
\mathcal{H}_\beta(t) = A_\beta(t) \sin(2\pi f t + \phi_0) e_\beta : D
\]

where \( \mathcal{H}_A(t) = h_A(t)e_A : D \) and \( A = +, \times \). \( \mathcal{H}_A \) are the two polarisations \( A = +, \times \) of the detector basis. This calculation of the galactic foreground is also presented in Cornish & Littenberg (2007).

3.2 Detector response function

The detector response functions, \( F_+ \) and \( F_\times \), for the location of the source at \((\theta, \phi)\) at the time \( t \) in the basis vector \( \hat{u}, \hat{v} \) are given by (see Fig. 7):

\[
F_+ = -\frac{\sqrt{3}}{4}(1 + \cos(\theta))^2 \sin(2\phi)
\]

\[
F_\times = -\frac{\sqrt{3}}{2} \cos(\theta) \cos(2\phi)
\]

with \( \hat{u}, \hat{z} = \sin(\phi + \pi/6) \sin \theta \) and \( \hat{v}, \hat{\beta} = \sin(\phi - \pi/6) \sin \theta \), see Cornish & Larson (2001). The orbit of LISA is one year around the sun, and also one year in revolution about itself (see Fig. 2). We need to consider the constellation orientation effects because LISA will not see the sky uniformly.

3.3 Signal of the DWD foreground measure by LISA

We can build the total signal of the DWD foreground measure by LISA; this is the sum of the waveforms for each DWD,

\[
s(t) = \sum_{i=1}^{N} \sum_{A=+}^{N} h_{A,i}(f_{orb,i}, M_1, M_2, X_i, Y_i, Z_i, t) \\
\times F_A(\theta, \phi, t)D(\theta, \phi, f)A : e_A
\]

with \( F_A \) the beam pattern function for the polarisations \( A = +, \times \), \( h_{A,i} = h_{A,i}e_A \) the tensor of the amplitude of the GW, and \( D \) the one-arm detector tensor and \( B_{A,i} \) the dimensionless GW amplitude of the binary \( i \) (see Eqs. 15 and 18).

Fig. 8 shows the gravitational waveforms of the five populations of DWDs from Lamberts et al. (2019). The waveform from CO-CO has the largest amplitude. The sum of the five...
populations becomes the waveform to be seen by \textit{LISA} (see Fig. 9). The modulation of the \textit{LISA} waveform is an orbital effect. In fact, when the \textit{LISA} constellation points toward the center of our Galaxy, the waveform amplitude will attain a maximum. Because of the symmetry of the plane passing through \( \hat{u} \) and \( \hat{v} \) (Fig. 7), this will happen twice per year.

4 SPECTRAL SEPARATION AND STUDY OF THE WAVEFORM

In this section we describe the calculation of the spectral energy density of the modulated DWDs, \( \Omega_{GW, DWD} \), that were introduced in Sec. 3. Fig. 9 is the modulated foreground for \textit{LISA}, with the DWDs from Lamberts et al. (2019). The simulated DWD population resembles the \( \text{DWD} \) population of the Milky Way.

4.1 Energy and Power Spectral Density

Given the power spectral density (PSD), we can compute the energy spectral density of the Galactic foreground that \textit{LISA} will observe:

\[
\Omega_{GW, DWD}(f) = \frac{4\pi^2}{3H_0^5} f^3 \frac{\text{PSD}(f)}{\mathcal{R}(f)},
\]

with \( H_0 \) the Hubble-Lemaître constant \( (H_0 \approx 2.175 \, 10^{-18} \, \text{Hz}) \), \( \text{PSD}(f) \) the power spectral density of the waveform of the Galactic foreground, and \( \mathcal{R}(f) \) the \textit{LISA} response function. We use the periodogram to estimate the PSD. For a waveform \( s(t) \) the periodogram is \( I_n(f_k) = |\tilde{s}(f_k)|^2 \), where \( \tilde{s}(f_k) = \frac{1}{\sqrt{T}} \sum_{i=1}^{N} s(t) e^{-itf_k} \) at Fourier frequencies \( f_k = 2\pi k/T, \, k = 0, \ldots, N = \frac{T}{2} - 1 \) and \( T \) the time duration of the signal for the different waveforms (total binaries, resolved or unresolved binaries). \( \mathcal{R}(f) \) is the detector polarisation and sky averaged response function, which can be approximated by (Robson et al. 2019):

\[
\mathcal{R}(f) \approx \frac{3}{10} \left( \frac{2\pi fL}{c} \right)^2 + 0.6 \left( \frac{2\pi fL}{c} \right)^2.
\]

The goal is to address the orbital motion of the \textit{LISA} constellation (Cornish & Rubbo 2003). We can calculate this quantity with the mean square antenna pattern (Cornish & Larson 2001), \( \mathcal{R}(f) = \frac{1}{T} \int \sum A D(\Omega, f) : e^{i\Lambda(t)} d\Omega \) (Cornish & Rubbo 2003). Fig. 10 gives the PSD for different types of WD cores, while Fig. 11 presents the total PSD, plus the PSDs from resolvable and unresolved DWDs. Fig. 11 shows that the PSD of the total waveform is not purely a power law. According to Adams & Cornish (2014, Fig. 4) and Breivik et al. (2020, Fig. 1), we have fewer binaries at higher frequencies.

4.2 Comparison of the energy spectral density from different catalogs

In this section we derive the normalised energy spectral density of the Galactic foreground \( \Omega_{GW, DWD} \) for different population models. We start with the population from the catalog \textit{LDC} 1-4. This population was simulated with the parameters from Nelemans et al. (2001b). In Fig. 12 we show that at low frequencies the energy spectral density of the population from the \textit{LISA} Data challenge can be fit by a power law \( \Omega_{GW-LDC 1-4}(f) \approx \Omega_{LDC 1-4} \left( \frac{f}{f_{ref}} \right)^\alpha \), with slope \( \alpha = 2/3 \). This is the slope expected for a \textit{GW} from binary systems (see grey line in Fig. 12). The black line is the energy spectral density of the Galactic foreground for the population of Lamberts et al. (2019). We have evidence that the power law can be fit at low frequencies (between \( 1 \times 10^{-5} \) and \( 1 \times 10^{-4} \, \text{Hz} \)) with the same slope \( \alpha = 2/3 \), but at higher frequencies this power law breaks down. In order to understand whether the DWD spatial distribution model is responsible for this difference, we can use the population of Lamberts et al. (2019) but we use the DWD spatial distribution from Nelemans et al. (2001b). This combination results in the blue line plot in Fig. 12, labeled Lamberts + Nelemans. As an example we also display a purple line representing \( \Omega_{GW}(f) = 2 \times 10^{-10} \left( \frac{f}{1 \times 10^{-3} \, \text{Hz}} \right)^{2/3} \) which lies over the \textit{LDC} 1-4 galactic foreground; this displays that the \textit{LDC} 1-4 galactic foreground can be approximate by a power law.

The break down of the power law at high frequencies is due to the spatial distribution of the DWDs. Indeed, the blue line (Lamberts et al. (2019) + Nelemans et al. (2001b)) can be represented by a power law with a slope in 2/3, represented in Fig. 12 as the green line of \( \Omega_{GW}(f) = 4 \times 10^{-10} \left( \frac{f}{1 \times 10^{-3} \, \text{Hz}} \right)^{2/3} \) in the frequency band \( [1 \times 10^{-4} \, \text{Hz}, 1 \times 10^{-3} \, \text{Hz}] \).

The catalog of Lamberts et al. (2019) for the Milky Way DWD distribution cannot be represented as a power law over the entire \textit{LISA} spectral band. However, we modify the function to better fit the scarcity of power at high frequencies, Eq. 26, as a broken power-law, namely:

\[
\Omega_{DWD}(A_1, a_1, A_2, a_2; f) = \frac{A_1}{1 + A_2 \left( \frac{f}{f_{ref}} \right)^{a_2}},
\]

in the remainder of this document we use \( f_{ref} = \frac{2 \pi L}{c} \approx 0.019 \, \text{Hz} \). For \( 1 \ll A_2 \left( \frac{f}{f_{ref}} \right)^{a_2} \) (low frequencies) this yields:

\[
\Omega_{DWD}(f) \approx A_1 \left( \frac{f}{f_{ref}} \right)^{a_1 - a_2},
\]

i.e. the energy spectral density at low frequencies can be approximated by a power law function; for a DWD foreground the slope \( a = a_1 - a_2 \) to be \( \frac{2}{3} \). For \( 1 \ll A_2 \left( \frac{f}{f_{ref}} \right)^{a_2} \) (high frequencies):

\[
\Omega_{DWD}(f) \approx A_1 \left( \frac{f}{f_{ref}} \right)^{a_1},
\]

i.e. for high frequencies the energy spectral density can also be approximated by a power law function but with different parameters. The differential \( d\Omega(f) \) is therefore:

\[
d\Omega(f) = \frac{dA_1}{A_1} \, \ln \left( \frac{f}{f_{ref}} \right) \, df_1 + \frac{dA_2}{1 + A_2 \left( \frac{f}{f_{ref}} \right)^{a_2}} \left[ \frac{dA_2}{A_2} \, \ln \left( \frac{f}{f_{ref}} \right) \left( \frac{f}{f_{ref}} \right)^{a_2} \right].
\]

To estimate the four parameters \( \Omega(A_1, a_1, A_2, a_2; f) \) of the model, we use an adaptive MCMC algorithm.
4.3 Stochastic Gravitational Wave Background

In the frequency band \([f, f+df]\), the normalised energy spectral density of an isotropic SGWB, \(\Omega_{GW}(f)\), can be modeled as a frequency variation of the energy density of the GW \(\rho_{GW}\). The energy spectral density is a function of the differential variation over the frequency of the energy density \(\rho_{GW}\) (Christensen 1992; Camp & Cornish 2004; Christensen 2019). The distribution of the energy density over the frequency domain can be expressed as

\[
\Omega_{GW}(f) = \frac{f}{\rho_c} \frac{d \rho_{GW}}{d \ln(f)} = \sum_k \Omega_{GW,k}(f).\tag{30}
\]

where \(k\) refers to a specific SGWB and the critical density of the universe is \(\rho_c = \frac{3 H_0^2 c^{-2}}{8\pi G}\). In this paper we approximate the SGWB energy spectral density as a sum of power laws. We also assume that the astrophysical (binary black hole produced) and cosmological backgrounds are isotropic.
Figure 10. PSD of the GW signal for the WD binary modulation seen by LISA (see Fig. 8). The set of binaries in blue, green, red, yellow and grey are respectively the different cores CO-CO, He-CO, CO-NeO, He-He and He-NeO. This is the direct periodogram of Fig. 8.

Figure 11. PSD of the GW signal for the WD binary modulation seen by LISA (see Fig. 8). The set of binaries is in black, while the resolved and unresolved are respectively in blue and orange. These are the same as the Fig. 4.

We have $\Omega_{GW} \approx \sum_k A_k \left(\frac{f}{f_{ref}}\right)^{\alpha_k}$, where the energy spectral density amplitude of the component $k$ (representing the different SGWBs) is $A_k$, the respective slopes are $\alpha_k$, and $f_{ref}$ is some reference frequency.

The energy spectral density of the the cosmological background should have a slope $\alpha \approx 0$. This is a good approximation for scale invariant processes and also for standard inflation, but certainly false for cosmic strings and turbulence. However, for our study here, we will model the cosmologically produced SGWB energy density with $\alpha = 0$. In addition, for a second isotropic SGWB, the compact binary product astrophysical background, we use $\alpha = \frac{2}{3}$. According to Farmer & Phinney (2003), the slope is $\alpha = \frac{2}{3}$ for quasi-circular binaries evolving purely under emission of GW. Eccentricity and environmental effects can alter the slope and gravitation frequencies of the binary. We also note the limitations of our cosmological power law model as phase transitions in the early universe need to be approximated with two-part power laws, with a traction between the rising and falling power law component at some particular frequency peak. However, as a starting point we use two isotopic backgrounds, each described by a simple power law. Since the two backgrounds are superimposed, the task is to simultaneously extract the
Figure 12. Normalised energy spectral density of the Galactic foreground $\Omega_{GW, DWD}$ for different population models of DWD in the Milky Way. The black line is the Lamberts et al. population, the gray line corresponds to the population of LDC (LDC1-4); this population can be fit by a power law, see the purple line ($\Omega_{GW} \propto f^{2/3}$). In blue, labeled by Lamberts + Nelemans, is a population generated with binaries where the galactic spatial positions are given by Nelemans et al., and the other parameters from Lamberts et al.. This "Lamberts + Nelemans" population can be fit by a power law $\Omega_{GW} \propto f^{2/3}$ in the frequency band $1 \times 10^{-4} \text{ Hz}, 1 \times 10^{-3} \text{ Hz}$.

astrophysical and cosmological components, that is, to simultaneously estimate the astrophysical and cosmological contributions to the energy spectral density of the SGWB. In addition to the two isotropic sources we will also consider the Galactic foreground, but as a broken power law.

For the purpose of this spectral separation study we will define the astrophysical background of GWs coming from the unresolved compact objects with the estimates of Chen et al. (2019), $\Omega_{GW, astro} \propto f^{3/2}$.

The amplitude of the cosmological background is a free parameter, and our goal is to determine how well LISA will do in providing an estimate for this parameter given the astrophysical background and Galactic foreground, plus LISA detector noise.

The spectral separability study of Boileau et al. (2021) was recently carried out in the context of LISA. There it was shown that it is possible for LISA to measure a cosmological background with an amplitude between $1 \times 10^{-13}$ and $1 \times 10^{-12}$ in the presence of the astrophysical background and LISA detector noise. In this present paper we include a galactic foreground, and we model the energy spectral density of the SGWB by

$$
\Omega_{GW} (f) = \Omega_{GW, DWD} (f) + \Omega_{GW, astro} (f) + \Omega_{GW, cosmo} (f) = A_1 \left( \frac{f}{f_{ref}} \right)^{a_1} + A_2 \left( \frac{f}{f_{ref}} \right)^{a_2} + \Omega_{astro} \left( \frac{f}{f_{ref}} \right)^{a_{astro}} + \Omega_{cosmo} \left( \frac{f}{f_{ref}} \right)^{a_{cosmo}}.
$$

4.4 Adaptive Markov Chain Monte-Carlo

4.4.1 Markov Chain Monte-Carlo

Bayesian inference is a method by which the probability distribution of various parameters are determined given the observation of events. It is based on Bayes’ theorem (see Eq. 32). The goal of a Bayesian study is to derive the posterior distribution of the parameters after observing the data. According to Bayes’ theorem, this is proportional to the likelihood, i.e. the distribution of the observations $d$ given the unknown parameters $x$ of our model, and the prior distribution of the parameters. Bayes’ theorem is given by:

$$
p(x|d) = \frac{p(d|x)p(x)}{p(d)}
$$

where $p(x)$ is the prior distribution, $p(x|d)$ is the posterior distribution, $p(d|x)$ is the likelihood, and $p(d)$ is the evidence. There are various sampling-based strategies for calculating the posterior distribution, so called MCMC methods (Metropolis et al. 1953; Gilks et al. 1995).

4.4.2 Metropolis-Hasting sampler

MCMC methods are based on the simulation of a Markov chain. To simulate from a Markov chain, we use the Metropolis-Hastings algorithm (Hastings 1970; Gilks et al. 1995). This is based on the rejection or acceptance of candidate parameters according to the likelihood ratio between two neighboring candidates. Thus, candidate parameters
with higher values of the posterior distribution are favored but candidates with lower values are accepted with a certain probability given by the Metropolis-Hastings ratio below:

**Metropolis-Hastings algorithm**

- initial point \(x_0\)
- at the i-th iteration:
  - Generate candidate \(x'\) from symmetric proposal density \(g(x'|x_i)\) (e.g. Gaussian with mean \(x_i\))
  - Evaluation
    - likelihood of \(x_i\) and \(x'\), \(p(d|x_i)\) and \(p(d|x')\)
    - prior of \(x_i\) and \(x'\), \(p(x'')\) and \(p(x_i)\)
    - ratio \(a = \frac{p(d|\text{null channel})}{p(d|x_i)} \frac{p(x_i)}{p(x')}\)
  - Accept/Reject
    - Generation of a uniform random number \(u\) on \([0, 1]\)
    - if \(u < a\), accept the candidate \(x_{i+1} = x'\)
    - if \(u > a\), recycle the previous value \(x_{i+1} = x_i\)

At the end of the algorithm, we have a certain acceptance rate. If this rate is too close to 0, it means that the Markov chain made frequent large moves into the tails of the posterior distribution which got rejected and therefore it mixed only very slowly; if the acceptance rate is too close to 1, the Markov chain made only small steps which had a high probability of getting accepted but it took a long time to traverse the entire parameter space. In either of these cases, the convergence towards the stationary distribution of the Markov chain will be slow. To control the acceptance rate we can introduce a step-size parameter; this is often the standard deviation of the jump proposal \(g(x'|x_i)\). This step-size parameter can be modified ‘on the fly’ while the algorithm is running to improve the exploration of the parameter space. Similarly, the proposal density should take correlations between the parameters into account to improve mixing. This can also be estimated ‘on the fly’ based on the previous values of the Markov chain and convergence of such an adaptive MCMC is guaranteed as long as a diminishing adaptation condition is met (Roberts & Rosenthal 2009). Post convergence of the MCMC, a histogram or kernel density estimate based on the samples of each parameter provides an estimate of its posterior density. To summarize the posterior distribution, the sample mean of the Markov chain gives a consistent estimate of its expectation. Similarly the sample standard deviation provides an estimate for its standard error. It is important to check whether the posterior distribution is different from the prior because otherwise the data will not have provided any additional information about the unknown parameters beyond that of the prior distribution.

### 4.4.3 Adaptive Markov Chain Monte-Carlo

We use the A-MCMC version from the Examples of Adaptive MCMC (Roberts & Rosenthal 2009). For a \(d\)-dimensional MCMC we can perform the Metropolis-Hastings sampling with a proposal density \(g_n(x)\) defined by:

\[
g_n(x) = (1 - \beta)N(x, (2.28)^2 \Sigma_n/d) + \beta N(x, (0.1)^2 I_d/d)
\]

with \(\Sigma_n\) the current empirical estimate of the covariance matrix obtained from the samples of the Markov chain, \(\beta = 0.25\) a constant, \(d\) the number of parameters, \(N\) the multi-normal distribution, and \(I_d\) the identity matrix. We estimate the covariance matrix based on the last one hundred samples of the chains.

### 5 LISA Stochastic Gravitational Wave Background Fitting with Adaptive Markov Chain Monte-Carlo

In this section we consider the LISA null channel \(T\), and the science channels \(A\) and \(E\). We assume that the observation of the noise in channel \(T\) informs us of the noise in channels \(A\) and \(E\). We follow the formalism of Smith & Caldwell (2019). Channels \(A, E\) and \(T\) are derived from channels \(X, Y\) and \(Z\) (Vallisneri & Galley 2012), the unequal-arm Michelsons centered on the three spacecraft.

We assume that the noise is uncorrelated between the channels \(X, Y, Z\). Nominaly, the channel \(T\) does not contain a GW signal, but contains the uncorrelated LISA noise. This assumption is not perfectly accurate, but for this analysis we will hold it to be true. The relations are:

\[
\begin{align*}
A &= \frac{1}{\sqrt{6}} (Z - X) \\
E &= \frac{1}{\sqrt{3}} (X - 2Y + Z) \\
T &= \frac{1}{\sqrt{3}} (X + Y + Z).
\end{align*}
\]

We assume that channels \(A\) and \(E\) contain the same GW information and the same noise PSD. Channel \(T\) has a different noise PSD but shares parameters with the noise PSDs of channels \(A\) and \(E\). Thus, in the context of a study of spectral separation of the SGWB, the use of the \(T\) channel allows us to simultaneously estimate the noise parameters for the LISA channels \(A\) and \(E\) more accurately. Without the simultaneous estimation of the LISA noise parameters from the \(T\) channel, it is possible to estimate the LISA noise parameters, but this estimate becomes less accurate. As a result, the SGWB parameter estimate accuracy is degraded. It is in this sense that it is also important to use the \(T\) channel.

This was also the motivation for the study of Boileau et al. (2021).

We simulate the noise and SGWB in the frequency domain assuming

\[
\begin{align*}
\text{PSD}_A &= S_A + N_A, \\
\text{PSD}_E &= S_E + N_E, \\
\text{PSD}_T &= N_T
\end{align*}
\]

with

\[
S_A(f) = S_E(f) = \frac{3H^2}{4\pi^2} \sum_k \Omega_{GW,k} R(f), \quad f_{\text{ref}} = 25 \text{ Hz}, \quad \Omega_{GW,k} = \Omega_{GW,0} \left( \frac{f}{f_{\text{ref}}} \right)^{n_0} + 3 \Omega_{GW,23} \left( \frac{f}{f_{\text{ref}}} \right)^{n_2/3} + \frac{A_1}{1 + A_2 \left( \frac{f}{f_{\text{ref}}} \right)^{n_1}}.
\]

The noise components \(N_A(f) = N_E(f)\) and \(N_T(f)\) can be written as:

\[
\begin{align*}
N_A &= N_1 - N_2, \\
N_T &= N_1 + 2N_2
\end{align*}
\]

with

\[
\begin{align*}
N_1(f) &= 4S_A(f) + 8 \left( 1 + \cos^2 \left( \frac{f}{f_{\text{ref}}} \right) \right) S_A(f) |W(f)|^2 \\
N_2(f) &= -8S_A(f) \cos \left( \frac{f}{f_{\text{ref}}} \right) |W(f)|^2
\end{align*}
\]
As such, we can estimate the induced uncertainty about power spectral densities with the partial derivative method.

The increase in complexity of the presence of an astrophysically produced SGWB, a Galactic level of detectability of a cosmologically produced SGWB in play the methods of spectral separability and determine the noise model of Smith & Caldwell (2019). Once again, the sampled SGWB components 

\[
\Omega_{GW,astro}(f) = \Omega_{astro}(f / f_{ref})^{\alpha_{astro}}
\]

and 

\[
\Omega_{GW,cosmo}(f) = \Omega_{cosmo}(f / f_{ref})^{\alpha_{cosmo}}
\]

Our model contains ten unknown parameters: \(\theta = (N_{acc}, N_{pos}, A_1, A_2, \Omega_{astro}, \sigma_{astro}, \Omega_{cosmo}, \sigma_{cosmo})\).

We calculate the propagation of uncertainties for the power spectral densities with the partial derivative method. As such, we can estimate the induced uncertainty about the PSD resulting from estimation uncertainty of \(\theta\),

\[
dPSD = \sum_{\theta} \left( \frac{dPSD}{d\theta} \right)^2 \, d\theta^2.
\]

We then obtain for three SGWB components

\[
\begin{align*}
\Omega_{GW,astro}(f) &= \Omega_{astro}(f / f_{ref})^{\alpha_{astro}}, \\
\Omega_{GW,cosmo}(f) &= \Omega_{cosmo}(f / f_{ref})^{\alpha_{cosmo}}
\end{align*}
\]

and 

\[
\Omega_{GW,astro}(f) = \Omega_{astro}(f / f_{ref})^{\alpha_{astro}}
\]

\[
\Omega_{GW,cosmo}(f) = \Omega_{cosmo}(f / f_{ref})^{\alpha_{cosmo}}
\]

Our model contains ten unknown parameters: \(\theta = (N_{acc}, N_{pos}, A_1, A_2, \sigma_{astro}, \Omega_{astro}, \sigma_{cosmo}, \sigma_{cosmo})\).

We calculate the propagation of uncertainties for the power spectral densities with the partial derivative method. As such, we can estimate the induced uncertainty about the PSD resulting from estimation uncertainty of \(\theta\),

\[
dPSD = \sum_{\theta} \left( \frac{dPSD}{d\theta} \right)^2 \, d\theta^2.
\]

We then obtain for three SGWB components

\[
\begin{align*}
\Omega_{GW,astro}(f) &= \Omega_{astro}(f / f_{ref})^{\alpha_{astro}}, \\
\Omega_{GW,cosmo}(f) &= \Omega_{cosmo}(f / f_{ref})^{\alpha_{cosmo}}
\end{align*}
\]

As described in Boileau et al. (2021), the inverse of the Fisher information matrix

\[
F_{ab} = \frac{1}{2} \sum_{k=0}^{N} \left( C^{-1} \, \frac{\partial C}{\partial \theta_a} \left( C^{-1} \frac{\partial C}{\partial \theta_b} \right) \right)
\]

is the asymptotic covariance matrix of the parameters, \(F_{ab} = \text{Cov}(a,b)\). The diagonal of this matrix gives the square of the standard error of the parameters, with \(M = D f_b\) (\(D\) is the time duration of the LISA mission and \(f_b\) the highest frequency of interest in the LISA band). Thus, we can calculate the estimation uncertainty of a parameter in addition to using MCMC, and then show the consistency of the two sets or results.

6 MEASURE OF THE AMPLITUDE OF THE DWD IN THE CONTEXT OF THE ORBITAL MODULATION

In this section, we focus on the measurement of the GW signal amplitude coming from our Galaxy (Edlund et al. 2005).
In light of the waveform (see Fig. 8), we note that if we want to estimate it correctly, we must account for the orbital motion of the \textit{LISA} constellation. The waveform is modulated in amplitude, and this modulation comes from the anisotropy of the Galactic foreground. The response of \textit{LISA} depends on its antenna pattern; the response is not homogeneous over the sky. At a particular time the \textit{LISA} response is maximal for sources localized on the orthogonal line passing through the center of the triangle which forms the \textit{LISA} constellation. This is like a "line of sight". The \textit{LISA} constellation is also in orbit around the sun and turns on itself. The line of sight does not always point in the same direction. If the GW background is isotropic, the detected amplitude is constant over time.

We cut the waveform into small-time sections, 50 per year, and assume that the waveform is approximately constant within these sections. For each section, we calculate the signal standard deviation. This approximation works well and is consistent with the results of Adams & Cornish (2014), and allows for a good fit of the orbital modulation.

It is then possible to calculate the amplitude of the spectral energy density, as by the methods of Thrane & Romano (2013):

\[
\Omega_{\text{Mod},i} = \frac{4\pi^2}{3H_0} \left( \frac{c}{2\pi L} \right)^2 A_i^2 \Omega_{\text{GW},i} \ (45)
\]

where \(\Omega_{\text{Mod},i}\) is the amplitude of the spectral energy density of the Galactic foreground at low frequencies for the section \(i\) of the waveform; this is plotted over a year in Fig. 13, and the modulation from the \textit{LISA} orbit is apparent. Here \(A_i\) is the amplitude of the characteristic strain for section \(i\) if we consider the characteristic strain of the section \(i\) as \(h_{c,i} = A_i \left( \frac{2\pi L}{c} \right)\), and the relation between the power spectral density \(S_{h,i}(f)\) of the time series \(h_i(t)\) and the spectral energy density of the section \(i\), \(\Omega_{\text{GW},i} = S_{h,i}(f) = \frac{3H_0^2}{4\pi^2} \Omega_{\text{GW},i} f^4\), where \(\Omega_{\text{GW},i} = \Omega_{\text{Mod},i} \left( \frac{2\pi f}{c} \right)^2 2\pi^2\).

The goal is to estimate the level of the amplitude and compute the Galactic contribution to the sum of all the stochastic background and noise signals for \textit{LISA}.

The grey curve in Fig. 13 is the amplitude of the spectral energy density calculated with this method. We cut the year long time series into 1500 sections. We observe the amplitude modulation, indeed it is always maximum when \textit{LISA} points to the center of our Galaxy. The blue line corresponds to the mean of the 1500 estimates of the DWD amplitude. The purple line is the estimate of the DWD amplitude DWD for the total waveform, (1 year).

As in Adams & Cornish (2014, Figure 2), we measure the amplitude of the Galactic foreground for 50 sections of the year-long observation. In order to study the spectral separation of the stochastic background, we add the \textit{LISA} noise (Smith & Caldwell 2019) and an astrophysical background (Chen et al. 2019) to the Galactic foreground and estimate the 8 parameters with an A-MCMC. The red scatterplot in Fig. 13 is the estimate of the amplitude of the Galactic foreground in the low frequency approximation based on 50 A-MCMC runs. We partition the waveform (see Fig. 9) into 50 sections, and for each section we calculate the periodogram and the energy spectral density of the SGWB in the context of \textit{LISA} noise and astrophysical background. We estimate the parameters of the model of Eq. 35 using Eq. 49 for the amplitude of the DWD SGWB at low frequencies.

With this method, we measure the spectral energy density’s amplitude of the Galactic foreground at different periods of the year.

The observed modulation is an effect of the \textit{LISA} measurement with the \textit{LISA} antenna pattern. For each section \(i\), we assume that the \textit{LISA} pattern antenna is constant. The waveform of the section \(i\) is:

\[
s_i(t) = h_{s,i}(t) + h_{c,i}(t)\Omega_{\text{GW},i} f^4
\]

(46)

The spectral energy density of the waveform \(s_i\) becomes:

\[
S_{h,i}(f) = \frac{\Omega_{\text{GW},i}}{\Omega_{\text{Mod},i}} (f^2 + f_{c,i}^2)
\]

(47)

where \(S_{h,i}(f) = 2\hat{h}_{s,i}(f)\hat{h}_{s,i}^*(f)\). For each section we have the estimate of the modulated DWD amplitude at low frequencies; each section corresponds to a different part of the year. We can thus measure the orbital effect of the change over the year:

\[
\Omega_{\text{Mod},i} = \Omega_{\text{DWD,LF}} (f^2 + f_{c,i}^2)
\]

(48)

where \(\Omega_{\text{DWD,LF}}\) is the unmodulated amplitude of the energy spectral density of the Galactic foreground at low frequencies.

As an example, in Fig. 14 we display the results from on the 50 A-MCMC runs, namely section 30 of the orbit. The blue lines are the three periodograms for the data channels \(A, E, T\) with \(N_{\text{acc}}, N_{\text{pos}} = \left(1.44 \times 10^{-48} \text{ s}^{-3} \text{ Hz}^{-1}, 3.6 \times 10^{-41} \text{ Hz}^{-1}\right)\). We estimate the two \textit{LISA} noise magnitudes and the 6 stochastic background parameters \((A_1, A_2, A_3)\) for the DWD and \((\Omega_{\text{GW,astro}}, a_{\text{astro}})\) for the astrophysical background. We use log uniform priors with five magnitudes for the five amplitude parameters \((N_{\text{acc}}, N_{\text{pos}}, A_1, A_2, \Omega_{\text{GW,astro}})\), and uniform priors for the slopes. The A-MCMC parameters are set to \(\beta = 0.01, N = 200 \ 000\), and we use 100 samples to estimate the covariance matrix. The orange lines represent the \textit{LISA} noise and the energy spectral density of the SGWBs; see Eq. 35. The green lines are the results of the A-MCMC, and in grey the 1 \(\sigma\) errors. Fig. 15 shows the corner plot of the A-MCMC orange line in the Fig 14; the marginal posterior distributions are symmetric.

It is also possible to have very efficient estimates of the different noise components thanks to the signal \(T\) being nominally devoid of GW signals. We have verified that over the one year of data, and the 50 A-MCMC results, the parameters are constant, except for the parameter \(A_1\), which varies due to the orbital modulation.

At low frequencies, the model of the broken power law of DWD energy spectral density (see Eq 26) can be approximated by a power law function, for a WD binary foreground the slope \(\alpha = a_1 - a_2 = \frac{3}{8}\). For \(1 \ll A_2 \left(\frac{f_{\text{ref}}}{f}\right)^{a_2}\) (low frequency: LF):

\[
\Omega_{\text{DWD,LF}}(f) \approx \frac{A_1}{A_2} \left(\frac{f}{f_{\text{ref}}}\right)^{a_1-a_2}
\]

(49)

In grey: 1500 estimations of the amplitude \( \Omega_{\text{mod},i} = \frac{4 \pi^2}{M_G} \left( \frac{c}{f_\text{ref}} \right)^3 A_f^2 \), where \( A_f \) is the amplitude of the characteristic strain of the section \( h_\text{c} \) of the waveform. The blue line is the mean of the 1500 estimations of the amplitude. In purple, the amplitude \( \Omega_{\text{mod}} \) of total waveform.

**Table 1.** Run N°30 of the 50 A-MCMC run parameter estimation results for the year of data with a GW background input of \( \Omega_{\text{GW,astro}} = 4.4 \times 10^{-12} \left( \frac{f}{\text{kHz}} \right)^{2/3} \), and the Galactic DWD binary foreground from Lamberts et al. (2019). In Fig. 15, the red lines correspond to the true values.

| \( \mu \) | \( \sigma_{\text{astro}} \) | \( \Omega_{\text{dwd,lf}} \) | \( \sigma_{\text{dwd,lf}} \) |
| --- | --- | --- | --- |
| 4.38 \times 10^{-12} | 0.66 | 2.01 \times 10^{-9} | 0.66 |

**Table 2.** 50 A-MCMC run parameter estimation results for the year of data with a GW background input of \( \Omega_{\text{GW,astro}} = 4.4 \times 10^{-12} \left( \frac{f}{\text{kHz}} \right)^{2/3} \), and the Galactic DWD binary foreground from Lamberts et al. (2019). In Fig. 17, the red lines correspond to the true values.

| \( \mu \) | \( \sigma_{\text{astro}} \) | \( \Omega_{\text{dwd,lf}} \) | \( \sigma_{\text{dwd,lf}} \) |
| --- | --- | --- | --- |
| 4.46 \times 10^{-12} | 0.65 | 5.67 \times 10^{-9} | 0.68 |

Presented in Fig. 13 with the dashed green line is an estimate of the modulated DWD amplitude of Eq. 48 from the 50 A-MCMC runs. We measure the amplitude of the energy spectral density of the Galactic foreground at low frequency \( \Omega_{\text{dwd,lf}}^{\nu} = (3.9 \pm 1.14) \times 10^{-9} \) for a reference frequency \( 3 \times 10^{-3} \) Hz. We use the `scipy.optimize.curve_fit` method of least squares to fit Eq. 48 to estimate the amplitude of the Galactic foreground at low frequencies (Virtanen et al. 2020). The input of the least squares approximation is the modulated DWD amplitude at low frequencies (see Eq. 49). We also use the estimated standard deviation from the 50 A-MCMC runs as an input to the least squares procedure, with the argument `sigma` set to the error from 50 A-MCMC. This result corresponds to the ‘real’ measurement of the Galactic foreground amplitude without the modulation. The brown line represents the spectral separability for the Bayesian study of the energy spectral density of the Galactic foreground with the low frequency limit for the total waveform length of one year.

The mean value of the 1500 estimates of \( \Omega_{\text{mod}} \) can be seen in blue, which is the mean of the grey curve. For the Bayesian analysis, the brown cross is no better, as no conclusive information appears. As can be seen with the error-bar, one cannot properly estimate the Galactic foreground amplitude without accounting for the changing LISA antenna response.

We have a good understanding of the signal modulation from the resolved binaries (Adams & Cornish 2014), and from theory. By identifying the resolvable foreground, one can predict the level of the unresolvable background. We note that the method presented in Adams & Cornish (2014) is more
Figure 14. Energy spectral density for the channels $A$, $E$, and $T$ from section 30 of the 50. Estimates are made for the two magnitudes of the LISA noise model from the proposal (Baker et al. 2019), the modulation of the WD foreground and the astrophysical background, with an A-MCMC of 8 parameters ($\text{BBH} + \text{DWD} + \text{LISA noise}$).
powerful, but for our present study the method we use is sufficient as an input to study the limitation of the measurement of the cosmological SGWB. We have consistent results with our algorithm. Indeed, we correctly estimate the limit at low frequencies, and moreover, the astrophysical background is also estimated accurately, with less than 3% error. We have more difficulty fitting the Galactic foreground (68% error); this is due to the low frequency adjustment. We note too that in Fig. 13 the second peak at 0.75 year is higher than the first at 0.25 year. This detail has been also noted by Edlund et al. and Adams & Cornish.

From the year of data, and the 50 A-MCMC results, the parameter estimates and errors for the Galactic foreground and astrophysical background are presented in Table 2 and Table 1. Fig 16 shows the energy spectral density estimates and Fig 17 displays the corner plots of all model parameters; these results were generated using a full year of data. This demonstrates that LISA can successfully observe and describe an astrophysically produced background from compact binaries, a Galactic DWD foreground, and LISA detector noise and separate these SGWB components.
Figure 16. Energy spectral density for the channels $A$, $E$, and $T$ from the total waveform. Estimates are made for the two magnitudes of the LISA noise model from the proposal (Baker et al. 2019), the modulation of the WD foreground, and the astrophysical background with an A-MCMC of 8 parameters (BBH + WD + LISA noise). One year of data was used.
7 MEASUREMENT OF THE COSMOLOGICAL SGWB

In this section, we present the goal of our study, namely the ability for LISA to measure a cosmological background in the presence of other stochastic signals and noise.

Boileau et al. (2021) presented the evidence for the separability of the cosmological and astrophysical backgrounds with a precision around $\Omega_{GW,\text{cosmo}} \approx 1 \times 10^{-12}$ to $1 \times 10^{-13}$.

As indicated in Section 5, it is possible to estimate the measurement error for each parameter using the Fisher matrix. Eq. 44 gives the Fisher matrix, which depends on the parameters to be estimated, and also on the data collection time. Indeed, we assume that LISA noise is a zero mean random noise, and that it is independent of the GW signal that we are trying to measure.

The SGWB signal from year to year is essentially the same. By integrating the data over time one can reduce the influence of the LISA noise on the SGWB search. We use the following for the magnitudes of the LISA noise: acceleration noise of the test-mass $N_{\text{acc}} = 1.44 \times 10^{-48}$ s$^{-1}$Hz$^{-1}$; and optical metrology system noise $N_{P\alpha} = 3.6 \times 10^{-41}$ Hz$^{-1}$). For the Fisher matrix study we consider observation times of 1,
4, 6, and 10 years. Thus, we will be able to see the effect of the integration of time in attempting to measure the cosmological background. We calculate the measurement uncertainty of the magnitude of the cosmological background for several mission durations and for cosmological normalised energy densities between 1 x 10^{-14} and 1 x 10^{-8}. We set a limit on the ability to detect a cosmological SGWB. We calculate the uncertainty of the measurement of the amplitude of the cosmological background. If this uncertainty is less than 50%, we claim that the background is detectable and separable from the cosmological background. This is an example of the separability of the astrophysical background and the cosmological background. If this uncertainty is less than 50%, we can predict that with our method it is possible to fit an SGWB of cosmological origin of \Omega_{\text{cosmo}} = 8 x 10^{-13}, given the values we have used for the LISA noise, the galactic foreground and the astrophysical background.

We also conduct a Bayesian study using an A-MCMC algorithm to estimate the parameters of our model: two magnitudes for the LISA noise; two parameters for the cosmological background (amplitude and slope); two parameters for the astrophysical background (amplitude and slope); and four parameters for the broken power law (two amplitudes and two slopes). In all, we estimate 10 parameters based on the three periodograms from channels A, E, and T. We use the astrophysical background from Chen et al. (2019). We vary the amplitude of the cosmological background to determine the precision with which it can be detected. Thus, we can produce parametric estimates using the A-MCMC for cosmological normalised energy densities injected with levels between 1 x 10^{-14} and 1 x 10^{-8}, all with a slope of a_{\text{cosmo}} = 0. In Fig. 18, the blue lines are the three periodograms for the data channels A, E, and T for one year of data simulated with \text{N}_{\text{acc}}, \text{N}_{\text{pos}} = \left(1.44 \times 10^{-18} \text{ s}^{-4} \text{Hz}^{-1}, 3.6 \times 10^{-41} \text{ Hz}^{-1}\right). We estimate the two LISA noise parameters and the 8 GW parameters (A_1, a_1, A_2, a_2) for the DWD, (\Omega_{\text{astro}}, \Omega_{\text{astro}}) for the astrophysical background and (\Omega_{\text{cosmo}}, \Omega_{\text{cosmo}}) for the cosmological background. This is an example of the separability with input comprising the Galactic binaries from Lamberst et al. and the astrophysical SGWB \Omega_{\text{astro}} = 4.4 \times 10^{-12} at 3 x 10^{-3} Hz with a slope of 2/3 and a flat (a_{\text{cosmo}} = 0) cosmological SGWB \Omega_{\text{cosmo}} = 8 \times 10^{-13}. The orange lines represent the model used, see Eq. 35. The A-MCMC is characterized by \beta = 0.01, N = 200 000, and we use 100 MCMC samples to estimate the co-variance matrix. We use log uniform priors with six magnitudes for two LISA noise magnitudes and the four SGWB amplitude parameters (\text{N}_{\text{acc}}, \text{N}_{\text{pos}}, A_1, A_2, \Omega_{\text{astro}}, \Omega_{\text{cosmo}}) and a uniform prior for the slopes (a_1, a_2, \Omega_{\text{astro}}, \Omega_{\text{cosmo}}) (2 degrees of freedom). The green lines are the results of the A-MCMC, and in grey the errors for 1 \sigma. Fig. 19 displays the corner plot for all parameters based on one year of data; the posterior distributions are symmetric. We have the evidence for a good fit for the astrophysical background and the cosmological background.

Table 3 is the summary of the results with the cosmological input \Omega_{\text{cosmo}} = 8 \times 10^{-13}. This is just at the level of detectability for the cosmological background. A year of data was used, and the results come from the 50 A-MCMC results. This shows that it will be possible for LISA to distinguish the cosmological background at this level from the astrophysical background, the Galactic DWD foreground, and LISA detector noise.

Fig. 20 displays the uncertainties for the measurement of the cosmological background as we vary its amplitude. We assume a flat background, with a_{\text{cosmo}} = 0 and \Omega_{\text{cosmo}} = \Omega_0. The results from two studies are presented. The first is the Fisher matrix study, presented as lines of blue, orange, green and red, corresponding to LISA observation durations of 1, 4, 6 and 10 years. We see that the effect of the duration does not have a large influence. Indeed, we explain this by noting the frequency dependence of the noise in the periodogram, which is predominantly at high frequencies, but we measure the GW backgrounds essentially at low frequencies. Despite this, we can see that the temporal dependence is not zero. A longer integration time allows a better fit. Our Bayesian study (see the black scatter), of which we present the results from A-MCMC runs for one year of data. Each point has an error bar obtained by estimating the standard deviation of the posterior distribution. Clearly, the measurement uncertainty is greater for low amplitudes of the cosmological SGWB.

7.1 Fisher Information Studies for modified Galactic Foreground Models

The galactic foreground as well as the astrophysical background are very uncertain. In our first study we considered different levels for the compact binary produced astrophysical background (\alpha = 2/3), in the range of \Omega_{\text{GW,astro}} (25 Hz) = 0.355 \rightarrow 35.5 x 10^{-5}; with this we showed that it would be possible with LISA to measure a cosmologically produced SGWB (\alpha = 0) in the range of \Omega_{\text{GW,cosmo}} \approx 1 x 10^{-12} to 1 x 10^{-13} with 4 years of observation (Boileau et al. 2021).

Now we address the uncertainty in the DWD galactic model. In this subsection, we investigate the effect of modifying the density model for the galactic foreground. We test the influence of modifications with a Fisher information study. Indeed, in this paper, we have shown that the two studies (Fisher and A-MCMC) give very similar results. First we introduce a modification of the amplitude of the galactic foreground by testing the separability for new forced values of the parameter A_1 such as A_{1,\text{new}} = d \times A_1 for d = 1, 2, 5, 10; see Eq. 26. Fig. 21 presents the uncertainty for the cosmologically produced SGWB normalized energy density with the variation of the amplitude A_1. Increasing the parameter A_1 only slightly decreases the possibility of measuring a SGWB of cosmological origin. This is a modification at very low frequencies \nu_{\text{GW}} < 7.2 x 10^{-5}, and does not significantly influence the estimation of the cosmological background by LISA.

We also introduce a modification of the frequency position of the zone of influence of the two spectral dependencies for the two slopes of our broken power law. It is possible to show that the cutoff frequency f_{\text{break}} is given by f_{\text{break}} = f_{\text{ref}} e^{-\frac{a_2}{a_1} \nu_{\text{GW}}}$. The change in frequency is given by a modification of the amplitude A_2 (again, see Eq. 26), such that the new amplitude is given by A_{2,\text{new}} = A_2 d^{-\alpha_2}, where d is the multiplying coefficient giving the new frequency of separation of the two spectral dependencies of the galactic foreground (f_{\text{new,break}} = d \times f_{\text{break}}). We conduct the Fisher
Figure 18. Energy spectral density for the channels $A$, $E$, and $T$ from the total waveform of 1 year data seen by LISA. Estimates are made for the two magnitudes of the LISA noise model from the proposal (Baker et al. 2019), the modulation of the WD foreground, the astrophysical background and a cosmological background with an A-MCMC of 10 parameters (cosmological + BBH + DWD + LISA noise).
Table 3. Results of the year long 50 A-MCMC runs with an input SGWB of $\Omega_{\text{astro}} = 4.4 \times 10^{-12} \left(\frac{f}{3 \times 10^{-3} \text{Hz}}\right)^{2/3}$, and a cosmological input $\Omega_{\text{cosmo}} = 8 \times 10^{-13}$ with a slope $\alpha_{\text{cosmo}} = 0$. We use as reference frequency $3 \times 10^{-3}$ Hz. Also presented are the low frequency (LF) results for the Galactic DWD. In Fig. 19 the red lines correspond the true values.

|        | $\Omega_{\text{astro}}$ | $\alpha_{\text{astro}}$ | $\Omega_{\text{cosmo}}$ | $\alpha_{\text{cosmo}}$ | $\Omega_{\text{DWD LF}}$ | $\alpha_{\text{DWD LF}}$ |
|--------|--------------------------|--------------------------|--------------------------|--------------------------|--------------------------|--------------------------|
| $\mu$  | $4.41 \times 10^{-12}$   | 0.67                     | $8.01 \times 10^{-13}$   | 0.04                     | $5.88 \times 10^{-9}$   | 0.68                     |
| $\sigma$ | $1.74 \times 10^{-13}$ | 0.06                     | $3.97 \times 10^{-13}$   | 0.09                     | $6.5 \times 10^{-9}$   | 0.13                     |

Figure 19. Corner plot for the A-MCMC of 10 parameters (BBH/BNS + WD (total waveform of 1 year data seen by LISA) + cosmo + LISA noise) using the channels A, E and T. The results are for the two magnitudes for the LISA noise model from the proposal (Baker et al. 2019), and two power law SGWB (amplitudes and spectral slopes) and the DWD (two magnitudes and two slopes). The vertical dashed lines on the posterior distribution represent from left to right the quantiles [16%, 50%, 84%]. The red lines are the "true" parameter values.
information study for \( d = 1, 2, 5, 10 \). In Fig. 22 we show the uncertainty of the cosmological SGWB estimation for different \( f_{\text{break}} \) values. We note that a spectral shift towards the higher frequencies, decreases our possibility of measuring the cosmological background. For a value of \( d = 10 \) the limit of detection is increased to \( \Omega_0 \approx 6 \times 10^{-12} \). This is logical because the shift of the galactic foreground to higher frequencies would more strongly affect the measurement of the cosmological background.

It is important to note that the galactic foreground will not be just DWDs; it may also contain WD-M-dwarf binaries (White dwarf + M dwarf binaries; a M dwarf can also be called a red dwarf), stripped stars or CVs. WD-M-dwarfs are few in comparison to DWDs, furthermore, we estimate that they are very low frequency objects so if we consider them we would expect a very slight increase in the \( A_1 \) parameter, which does not change our results (Skinner et al. 2017). From Fig. 2 of Göteborg et al. (2020), we see that binary stripped stars are less numerous than DWDs, they are also present at very low frequency. Moreover from Fig. 3 of Göteborg et al. (2020) the chirp mass is most important. So, adding this population also modifies the \( A_1 \) parameter, which should not change our conclusion. There are likely too few CVs to generate a significant high frequency foreground (Meliani et al. 2000; Marsh 2011; van der Sluys 2011; Pala et al. 2020) most of the high amplitude and high frequency CV sources will produce resolved events. Another important LISA signal source are AM Canum Venaticorum (AM CVn) stars. AM CVn binaries have been observed with periods between 5 and 65 minutes, hence gravitational-wave sources from \( 5 \times 10^{-4} \) to \( 7 \times 10^{-3} \) Hz (van der Sluys 2011). Much is still unknown about their space density from observations (Carter et al. 2012, 2013) and theoretical studies (Nelemans 2005; Kremer et al. 2017; Breivik et al. 2018), and estimates of the space density can vary by several orders of magnitude. Clearly the importance of understanding the binaries in the Milky Way will be meaningful for LISA searches, including the SGWB.

8 CONCLUSIONS

This study has displayed what may be possible for LISA in its ability to observe a cosmologically produced SGWB in the presence of an astrophysical BBH produced background, a Galactic DWD foreground, and inherent LISA detector noise. This paper also presents a comparison between two DWD catalogs (Lamerts et al. 2019; Nelemans et al. 2001b).

We find that the positional distribution of DWD does change the shape of the energy spectrum of the Galactic foreground. Our study can be easily applied to other catalogs of DWDs. For preparations of the LISA SGWB observations, it will be important to consider models that are as close as possible to the real Galactic distribution. LISA will have the ability to observe Galactic DWDs, both with resolvable binaries and the stochastic foreground, and make important statements about the distribution in the Galaxy. In this present study we do not observe significant changes to the GW power spectrum between resolved and unresolved DWDs. This is also the case for the different compositions of the cores of the WDs. We have studied the distribution of resolved and unresolved binaries according to their core compositions. It does not seem possible to us to extrapolate the chemical composition of all the binaries with the resolved binaries.

Our analysis considered the distribution of DWD produced GW signals in the Galaxy, and the detection response by
Figure 21. Uncertainty estimation of the cosmologically produced SGWB from the Fisher information study (represented as the colored lines for 4 different amplitudes $A_1$) and the parameter estimation from the A-MCMC (in scatters) for the channels $A$ and $E$ with the noise channel $T$. The upper horizontal dashed line represents the error level 50%. Above the line the error is greater than 50%. The parameter representing the magnitude of the galactic foreground has been modified, namely $A_{1,new} = d \times A_1$ for $d = 1, 2, 5, 10$; see Eq. 26.

Figure 22. Uncertainty estimation of the cosmologically produced SGWB from the Fisher information study (represented as the colored lines for 4 different peak frequencies in changing the spectral dependence $f_{\text{break}}$) and the parameter estimation from the A-MCMC (in scatters) for the channels $A$ and $E$ with the noise channel $T$. A factor $d$ defines a new frequency of separation of the two spectral dependencies of the galactic foreground, $f_{\text{new, break}} = d \times f_{\text{break}}$. We test $d = 1, 2, 5, 10$. The upper horizontal dashed line represents the error level 50%. Above the line the error is greater than 50%.
LISA as it orbits the sun, rotates its configuration, and changes its orientation with respect to the Galaxy. A modulation of the observed Galactic DWD foreground appears. Accurate parameter estimation for the different SGWB backgrounds (astrophysical, cosmological) must accurately estimate the signal modulation and amplitude from the Galactic foreground. Building on previous analyses addressing the modulated signal from the Galaxy (Edlund et al. 2005; Adams & Cornish 2014), we have presented a strategy to demodulate and measure the spectral energy density of the Galactic foreground at low frequencies. The orbital modulation of the Galactic foreground aids in the parameter estimation for the isotropic (and hence unmodulated) astrophysical and cosmological SGWBs.

We show that it will be possible to measure the SGWB amplitude of cosmological origin $\Omega_{GW,\text{cosmo}} \approx 8 \times 10^{-13}$ with an error of less than 50%. In our study, we consider this SGWB to have flat spectral energy density $s(\nu) \propto \nu^n$ (Sachdev et al. 2020); we note that this is an approximation for more complex cosmological backgrounds. Phase transition in the early universe can produce two-part power laws, with a transition between the rising and falling power law components at some peak frequency; a more complex version of our algorithm should be able to perform parameter estimation for these types of backgrounds as well. In our present study, the cosmological background prediction is obtained with an astrophysical background estimated to be at a level consistent with the observations made by Advanced LIGO and Advanced Virgo (Chen et al. 2019). It is important to note that this astrophysically produced SGWB is the main source of limitation for LISA in its effort to observe a cosmologically produced SGWB. An extragalactic background from DWDs could increase complexity as well.

Future third-generation projects, the Einstein telescope (Punturo et al. 2010) or Cosmic Explorer (Reitze et al. 2019), will also be trying to observe a cosmologically produced SGWB in the presence of an astrophysically produced background. However, these third generation detectors operating at higher frequencies, above 5 Hz, could have such detection sensitivity that almost all binary black hole mergers in the observable universe would be directly observable (Regimbau et al. 2017), and then could be removed from the SGWB search. The first consequence is therefore the disappearance of the astrophysical SGWB from the study of separability. So according to Sachdev et al. (2020) the ability to detect the cosmological background will be further improved.

DATA AVAILABILITY

The data generated for our study presented in this article will be shared upon reasonable request to the corresponding author.

ACKNOWLEDGEMENTS

GB, AL, NC and NJC thank the Centre national d'études spatiales (CNES) for support for this research. NJC appreciates the support of the NASA LISA Preparatory Science grant 80NSSC19K0320. RM acknowledges support by the James Cook Fellowship from Government funding, administered by the Royal Society Te Apārangi and DFG Grant KI 1443/3-2.
