Abstract
This article investigates a multi-hop cognitive radio network in terms of end-to-end bit delivery. The network exploits backscatter communication (BackCom) and harvest-then-transmit (HTT) mode in a hybrid manner. Such a network can be used in Internet of Things (IoT) applications in which IoT users coexist with a primary network and use the primary spectrum to transmit data in both BackCom and HTT modes. Besides, such users can harvest energy from the primary signals. A novel hybrid backscatter and conventional transmission (HBCT) algorithm is proposed in order to maximize end-to-end bit delivery by jointly optimizing time and power allocations. For this goal, we formulate a non-convex optimization problem. Next, we transform the problem into a convex one and develop a new analytical formulation by which we calculate the optimal power and time allocation in closed-form equations. The numerical results demonstrate the superiority of HBCT compared with current schemes.

1 | INTRODUCTION

The emergence of the Internet of Things (IoT) will involve a wide variety of interconnected devices in the upcoming years. Monitoring and managing urban noises, street lighting, irrigation, and waste disposal can be done more effectively. Multi-hop communication could be an excellent way to improve the coverage area of IoT networks. On the other hand, energy constraint is a critical issue in IoT applications because a remote device could be located in an area that battery replacement or recharge is impossible or difficult.

In recent years, energy harvesting has attracted significant attention in order to prolong the lifetime of remote devices. Energy can be harvested from different sources like wind, thermal, solar, and wireless radio-frequency (RF), but the efficiency of each method depends on its availability. RF signals are accessible in various environmental conditions; hence, it is appropriate to be utilized in IoT applications. Another crucial concern in IoT applications is the availability of frequency spectrum. Recently, cognitive radio networks (CRNs) have been proposed to solve this problem. Cognitive radio can be adopted in various networks to enhance the efficiency of the spectrum and improve the performance of the system. By adopting energy harvesting in CRNs, we can simultaneously exploit the advantages of energy harvesting and cognitive radio. This kind of network is called energy harvesting CRNs (EH-CRNs). In the EH-CRNs, all secondary users (SUs) are battery-free and could be equipped with a super-capacitor that can keep harvested energy temporarily due to its high rate of self-discharge characteristic. Therefore, each SU can harvest energy just prior to the transmission mode. This method is known as harvest-then-transmit (HTT).

Backscatter communication (BackCom) is another promising technology that can be considered for IoT applications. A backscatter device transmits data by backscattering incident signals. Due to its lack of oscillators and analog-to-digital converters (ADCs), the circuit power consumption is significantly reduced. Consequently, SUs can transmit data as
long as incident signals are available. The incident signals could be ambient signals, for example, TV, WiFi, or dedicated signals scattered by a carrier emitter.

This article studies a multi-hop EH-CRN scheme that enjoys BackCom’s advantages and obtains optimal resource allocation to maximize end-to-end bit delivery. A multi-hop network can be more suitable for IoT applications. In such a network, nodes work in short-range, consume less energy, and impose less interference to the other primary and secondary users. To improve the performance of such a network, we develop an algorithm for multi-hop BackCom-EH-CRNs, namely hybrid backscatter and conventional transmission (HBCT). The proposed algorithm enables SUs to transmit conventional or backscatter data while harvesting energy. It is worth mentioning that in this article, we refer HTT method as conventional communication. First, the problem is formulated as a nonconvex optimization problem. Next, we prove Lemma 1, by which the problem is transformed into a convex one. We develop a new analytical formulation by which we solve the optimization problem and obtain the optimal resource allocations in closed-form equations. To evaluate the proposed algorithm, we design a typical scenario and compare the HBCT algorithm with joint optimal time and power allocation (JOTPA) and simple ambient backscatter (AB) algorithms to demonstrate the superiority of the proposed algorithm.

The main contribution of this article can be summarized as follows:

- Different from current algorithms in multi-hop networks, the proposed HBCT algorithm enables SUs to work either in conventional or backscatter modes to provide better performance in terms of end-to-end bit delivery. To the best of our knowledge, the hybrid structure of conventional and backscatter communication in multi-hop networks has not been studied before.
- We prove new lemmas and develop our analytical structure to derive closed-form equations for resource allocations in a K-hop network.
- We analytically prove that the HBCT algorithm performs better than JOTPA and AB algorithms.

The rest of this article is organized as follows. In Section 2, we give an overview of related works. Section 3 presents the system model and expresses transmitted bits of each SU. In Section 4, we formulate an optimization problem and obtain an optimal solution for the proposed algorithm. Simulation results and numerical analysis are discussed in Section 5, and the conclusion of this work can be found in Section 6.

2 RELATED WORK

In recent years, energy harvesting has attracted much attention. In Reference 14, resource allocation and fairness have been investigated to maximize sum-throughput. As an extension of Reference 14, the authors in Reference 15 studied a wireless powered communication network (WPCN) with a full-duplex hybrid access point (HAP) that enables the HAP to broadcast energy and receive independent information from the users simultaneously. Energy harvesting CRNs (EH-CRNs) have been introduced for many sensor network applications. For applications with higher energy consumption, WPCN can be combined with a CRN to form cognitive-WPCN (CWPCN). In Reference 16, the authors studied the sum-throughput maximization problem for a CWPCN, in which SUs utilize an existing licensed spectrum for energy harvesting and data transmission. A multi-user MIMO CWPCN is studied in Reference 17, wherein the optimal time allocation and transmit covariance matrices have been provided to maximize the network sum-throughput. A new frame structure has been suggested in Reference 18. The authors split the time frame into four slots for spectrum sensing and data transmission, each with a separate energy harvesting time slot. Then they obtained power outage probability. In Reference 19, the authors integrated an energy harvesting network with a cooperative CRN. They proposed a novel scheme and investigated resource allocation and fairness problems. The authors in Reference 20 studied the sum-throughput maximization problem in a WPCN, wherein users transmit to the HAP in a dual-hop manner. An underlay multi-hop EH-CRN has been investigated in Reference 10. The authors studied the end-to-end throughput maximization problem and calculated time and power allocations thanks to the convex optimization techniques.

Recently, some authors paid attention to backscatter communications as a promising technique to improve the system’s performance. Experimental results have shown that by using such a technique, achieving at least 1 kbps bitrate in about 100 m communication range for bistatic backscatter communication systems (BBCSs), and about 1 to 5 m communication range for ambient backscatter communication systems (ABCSs) is feasible. A backscatter receiver is designed
in Reference 22, in which carrier frequency offset (CFO) is eliminated, and near-optimal detectors are adopted to increase the communication range of BBCSs. The authors in Reference 23 suggested two-phase filtering in order to increase the communication range of BBCSs. In Reference 24, an actual channel coding is proposed to reduce bit error rate (BER) and therefore increase the communication coverage of BBCSs. Different from References 22-24, a prototype of ABCSs is introduced in Reference 21. In this prototype, a backscatter pair can communicate at 1 kbps bitrate in a distance of 2.5 and 1.5 ft ranges, in outdoor and indoor environments, respectively. The authors in Reference 25 developed an ABCS that exploits FM signals broadcasted by an FM radio station. They adopted FM0 encoding and ON-OFF keying (OOK) modulation for the backscatter transmitter. The prototype is deployed and tested in an indoor environment, and 5 m distance leading to 2.5 kbps of bitrate. In Reference 26, the authors improved transmission range and communication bitrate by introducing a multi-antenna transmitter and a code-division multiple access (CDMA) mechanism. In Reference 27, the authors proposed a communication system, named BackFi, that enables IoT sensors to utilize ambient WiFi signals and transmit data to the WiFi access point (AP). They designed a prototype and showed that bitrate up to 5 Mbps over 1 m of distance, and 1 Mbps over 5 m of distance, are possible.

As EH-CRNs, backscatter communication enables sensors to operate low-power and utilize existing frequencies. Accordingly, integrating backscatter communication and EH-CRN can bring more efficiency into IoT applications. In Reference 12, a novel protocol is proposed to improve the performance of the secondary system, based on integrating ambient backscatter technique with a CRN. The authors considered only a couple of SUs as transmitter and receiver and then maximized throughput by finding a trade-off between backscatter time, harvest time, and transmit time in underlay and overlay CRNs. A backscatter-assisted WPCN has been investigated in Reference 28 to maximize sum-throughput. A convex optimization problem is formulated, and optimal time allocations and SU's working mode permutations are obtained. Nevertheless, in that scheme, only one user can work in backscatter mode, and the rest of the users aligned before that one are unable to transmit data to the HAP. The authors in Reference 13 take into consideration a CWPCN with hybrid backscatter assisted for IoT applications. They utilize bistatic backscatter and ambient backscatter in an overlay CWPCN to improve network performance. Next, they calculated the optimal solution for only a single SU using convex optimization techniques. Besides the works mentioned above, several papers in the literature studied the performance of adopting backscatter communication in wireless communication networks.29-33

Unlike the aforementioned works, we consider a multi-hop network and develop a hybrid algorithm to utilize both backscatter and conventional transmission methods. Besides, convex optimization techniques provide an analytical structure by which closed-form equations for K-hop networks are derived.

3 | SYSTEM MODEL

In this section, we propose a system model which can be utilized in IoT applications. Figure 1 depicts an underlay multi-hop BackCom-EH-CRN secondary network coexisting with a primary network (PN). The PN consists of a primary transmitter (PT) and a primary receiver (PR), operating in a licensed spectrum. The secondary network consists of K SUs, where SU\(_k\) indicates kth user. The secondary network works in a multi-hop method to deliver data from the source, SU\(_1\), to the destination, SU\(_K\). Each SU\(_k\) has two options for transmitting data, that is, HTT mode and BackCom mode. However, SUs cannot use these two methods simultaneously.34 We suppose SUs are battery-free but equipped with a super-capacitor and harvest energy from the PT to transmit their data to the next hop in HTT mode. Hence, the SUs exploit both spectra and energy from the PT, as assumed in Reference 10. Besides the HTT method, each SU is equipped with a BackCom transceiver; hence, it can backscatter data to the next hop. In fact, in the case of BackCom mode, SUs exploit primary signals as incident signals.12,13 It is worth noting that in BackCom mode, we consider incident signal as excitation signal; therefore, the harvesting energy phase is not required for BackCom mode.13

The block structure adopted for this network is illustrated in Figure 2, with total duration T. At the beginning of each time block, all SUs start to harvest energy from the PT in order to charge their super-capacitors for transmitting information in the HTT mode. Each SU\(_k\) continues to harvest energy up to its transmission period, that is, \(t_k\). However, at the beginning of the time block, all users are out of energy; therefore, there is an initial energy harvesting period \(t_0\) in which all users are silent and just harvest energy. For each time block, we have

\[
\sum_{k=0}^{K} t_k \leq T. \tag{1}
\]
The channel power gains between the PT and SU$_k$, SU$_k$, and SU$_{k+1}$, and between SU$_k$ and the PR, are denoted by $h_k$, $g_k$, and $f_k$, respectively. It is assumed that all channels are quasi-static flat-fading. Hence, the channel gains remain constant during each time block but can change from one block to another. It is further assumed that channels are well known at the SUs by using common techniques for estimating channels.\textsuperscript{10}

Each SU$_k$ can transmit data to the next hop in a hybrid conventional and backscatter manner. Each SU$_k$ can harvest energy just before its transmission time slot for conventional transmission. The transmission power of each SU$_k$ should be under a predetermined threshold to prevent harmful interference to the PR. As depicted in Figure 2, each time slot is divided into two subslots. The first subslot lasts $\varphi_k$ for conventional transmission, and the other lasts $\tau_k - \varphi_k$ for backscatter transmission. Each SU$_k$ has a super-capacitor to store harvested energy for conventional data transmission. Super-capacitors charge very rapidly; however, due to the high self-discharge rate, they discharge quite fast as well.\textsuperscript{11} Consequently, each SU$_k$ may spend its energy to transmit data right after the harvesting period. In this article, we assume that the remaining energy in the super-capacitor or the energy harvested after the transmission cannot be used in the next time block due to the high self-discharge of the super-capacitor.\textsuperscript{10,35} Based on this assumption, the stored energy of SU$_k$ is harvested solely during the interval $\sum_{i=0}^{k-1} \tau_i$, $k = 1, \ldots, K$, and is equal to\textsuperscript{10}

$$E_k = \zeta_k P_t \sum_{i=0}^{k-1} \tau_i,$$

where $0 \leq \zeta_k \leq 1$, $k = 1, \ldots, K$, is the energy harvesting efficiency at SU$_k$, and $P_t$ is the transmission power of the PT. We consider all energy harvesting coefficients of SUs are the same, $\zeta_1 = \zeta_2 = \cdots = \zeta_K = \zeta$. It is worth mentioning that in this article, we consider non-intended limited energy harvesting from the primary transmitter, which is enough for low-power sensor networks.\textsuperscript{10,11} Hence, in the multi-hop scenario, the transmit power of each SU$_k$ is limited and we assume the transmission range is one hop. Therefore, we only consider the primary signal as the source of energy harvesting, as expressed in (2).\textsuperscript{10}

The signal is received at the SU$_k$ in the primary band, that is, $y_k$, is the superposition of those from SU$_{k-1}$, and the PT. We consider two different modes of conventional and backscatter transmission, and in each case, we show that SU$_k$ can separate the received data signal and energy signal.
At conventional mode, these components are shown by \( x_{k-1} \) and \( x_p \), respectively. Therefore

\[
y_k = \sqrt{P_t h_k x_p} + \sqrt{P_t h_k x_{k-1}} + n_k,
\]

where \( n_k \sim N(0, \sigma^2_k) \) is the additive white Gaussian noise (AWGN) at SU \( k \). In this article, we consider \( \sigma^2_1 = \sigma^2_2 = \cdots = \sigma^2_K \), \( x_p \) and \( x_{k-1} \) are uncorrelated satisfying \( E[|x_p|^2] = 1 \) and \( E[|x_{k-1}|^2] = 1 \). Therefore, \( x_p \) can be converted into energy by an RF-DC circuit, and \( x_{k-1} \) can be decoded by the SU \( k \).

At backscatter mode, we show the component from PT by \( x_p \), and the bits transmitted by the SU \( k-1 \) by \( s_{k-1} \). Then, the received signal at the receiver is

\[
y_k = \sqrt{P_t h_k x_p} + \sqrt{P_t h_k s_{k-1}} + n_k.
\]

The passive coherent processing can be used to separate backscatter and primary signals. Specifically, by using a remodulation stage, the receiver can isolate a copy of \( x_p \) from the received signal \( y_k \) by adopting modulators and a demodulator. Hence, the \( x_p \) can be separated and converted into energy, and \( s_{k-1} \) can be decoded.

Each SU \( k \) has to guarantee that its conventional transmission power remains under a predetermined threshold to avoid harmful interference to the PR. The interference power constraint (IPC) can be expressed as

\[
p_k \phi_k \leq I_p,
\]

where \( I_p \) is the threshold, and \( p_k \) is the allocated power to SU \( k \). The energy consumed during conventional transmission by each SU \( k \) should not exceed the harvested energy; accordingly, we can state consumed power constraint (CPC) with respect to (2) as

\[
p_k \phi_k \leq \zeta P_t h_k \sum_{l=0}^{k-1} \tau_l.
\]

It is worth mentioning that in this work, we do not consider circuit power consumption for calculation simplicity. Since the benchmark scheme does not consider circuit power consumption, the comparison between the proposed scheme and the benchmark is valid. The number of transmitted bits of SU \( k \) can be found as

\[
R_k(\tau_k, \phi_k, p_k) = \phi_k W \log_2(1 + p_k \gamma_k) + (\tau_k - \phi_k) B^b_k,
\]

where \( W \) is the bandwidth, \( B^b_k \) is the backscatter rate of SU \( k \) determined by the receiver’s RC circuit, and \( \gamma_k = \frac{h_k}{\sigma^2} \). It is worth noting that the signals emitted by the PT are no longer considered as interference, and it is converted into energy.

### 4 | OPTIMAL RESOURCE ALLOCATION

In this section, we provide a solution for the end-to-end bit delivery maximization problem for the proposed HBCT algorithm. The bottleneck link restricts the end-to-end bit delivery of a multi-hop path. Let us assume \( \tau = [\tau_1, \ldots, \tau_K] \) as the vector of total allocated time to SUs, \( \phi = [\phi_1, \ldots, \phi_K] \) and \( p = [p_1, \ldots, p_K] \) as vectors of allocated time and power for the conventional transmission, respectively. The total end-to-end bit delivery can be expressed as

\[
R(\tau, \phi, p) = \min_{1 \leq k \leq K} R_k(\tau_k, \phi_k, p_k).
\]

To maximize \( R(\tau, \phi, p) \), the following optimization problem is formulated.

\[
\max_{\tau, \phi, p} R(\tau, \phi, p), \quad \text{s.t.} \quad (1), (5), (6), \quad 0 \leq \phi_k \leq \tau_k,
\]
0 ≤ τ_k ≤ T. \hfill (11)

Since there is a product of two optimization variables, that is, \( p_k \) and \( τ_k \) in (6), problem (9) is nonconvex. Regarding Equations (8), (5), and (6), and by substituting \( p_k = \frac{e_k}{ϕ_k} \), problem (9) is transformed to a convex optimization problem as

\[
\max_{τ,ϕ,e} \min_{1 ≤ k ≤ K} R_k(τ_k, ϕ_k, e_k), \hfill (12)
\]

s.t. 
\[
(1), (9), (11),
\]
\[
e_k ≤ ζP_i h_k \sum_{i=0}^{k-1} τ_i, \quad k = 1, \ldots, K, \hfill (13)
\]
\[
e_k ≤ \frac{I_{pk}}{ή_k}ϕ_k, \quad k = 1, \ldots, K. \hfill (14)
\]

where \( e = [e_1, \ldots, e_K] \) is the vector of allocated energy to SUs, and \( R_k(τ_k, ϕ_k, e_k) \) is as

\[
R_k(τ_k, ϕ_k, e_k) = ϕ_k W \log_2 \left( 1 + \frac{e_k}{ϕ_k} γ_k \right) + (∆k - ϕ_k)B_{Bk}^k. \hfill (15)
\]

**Lemma 1.** \( R(τ,ϕ,e) = \min_{0 ≤ k ≤ K} R_k(τ_k, ϕ_k, e_k) \) is a jointly concave function of \( τ, ϕ, \) and \( e \).

**Proof.** See Appendix A. \hfill □

From Lemma 1 and all the affine constraints, it is observed that problem (12) is a convex optimization problem. The maximum end-to-end bit delivery can be achieved by utilizing the following propositions.

**Proposition 1.** The end-to-end bit delivery is maximum when we have

\[
\sum_{k=0}^{K} τ_k = T. \hfill (16)
\]

**Proof.** See Appendix B. \hfill □

**Proposition 2.** The end-to-end bit delivery is maximum when the number of transmission bits of all SUs is equal, that is, \( R_1(τ_1, ϕ_1, e_1) = R_2(τ_2, ϕ_2, e_2) = \cdots = R_K(τ_K, ϕ_K, e_K) \).

**Proof.** Please refer to Reference 10. \hfill □

Proposition 2 states that all links in the multi-hop path should have the same delivery bits for maximizing end-to-end bit delivery.

Next, we introduce \( R \) as a new optimization variable which is a lower bound on each link’s bit delivery. Hence, maximization of \( R \) guarantees that the bit delivery of the bottleneck is maximum, and maximum end-to-end bit delivery reaches. Therefore, we can reformulate problem (12) as

\[
\max_{τ,ϕ,e,R} R, \hfill (17)
\]

s.t. 
\[
R_k(τ_k, ϕ_k, e_k) ≥ R, \quad k = 1, \ldots, K, \hfill (18)
\]

Since (12) is concave, problem (17) is also concave and satisfies Slater’s condition. \hfill □

Therefore, we can solve the dual problem because the duality gap between the primal and dual problems is zero. To do so, we first provide the partial Lagrangian function of problem (17) with respect to (18) as
\[ L(\tau, \varphi, e, \lambda) = R - \sum_{k=1}^{K} \lambda_k (R - R_k(\tau_k, \varphi_k, e_k)) \]
\[ = R \left( 1 - \sum_{k=1}^{K} \lambda_k \right) + \sum_{k=1}^{K} \lambda_k R_k(\tau_k, \varphi_k, e_k), \quad (19) \]

where \( \lambda = [\lambda_1, \ldots, \lambda_K] \) is the vector of non-negative Lagrange multipliers associated with the constraints in (18). Then, the dual function of problem (17) can be obtained as

\[ G(\lambda) = \max_{(\tau, \varphi, e) \in D} L(\tau, \varphi, e, \lambda), \quad (20) \]

where \( D \) is the feasible set of \((\tau, \varphi, e)\) determined by (1), (10), (11), (13), and (14). Thus, the Lagrange dual problem of the problem (17) is given by \( \min_{\lambda \geq 0} G(\lambda) \). With a given \( \lambda \), we can reformulate (20) as

\[ \max_{\tau, \varphi, e} \sum_{k=1}^{K} \lambda_k R_k(\tau_k, \varphi_k, e_k), \]
\[ \text{s.t.} \quad (1), (10), (11), (13), (14). \quad (21) \]

Note that the constant term of \( R(1 - \sum_{k=1}^{K} \lambda_k) \) is eliminated because it does not affect convexity. In problem (21), constraints (1) and (13) are coupling constraints, while (10), (11), and (14) are coupling variables. To handle this problem, we utilize the decomposition method to relax constraints (1), (10), and (13).\(^{38}\) Hence, the partial Lagrangian function of problem (21) can be expressed as

\[ L'(\tau, \varphi, e, \mu, \xi, \nu) = \sum_{k=1}^{K} \lambda_k R_k(\tau_k, \varphi_k, e_k) \]
\[ - \sum_{k=1}^{K} \mu_k \left( e_k - \zeta P\gamma_k h_k \sum_{n=0}^{k-1} \tau_n \right) \]
\[ - \sum_{k=1}^{K} \xi_k (\varphi_k - \tau_k) - \nu \left( \sum_{k=0}^{K} \tau_k - T \right), \quad (22) \]

where \( \mu = [\mu_1, \ldots, \mu_K] \) and \( \xi = [\xi_1, \ldots, \xi_K] \) are vectors of Lagrangian multipliers associated with (13) and (10), respectively, and \( \nu \) is the Lagrangian multiplier associated with (1). The Lagrange dual function of problem (21) is expressed as

\[ G'(\mu, \xi, \nu) = \max_{(\tau, \varphi, e, \mu, \xi, \nu) \in D'} L'(\tau, \varphi, e, \mu, \xi, \nu), \]

where \( D' \) is the feasible set associated with (11) and (14). Then, we can obtain the Lagrangian dual problem of the problem (21) as \( \min_{\mu, \xi, \nu \geq 0} G'(\mu, \xi, \nu) \).

The optimal power allocation for the HBCT algorithm provides by Lemma 2.

**Note:** We use * as a superscript of variables to indicate their optimal values. For example, \( p_k^* \) means the optimal value of \( p_k \).

**Lemma 2.** For a given \( \lambda_k \) and by considering inequality (5), the optimal power allocation for the proposed HBCT algorithm is given by

\[ p_k^* = \min \left\{ \frac{e_k}{\varphi_k}, \frac{f_k}{f_k} \right\}, \quad (23) \]

where \( \frac{e_k}{\varphi_k} \) can be obtained from the following equation in which for the sake of simplicity, we use \( A_k \) to indicate \( 1 + \frac{e_k}{\varphi_k} \gamma_k \).

\[ f(A_k) - \zeta P\gamma_k h_k + 1 = 0, \quad (24) \]
where

\[ f(x_k) = x_k \ln x_k - x_k \left( \frac{\xi P_t}{\lambda_k} \sum_{i=1}^{k-1} \frac{\lambda_i h_i}{X_i} + 1 \right). \]

**Proof.** See Appendix C. \[\blacksquare\]

Having found \( p_k^* \), we can write \( p_k^* = \frac{e_k^*}{\varphi_k^*} \), where \( e_k^* \) and \( \varphi_k^* \) represent the optimal values of \( e_k \) and \( \varphi_k \), respectively. Then, we can calculate the optimal bit rate of conventional transmission as

\[ \Omega_k^* = W \log_2 (1 + p_k^* \gamma_k). \] (25)

Also, for notation simplicity, we introduce a new variable \( c_k \), such that \( \varphi_k = (1 - c_k) \tau_k \), \( 0 \leq c_k \leq 1 \). Hence, \( c_k \) indicates the portion of time in time slot \( \tau_k \) that \( SU_k \) spends in BackCom mode. With respect to (16) and Proposition 2, the end-to-end bit delivery can be achieved by

\[ R_k(\tau_k, \varphi_k, e_k) = \tau_k X_k = \frac{T - \tau_0}{\sum_{i=1}^{K} \frac{1}{X_i}}. \] (26)

where

\[ X_k = B_b^k + (1 - c_k) \left( \Omega_k - B_b^k \right). \] (27)

The following lemma guarantees that the source node, that is, \( SU_1 \), consumes the harvested energy completely in conventional mode. In fact, if the network decides to achieve maximum end-to-end bit delivery, the source node has to produce as much data as it can.

**Lemma 3.** The maximum end-to-end bit delivery is achievable when the source node consumes harvested energy completely.

**Proof.** See Appendix D. \[\blacksquare\]

Ultimately, Lemma 4 expresses the optimal time allocation for the proposed algorithm.

**Lemma 4.** The optimal time allocation of HBCT is given by

\[ \tau_0^* = \frac{(1 - c_1^*) p_1^*}{\xi P_t h_1} \tau_1^*, \] (28)

\[ \tau_k^* = \frac{T}{X_k^* \left( \frac{(1 - c_k^*) p_k^*}{\xi P_t h_k} + \sum_{i=1}^{k-1} \frac{1}{X_i} \right)}, \] (29)

where \( X_k^* = B_b^k + (1 - c_k^*) \left( \Omega_k^* - B_b^k \right) \) and the optimal value of \( c_k \) (i.e., \( c_k^* \)) is given by the following equations.

\[ c_k^* = \begin{cases} 
1 & \text{if } \Omega_k^* < B_b^k \left( 1 + \frac{p_k^*}{\xi P_t h_k} \right), \\
0 & \text{if } \Omega_k^* > B_b^k \left( 1 + \frac{p_k^*}{\xi P_t h_k} \right), \\
1 & \text{if } \Omega_k^* < B_b^k, \quad k = 2, 3, \ldots, K, \\
0 & \text{if } \Omega_k^* > B_b^k, \quad k = 2, 3, \ldots, K.
\end{cases} \] (30)

**Proof.** See Appendix E. \[\blacksquare\]

With respect to Lemma 4, if \( c_k^* = 1 \), \( SU_k \) transmits data only in BackCom mode during \( \tau_k^* \). However, when \( c_k^* = 0 \), transmission happens only in conventional mode. The following Lemma will prove that the proposed HBCT algorithm always performs better than JOTPA and AB.
Lemma 5. The proposed HBCT algorithm performs better, or at least the same as the JOTPA and AB algorithms for different powers of the PT.

Proof. See Appendix F. □

5 NUMERICAL RESULTS

In this section, some related studies in References 10, 12-14, 16, 20, and 28 are considered and discussed.

In Reference 12, the authors studied a pair of SUs as the secondary transmitter (ST) and secondary receiver (SR), working in a hybrid method that incorporates HTT and AB algorithms to improve the performance of the system. However, this work considers only a pair of users, not a multi-hop, as studied in this article. In Reference 13, a CWPCN took into consideration that enjoys a hybrid scheme working with either HTT or AB algorithms. However, the scenario investigated in Reference 13 is not a multi-hop one, so it cannot compare with our work. The scenarios investigated in References 14, 16, 20, and 28, are also a WPCN, therefore as Reference 13, these papers cannot compare with a multi-hop scenario investigated in this article. Besides, the works in References 14, 20, and 28 have not been studied in the context of cognitive radio.

Different from those in References 12-14, 16, 20, and 28, the work investigated in Reference 10 is the most relevant work to our study. The authors of Reference 10 have studied a multi-hop energy harvesting CRN that enjoys only conventional communication. They proposed an algorithm to maximize end-to-end throughput with joint time and power allocations optimization, named JOTPA. As investigated in Reference 10, we study a multi-hop network and propose the HBCT algorithm to maximize end-to-end bit delivery through time and power allocation optimization. The difference between JOTPA and HBCT algorithms is that JOTPA is an algorithm that works only in the conventional manner; however, HBCT is a hybrid algorithm that works with both conventional and backscatter manners.

Algorithm 1. HBCT algorithm for BackCom-EH-CRN

| Input: K, P, I, T, 𝜇, σ², g, h, f, B_k² for k = 1, …, K; |
| Output: p*, τ*, c*; |
| 1 Initialization λ ≥ 0; |
| 2 Find A, p, Ω, c, X, τ by (24), (23), (25), (30), (27), (28), (29), respectively; |
| 3 Optimize λ using fminunc tool in MATLAB to find the maximum value of (7); |

In the following, we present numerical results and compare the proposed algorithm with JOTPA suggested in Reference 10 and AB algorithm. The pseudo-code of the proposed HBCT algorithm is summarized in Algorithm 1. It is worth mentioning that A = [A1, …, AK]. As proved in Proposition 2, to maximize end-to-end bit delivery, the number of transmission bits for all users should be equal. The problem is solved by considering Proposition 2; hence, substituting optimal solutions into (7) gives us maximum end-to-end bit delivery for a given λ. To find the optimal solution for λ, we adopt the fminunc tool in MATLAB. We assume that the length of each time block is T = 1. The channel power gains are calculated as Y_k = |β_k^Y|^2 (d_k^Y)^−α Y = h, g, f). We assume fading channels have independent Rayleigh fading; hence, |β_k^Y|^2 is an independent exponential random variable. d_k^Y is the link distance, d_0 is the reference distance, and α is the path-loss exponent. Similar to those in References 10, 14, 15, and 39, the value of the path-loss exponent is considered α = 2, which is for free space environments. Herein, we assume that the reference distance is d_0 = 1. The number of hops is considered K = 3 unless mentioned else. We assume that energy harvesting efficiency in each SU_k is ζ = 0.8.6,10 The noise power in received signals at each SU_k is assumed to be σ² = 1. Therefore, the powers of all devices are normalized to σ². The power of signals emitted by the PT and the tolerable interference in PR are P = 40 dB and I = 0 dB, respectively. The location of PT and PR is (−8, 10) and (−2, 10), respectively. The location of the source node, that is, SU_1, and the destination node, that is, the SU_K, is assumed to be (−10, 0) and (0, 0), respectively. We assume that the intermediate nodes are located in a straight line from SU_1 to the SU_K. The bitrate of backscatter transmission is summarized in Table 1. These values are obtained from a practical experiment presented in Reference 27. List of parameters and their values are summarized in Table 2.
The performance of the network vs different amounts of the power of PT is illustrated in Figure 3. According to Figure 3A, the proposed HBCT algorithm always performs better, or at least the same as the JOTPA and AB algorithms in terms of end-to-end bit delivery, as proved in Lemma 5. As shown in Figure 3A, in the low power of the PT, that is, $P_t = 10$ dB, the gap between end-to-end bit delivery in the HBCT and JOTPA algorithms is maximum. As the power of PT increases, the gap decreases. Ultimately, the gap converges to zero when the $P_t$ is large, that is, $P_t > 46$ dB. It means that, for high powers of the PT, the end-to-end bit delivery in both HBCT and JOTPA algorithms are identical. In comparison with JOTPA and AB algorithms, HBCT performs better. In fact, in JOTPA and AB, only conventional and backscatter communications are used, respectively. Nevertheless, HBCT uses the benefits of both backscatter and conventional methods. Hence, each SU selects the conventional or backscatter method depending on which of them performs better. For this reason, HBCT always has a more significant bit delivery. When we compare JOTPA and AB, we see that in the low powers of PT, that is, $P_t < 24$ dB, the JOTPA algorithm performs worse than the AB algorithm in terms of end-to-end bit delivery. This happens because JOTPA harvests lower energy in the low powers of PT. Therefore, it cannot deliver bits as AB can deliver. However, when PT power increases, the end-to-end bit delivery of JOTPA increases and becomes more than the end-to-end bit delivery of the AB algorithm.

In the following, we interpret the behavior of the proposed HBCT algorithm more clearly. Thus, we present the backscatter usage tendency of SUs in Figure 3B. The backscatter usage tendency is the average backscatter usage by each SU. According to Figure 3B, with low PT power, that is, $P_t = 10$ dB, SU1 transmits data in the backscatter way with a tendency of 100% on average. However, the SU2 and SU3 transmit data in the backscatter manner with a tendency near 2% on average. Instead, SU2 and SU3 almost use the conventional method. Because the SU1 can transmit data in the backscatter method, the end-to-end bit delivery in the HBCT algorithm is kept much higher than the JOTPA algorithm in low powers of the PT, as depicted in Figure 3A. Note that, as mentioned before, the end-to-end bit delivery of the JOTPA algorithm depends on the amount of harvested energy. The amount of harvested energy in the low power of the PT is less to support conventional transmission, especially in the SU1. For this reason, in the low power of PT, SU1 in JOTPA cannot deliver much data compared to SU1 in HBCT; therefore, the total bit delivery of JOTPA is low compared to HBCT and even AB algorithms. To explain more, the amount of harvested energy depends on the power of PT and the amount of harvesting time, according to Equation (2). In the JOTPA algorithm, the allocated time to the energy harvesting phase is very high for low PT powers, as depicted in Figure 4B. Hence, the allocated time for data transmission to SU1 is very low. Therefore SU1 cannot produce much data. This event results in low end-to-end bit delivery. However, by exploiting the backscatter method by the SU1, the HBCT algorithm keeps its performance much better than the JOTPA due to the improved data transmission by SU1. As the power of PT increases, the tendency for exploiting the backscatter method by SU1 decreases.
FIGURE 3 (A) End-to-end bit delivery vs transmission power of the PT for different algorithms. (B) Backscatter usage vs transmission power of the PT

FIGURE 4 Average allocated time of (A) HBCT and (B) JOTPA algorithms vs power of PT
This is because the amount of harvested energy by SU\(_1\) increases according to Equation (2). Ultimately, at high PT power levels, that is, \(P_t = 50\ dB\), all SUs transmit data in the conventional manner by a tendency of about 98\%, as depicted in Figure 3B. Therefore, both HBCT and JOTPA use the conventional method, and as a result, the end-to-end bit delivery by HBCT and JOTPA algorithms converges to each other, as shown in Figure 3A. It is worth noting that in the low power of PT, if all SUs utilize the backscatter method, the gap between HBCT and AB algorithms converges to zero in Figure 3A.

Figure 4A,B presents the average time allocated to each SU\(_k\) in HBCT and JOTPA for different amounts of PT power, respectively. As mentioned before, the amount of harvested energy by each SU\(_k\) depends on the power of PT and the amount of harvesting time. According to Equation (2), the amount of harvesting time for SU\(_1\) is \(\tau_0\). Since SU\(_1\) has the least harvesting time among all SUs, it suffers from less harvested energy. Hence, it prefers to utilize the backscatter method more than the other SUs. This event has been depicted in Figure 3B, in which SU\(_1\) has a greater tendency to transmit data in the backscatter manner, especially at the low powers of PT. According to Figure 4A, in the HBCT algorithm, SU\(_2\) and SU\(_3\) have a significant amount of time to harvest energy. The amount of time for harvesting energy by SU\(_2\) and SU\(_3\) are \(\tau_0 + \tau_1\) and \(\tau_0 + \tau_1 + \tau_2\), respectively. Such amounts of times are much greater than \(\tau_0\) in the low powers of PT. Therefore, SU\(_2\) and SU\(_3\) have a slight tendency to transmit data in the backscatter manner on average due to the availability of enough harvested energy. Note that when \(P_t = 10\ dB\), the amount of time allocated to the harvesting phase, that is, \(\tau_0\), converges to zero. This is because SU\(_1\) has a tendency of 100\% on average to utilize the backscatter method. Therefore, for \(P_t = 10\ dB\), we always have \(c_1 = 1\) (see Equation (30)). Hence, according to Equation (28), the amount of allocated time to the harvesting phase is always zero, that is, \(\tau_0 = 0\). As the power of PT increases, the tendency of SU\(_1\) to exploit the conventional method increases, as depicted in Figure 3B. Therefore, the harvesting time increases because the conventional method needs the harvesting phase. The interesting point is that the amount of \(\tau_0\) reaches its peak in some value of PT power which is \(P_t = 34\ dB\) in our scenario. For \(P_t > 34\ dB\), the amount of \(\tau_0\) is decreased. This is because the \(P_t\) is high enough; therefore, the system prefers to spend less time in the harvesting phase. Instead, the amount of time allocated to each SU\(_k\) for transmission data increases. The higher allocated time for transmission results in higher transmitted bits.

In order to elaborate on the behavior of SUs in JOTPA, we refer to Figure 4B. As depicted in Figure 4B, in comparison with Figure 4A, much amount of time in a frame is allocated to the energy harvesting phase in the JOTPA algorithm, especially in the low powers of PT. Since the amount of harvesting time, that is, \(\tau_0\), in the low powers of PT is relatively high, the SUs have little time to transmit data. This phenomenon can also be shown in Figure 3A, in which JOTPA presents low end-to-end bit delivery for low powers of PT. Nonetheless, the HBCT algorithm does not suffer from such a phenomenon. This can be seen in Figure 4A, in which the amount of time allocated to the SUs for transmitting data is significantly increased in the HBCT algorithm, especially in the low powers of PT, thanks to the backscatter communication method.

Figure 5 presents end-to-end bit delivery vs the number of hops in different algorithms. As shown in Figure 5, the proposed HBCT algorithm performs better than JOTPA and AB algorithms. As the number of hops increases, the end-to-end
bit delivery increases due to the better data channel gains between two consecutive hops. However, in this scenario, the multi-hop network reaches its peak at $K = 4$. For $K > 4$, the end-to-end bit delivery is decreased. This phenomenon occurs because as the number of hops increases, the time frame has to divide into more time-slots for more SUs. Therefore, each $SU_k$ has less amount of time to transmit data. The less amount of time for transmission results in less transmitted bits. In other words, for $K > 4$, the amount of transmitted time is dominant than the better data channel gains. If the number of hops is very large, the amount of allocated time to each $SU_k$ is very small. Hence, according to Equation (26), the transmitted bits converge to zero. It is important to note that the optimal amount of $K$ can be obtained by searching among the integer numbers since it cannot be calculated by a closed-form expression.

Figure 6 presents the performance of the network vs IPC. To explain Figure 6A, we use the results depicted in Figure 6B. As can be seen in Figure 6A, the HBCT algorithm performs better than JOTPA and AB algorithms in terms of end-to-end bit delivery vs different amounts of IPC. According to Figure 6A, for the low amount of IPC, that is, $I_p = -30$ dB, the HBCT performs as same as the AB algorithm. This phenomenon occurs because, in $I_p = -30$ dB, all SUs tend to utilize backscatter, as depicted in Figure 6B. In this condition, the IPC is stringent; therefore, SUs cannot utilize the conventional method. However, the JOTPA algorithm does not enjoy from backscatter method; hence, it cannot transmit data. For low amounts of IPC, that is, $I_p \leq -15$ dB, those $SU_k$s which are closer to PR have more tendency to utilize the

![Image of Figure 6](image-url)
backscatter method, as shown in Figure 6B. This event occurs because those SUk$s which are closer to the PR have better interference channel gain to the PR; therefore, they suffer from the IPC more than the other SUs. The backscatter usage tendency decreases as the $I_p$ increases due to the lower IPC. For $I_p > 0$ dB, the SU1 has a constant tendency of exploiting backscatter manner of about 10% on average, but SU2 and SU3 do not tend to transmit by backscatter method, as depicted in Figure 6B. In fact, in our scenario, for $I_p > 0$, the allocated power of each SUk which causes interference at PR is lower than the tolerable threshold. Besides, in our scenario, when $I_p > 0$, $\frac{\varphi_k}{\varphi_k^*} < \frac{I_p}{I_p^*}$. Hence, SUk selects $p_k^*$ as $\frac{\varphi_k}{\varphi_k^*}$ according to Equation (23). In this situation, $I_p$ does not affect the $p_k^*$; therefore, it does not affect the conventional rate. This means that the more increase in $I_p$ does not affect the tendency to utilize the backscatter method by SUs. It is important to point out that in other scenarios, such an explained situation will happen for some other intervals of $I_p$. This constant tendency to transmit data in the backscatter manner by SU1 results from critical harvesting time. However, SU2 and SU3 have enough time to harvest energy; therefore, they do not intend to use the backscatter method.

6 | CONCLUSION

In this article, we investigated a multi-hop network and proposed a novel algorithm named HBCT, in which the users in the network exploit both conventional and backscatter communication. Our proposed algorithm utilizes the primary spectrum to transmit data in a conventional cognitive radio manner and exploits the primary signals to harvest energy. The algorithm also uses primary signals as incident signals to backscatter data. More specifically, the proposed HBCT algorithm combines conventional and backscatter methods. In each circumstance, the algorithm uses one of such methods depending on which performs better. The source node should deliver data to the destination in a multi-hop manner. The numerical results revealed that the HBCT algorithm performs better than JOTPA and AB under various conditions. With HBCT, harvesting time decreases significantly; therefore, the SUs spend more time on data transmission.

APPENDIX A. PROOF OF LEMMA 1

First, we define $\Phi_k$ as

$$
\Phi_k = \log_2(1 + e_k \gamma_k).
$$

We know that $\Phi_k$ is a concave function of $e$. Hence, $\varphi_k W \log_2(1 + \frac{e_k}{\varphi_k} \gamma_k)$ is the perspective of $\Phi_k$. As the perspective operation preserves convexity, it is a concave function of $e_k$ and $\varphi_k$. Then, we can observe that $R_k(\tau_k, \varphi_k, e_k)$ is the pointwise minimum of $K$ concave functions, $R(\tau, \varphi, e)$ is a jointly concave function of $\tau$, $\varphi$, and $e$.

APPENDIX B. PROOF OF PROPOSITION 1

From (1), we can write

$$
\tau_k = T - \sum_{i \neq k} \tau_i - \tau',
$$

where $\tau'$ is the unused amount of time in each time block. Note that $\varphi_k = (1 - c_k)\tau_k$, $0 \leq c_k \leq 1$, which shows $\varphi_k$ and $\tau_k$ are dependent by parameter $c_k$. $c_k$ shows the portion of time in time slot $\tau_k$ which SU$_k$ spends in BackCom mode. By substituting this formula into Equation (15), we have the following equation.

$$
R_k(\tau_k, c_k, e_k) = (1 - c_k)\tau_k W \log_2 \left( 1 + \frac{e_k}{(1 - c_k)\tau_k} \gamma_k \right) + c_k \tau_k B_k^B.
$$

Later on, in Lemma 4, we will show that $c_k$ can be only 1 or 0. In both of these two cases, it is straightforward to show that $\frac{\partial R_k(\tau_k, c_k)}{\partial \tau_k} > 0$. Hence, $R_k$ is monotonically increasing with respect to $\tau_k$; thus, it is maximum when $\tau_k$ is maximum. Therefore, from (B1), $\tau_k$ is maximum when $\tau' = 0$. Subsequently

$$
\sum_{i=0}^{K} \tau_i = T,
$$

and the proof is completed.

APPENDIX C. PROOF OF LEMMA 2

Problem (21) is a convex optimization problem, and it is straightforward to show that it satisfies Slater’s condition. Therefore, Karush-Kuhn-Tucker (KKT) conditions must be established at the optimal point. That is

$$
\frac{\partial L'(\tau, \varphi, e, \mu, \xi, \nu)}{\partial y} = 0,
$$

where $y = \tau_0, \tau_k, \varphi_k, e_k, k = 1, \ldots, K$, to derive (C2), (C3), (C4), (C5), respectively.

$$
\zeta P_t \sum_{i=1}^{K} \mu_i h_i - \nu = 0,
$$

$$
\lambda_k B_k^B + \zeta P_t \sum_{i=k+1}^{K} \mu_i h_i - \nu + \xi_k = 0,
$$
where as stated in Lemma 2, $A_k = 1 + \frac{\xi_k}{\varphi_k}$. In the above equations, $A_k$ is unknown. Using Equations (C2) to (C5), it is straightforward to show that $A_k$ can be found from Equation (24). Having found $A_k$, $\frac{\xi_k}{\varphi_k}$ can be calculated as $\frac{A_k - 1}{r_k}$. Next, using the value of $\frac{\xi_k}{\varphi_k}$ and inequality (5), $p^*_k$ can be found from (23).

**APPENDIX D. PROOF OF LEMMA 3**

Equation (13) states that the allocated energy to each SU$_k$ should not exceed the amount of harvested energy. From (13), the harvesting time allocation $\tau_0$, when optimum value $e^*_1$ harvested by SU$_1$, must satisfy the following constraint:

$$\tau_0 \geq \frac{e^*_1}{\zeta P_1 h_1}.$$  \hspace{1cm} (D1)

On the other hand, from (26), it is obvious that $R_k$ is a descending function of $\tau_0$; therefore, $R_k$ is maximum when $\tau_0$ is minimum. Thus, from (D1), we can obtain the optimal value of $\tau_0$ as

$$\tau^*_0 = \frac{e^*_1}{\zeta P_1 h_1}.$$ \hspace{1cm} (D2)

Equation (D2) can be state as $e^*_1 = \zeta P_1 h_1 \tau^*_0$, which means that the allocated energy to SU$_1$ should be equal to the harvested energy by this node, and the proof is completed.

**APPENDIX E. PROOF OF LEMMA 4**

As mentioned next after Lemma 2, we have $p^*_1 = \frac{\varphi^*_1}{e^*_1}$. Further to that, $\varphi^*_1 = (1 - c^*_1) r^*_1$. Hence, we can write $e^*_1 = (1 - c^*_1) p^*_1 r^*_1$. By substituting $e^*_1$ in Equation (D2), we can calculate $r^*_0$ as (28).

Now, from Proposition 2, the end-to-end bit delivery is maximum if $R_1(\tau_1, \varphi_1, e_1) = R_2(\tau_2, \varphi_2, e_2) = \cdots = R_K(\tau_K, \varphi_K, e_K)$. On the other hand, from Equation (26), $R_k = \tau_k X_k$. Hence, $\tau_1 X_1 = \tau_k X_k, \ k = 2, \ldots, K$. The equation is also correct for the optimal values that is $\tau^*_1 X^*_1 = \tau^*_k X^*_k$. Thus, $\tau^*_1$ can be expressed as

$$\tau^*_1 = \frac{X^*_1}{X^*_1} \tau_k.$$ \hspace{1cm} (E1)

With substitute (E1) into (28), we can derive

$$\tau^*_0 = \frac{(1 - c^*_1) p^*_1 X^*_1}{\zeta P_1 h_1 X^*_1} \tau^*_1.$$ \hspace{1cm} (E2)

Now, with substituting (E2) into the optimal form of Equation (26), we can derive

$$\tau^*_k X^*_k = \frac{T - \frac{(1 - c^*_1) p^*_1 X^*_1}{\zeta P_1 h_1 X^*_1} \tau^*_1}{\sum_{i=1}^{K} \frac{1}{X^*_i}}.$$ \hspace{1cm} (E3)

From Equation (E3) and with some mathematical manipulation, we can find optimal time allocation as Equation (29).
Now, we want to find optimal amounts of $c_k$. By arranging Equation (29), we can obtain end-to-end bit delivery as

$$R_k = X_k \tau_k^* = \frac{T}{(1-c_1)p^*_1 \zeta P h_1 X_1} + \sum_{i=1}^{K} \frac{1}{X_i}.$$  \hspace{1cm} (E4)

The derivative of $R_k$ with respect to $c_1$ and $c_k$ is obtained as follows. Note that $X_k$ is related to $c_k$ as in Equation (27).

$$\frac{\partial R_k}{\partial c_1} = \frac{T (\frac{p^*_1}{\zeta P h_1}) (\frac{1}{\zeta P h_1} + \sum_{i=1}^{K} \frac{1}{X_i})^2}{(1-c_1)p^*_1 \zeta P h_1 X_1},$$

$$\frac{\partial R_k}{\partial c_k} = \frac{T (\frac{p^*_k-\Omega^*_k}{X_i^2}) (\frac{1}{\zeta P h_1} + \sum_{i=1}^{K} \frac{1}{X_i})^2}{(1-c_1)p^*_1 \zeta P h_1 X_1}, \quad i = 2, 3, \ldots, K.$$  \hspace{1cm} (E5)

(E6)

It is straightforward to see that, if $\Omega^*_1 < B^*_1 (1 + \frac{P^*_1}{\zeta P h_1})$, $R_k$ is an ascending function of $c_1$, if $\Omega^*_1 > B^*_1 (1 + \frac{P^*_1}{\zeta P h_1})$, $R_k$ is a descending function of $c_1$, if $\Omega^*_k < B^*_k$, $R_k$ is an ascending function of $c_k, k = 2, 3, \ldots, K$, and if $\Omega^*_k > B^*_k$, $R_k$ is a descending function of $c_k, k = 2, 3, \ldots, K$. Therefore, the maximum of $R_k$ is take place when $c_k$ is calculated as (30).

**APPENDIX F. PROOF OF LEMMA 5**

The maximum end-to-end bit delivery for the HBCT algorithm is represented as

$$R^*_H = X^*_k \tau^*_k = \frac{T}{(1-c^*_1)p^*_1 \zeta P h_1 X_1} + \sum_{i=1}^{K} \frac{1}{X_i}.$$  \hspace{1cm} (F1)

We define the vector of optimal variables for HBCT algorithm as $V^* = \{\tau^*_0, \tau^*_k, c^*_k \text{ and } p^*_k, k = 1, 2, \ldots, K\}$. By applying the same procedure to the JOTPA algorithm, we can find the maximum end-to-end bit delivery for the JOTPA algorithm as

$$\hat{R}_j = \frac{T}{\zeta P h_1 \hat{\Omega}_j} + \sum_{i=1}^{K} \frac{1}{\hat{\Omega}_i},$$  \hspace{1cm} (F2)

where notation "\{" represents optimum values of $\tau_0, \tau_k$ and $p_k, k = 1, 2, \ldots, K$ by which $R_j$ takes its maximum value. Here also we indicate optimum values by the set $\hat{V} = \{\hat{\tau}_0, \hat{\tau}_k, \text{and } \hat{P}_k, k = 1, 2, \ldots, K\}$.

First, we assume that the following inequality is correct for all values of PT power.

$$\hat{R}_j > R^*_H,$$  \hspace{1cm} (F3)

The inequality (F3) states that JOTPA performs better than the HBCT algorithm in terms of maximum end-to-end bit delivery, while $\hat{V}$ is the vector of optimal values used by JOTPA, and $V^*$ is the vector of optimal values used by HBCT. Now, we want to prove that this assumption cannot be correct. For this purpose, we replace the set of optimal values $V^*$ by $\hat{V}$ in Equation (F1), and set all $c_k = 0$. Therefore, we have the following equation.

$$\hat{R}_H = \frac{T}{\zeta P h_1 \hat{\Omega}_j} + \sum_{i=1}^{K} \frac{1}{\hat{\Omega}_i} = \hat{R}_j,$$  \hspace{1cm} (F4)

where $\hat{R}_H$ is the HBCT end-to-end bit delivery when the set of $\hat{V}$ values are used. It is important to note that the $R^*_H$, which is obtained by the set of $V^*$ values, is the maximum value, and those end-to-end bit delivery of HBCT which are obtained by setting all $c_k = 0$ are always less than or equal to such a maximum value, that is $R^*_H \geq \hat{R}_H$. Hence, regarding (F4), $R^*_H \geq \hat{R}_j$, which is in contrast with our first assumption of $\hat{R}_j > R^*_H$. This means that the first assumption that has
been made in (F3) is not true, and we can set HBCT in a way that performs better than JOTPA. All concludes that the proposed HBCT algorithm always performs better than or as same as the JOTPA algorithm.

Similarly, we assume that the AB algorithm performs better than HBCT.

\[ R_A > R_H. \]  
\[ (F5) \]

It is straightforward to show that end-to-end bit delivery for the AB algorithm can be found from the following equation.

\[ R_A = \frac{T}{\sum_{i=1}^{K} \frac{1}{p_i}}. \]  
\[ (F6) \]

In this case, we can set all SUs in the HBCT algorithm to work in backscatter mode by setting \( c_k = 1 \). In such a case, \( X_k = B_k^* \); thus, from (F1), we can write \( R_H \) as

\[ R_H = \frac{T}{\sum_{i=1}^{K} \frac{1}{p_i}}. \]  
\[ (F7) \]

It is worth noting that in this circumstance, according to (28), we can obtain \( \tau_0^* = 0 \). On the other hand, we have \( R_H^* \geq R_H \) for the optimum \( V^* \) values. Hence, from Equations (F6) and (F7), we can conclude that \( R_H^* \geq R_A \), which means that the assumption in (F5) cannot be true, and the HBCT algorithm always performs better than, or as same as AB.
