• Determination of Cr(III)+Cr(VI). To 25 mL of sample, add 0.3 mL of 8% PHP, adjust pH to 3.5, and add 3 mL of 10% APDC and 5 mL of PHP-saturated MIBK. Extract for 20 min. Determine Cr(III)+Cr(VI) in the MIBK layer.
• Determination of Cr(VI). Proceed as above except for the addition of 3 mL of 8% PHP and 3 mL of 2% APDC and for the extraction time of 10 min.
• Determination of Cr(III). The value of Cr(III) is obtained as the difference between Cr(III)+Cr(VI) and Cr(VI). The concentration of Cr(III) is also determined by the SM-7 ion exchange procedure [1].

In all the above cases, the Cr atomic absorption signal was measured by using the dry/atomize program of 900 °C-30 s (ramp)-30 s (hold)/2500 °C-0 s (ramp)-6 s (hold).

2. Sample Preparation
The six solid and two water matrices studied are listed in table 1. These were chosen so that results obtained could be compared to a reference value. The elements studied were arsenic, selenium, cadmium, and lead.

Table 1. Sample types
1. NBS Spinach
2. NBS Orchard Leaves
3. NBS Oyster Tissue
4. NBS River Sediment
5. EPA Sludge
6. Urban Particulate
7. Drinking Water
8. Wastewater

3. Instrumentation
Analysis was performed using a Perkin-Elmer Zeeman 5000 atomic absorption spectrophotometer equipped with an AS-40 auto-sampler and 3600 data station.\(^1\)

4. Analysis Protocol
The study was designed so that all three desired comparisons could be done from a single run by storing each atomization peak on a computer disk.

\(^1\) Disclaimer: Mention of trade names does not constitute endorsement by U.S. EPA.
Each sample matrix was injected in duplicate in the following manner:

Cup 1—Straight sample.
Cup 2—Sample diluted 50% with 0.5% HNO₃.
Cup 3—Sample diluted 50% with 20 µg/L standard.
Cup 4—Sample diluted 50% with 50 µg/L standard.

A computer program calculates peak height and peak area for each atomization peak so that the first injection for cup 1 was used for the direct calibration single injection for both peak height and peak area. The average value obtained from the first and second injections was used for the duplicate injection calculation. A separate least-squares linear fit program provided the MSA values from cups 2, 3, and 4. This protocol was repeated on three additional runs, usually on different days.

5. Results

All results were normalized to the appropriate percentage of the reference or theoretical values. The concentration in solution in µg/L is also shown. Thirteen of the 32 required dilutions varying from 1 to 2 to 1 to 200 to bring them on scale for HGA analysis. Table 2 shows the mean and standard deviation for each comparison.

Table 2. Mean and standard deviation for comparison.
6. Statistical Evaluation

6.1 Bias

Comparison of methods for bias (differences between the modes compared) was accomplished by pooling the mean recoveries of each method and using Student's t test in the form:

\[
t = \frac{\overline{d}}{s_d},
\]

where \( \overline{d} \) = average difference between each "method mean"
\( s_d \) = standard deviation of these differences
\( n \) = number of differences

If \( |t| > t_{0.05} \), i.e., 3.18 in the case of four replicates, then the means of the two methods are considered to be statistically significantly different.

6.2 Precision

Equality of pooled within-sample variance for the modes compared was tested using the F test in the form:

\[
F = \frac{s^2_{D}}{s^2_{M}}, \quad \text{where } s^2_{D} > s^2_{M}
\]

If \( F > F_{0.05} \), i.e., 15.4 in the case of four replicates, then there is a statistically significant difference between variances.

7. Discussion

7.1 Precision

There were no significant differences in variance for any of the comparisons as summarized in Table 3. Precision is not improved with peak area as compared to peak height or method of additions vs direct calibration.

Although not significant in this study possibly due to the small number of replications, we believe generally that precision is degraded in MSA analysis due to the multiple injections required. One of the primary objectives of this work was to investigate the value of duplicate injections. This practice is common in many, if not most, analytical laboratories. Duplicate injections essentially double the analysis time. If precision is not improved, then single injections would improve a laboratory's efficiency. This study indicated no significant improvement in precision. It has been our experience that poor precision is usually due to what we call "correctable problems." These include poor injection practices; improper furnace conditions; tube, platform, or contract ring conditions; inadequate background correction; or improper matrix modification. These and other such conditions should be corrected before continuing analysis. Duplicate injections do not correct these conditions. As a result of this work and discussions with other analysts, we have discontinued the practice of duplicate injections.

Table 3. Statistical evaluation

| Comparison            | As  | Se  | Cd  | Pb  |
|-----------------------|-----|-----|-----|-----|
| MSA vs DC             | 1.3 | 1.1 | 2.0 | 1.9 |
| Pk Ht vs Pk A         | 1.0 | 1.7 | 2.9 | 1.3 |
| Single vs Double      | 1.4 | 1.3 | 1.1 | 1.2 |

No statistically significant differences.

| Comparison            | As  | Se  | Cd  | Pb  |
|-----------------------|-----|-----|-----|-----|
| MSA vs DC             | 4.7*| 1.9 | 0.5 | 3.2*|
| Pk Ht vs Pk A         | 4.8*| 2.4 | 3.4*| 0.5 |
| Single vs Double      | 0.5 | 0.6 | 1.8 | 0.6 |

* Indicates statistically significant difference.

7.2 Bias

In the context of this study, bias is concerned with the agreement of the two modes compared. As was anticipated, direct calibration produced results that were generally lower than those by the method of additions. We have observed that interferences do sometimes tend to bias direct calibration results low. We have also noticed a high bias in the MSA results which we have not been able to explain.

For Se and Cd, the differences between direct calibration and MSA were not statistically significant. The 15% difference found for arsenic was significant. Both direct calibration and MSA gave only 26% recovery for sample type 5—the EPA Municipal Digested Sludge sample. We believe, as do other workers, that the true value may be less than that found by analysis [1]. Looking at the other seven sample types, the MSA mean recovery...
is 106% and the direct calibration is 88%, indicating that even though the MSA value is biased high, it is somewhat better than that resulting from direct calibration. The statistically significant difference found for lead is interesting in that the direct calibration results were somewhat better than the MSA results. The direct calibration averaged 96% recovery, and the MSA averaged 108%. Lead is a good example of the strides that have been made in eliminating interferences in graphite furnace. Only a few years ago, lead recoveries were often low. This was usually attributed to chloride interferences. Now accurate results may be obtained for lead even in hydrochloric acid.

Selenium analysis is a good example of how statistical evaluation may sometimes be misleading. The differences in precision and bias found between MSA and direct calibration were not statistically significant. However, the difference for the NBS oyster tissue was the largest of any observed, the recoveries being 86% for MSA and only 41% by direct calibration. Since selenium is often present in tissue at significant levels, accurate analysis is important. These results indicate that one would not want to attempt selenium analysis for tissue using these conditions by direct calibration.

This example demonstrates that, for complex and difficult matrices, more work needs to be done to remove interferences. For selenium and arsenic, perhaps palladium or a mixed palladium matrix modification may be the answer (see [2]). Although there are cases such as the above where the method of additions is required, we also believe that it is possible to overcome these interferences. For selenium and arsenic, perhaps palladium or a mixed palladium matrix modification may be the answer (see [2]). Although there are cases such as the above where the method of additions is required, we also believe that it is possible to overcome these interferences.

Errors introduced due to inappropriate spiking level and calibration error is discussed by Gaind and Odell [3]. They address the EPA contract lab "continuing calibration" criteria of ±10% and its effect on the probability of successful spike recovery. This probability is low and they believe the 10% limit is too wide.

8. Conclusion

We believe that the data from this study demonstrate that reliable analytical data can be achieved, whether these data are obtained from peak height or peak area, single or double injections, or direct calibration or the method of additions. Certainly, there are exceptions to every rule, but we believe that advances have made the interferences the exception. These advances include such things as improved background correction, delayed atomization, automatic injection, and matrix modification. We are approaching the "standardless graphite furnace analysis" proposed by Walter Slavin and co-workers [4]. In the absence of interferences, absolute calibration by a "characteristic mass" could be a powerful concept in accurate trace analysis.
