Catalytic N-radical cascade reaction of hydrazones by oxidative deprotonation electron transfer and TEMPO mediation

Xiao-Qiang Hu1, Xiaotian Qi2, Jia-Rong Chen1, Quan-Qing Zhao1, Qiang Wei1, Yu Lan2 & Wen-Jing Xiao1

Compared with the popularity of various C-centred radicals, the N-centred radicals remain largely unexplored in catalytic radical cascade reactions because of a lack of convenient methods for their generation. Known methods for their generation typically require the use of N-functionalized precursors or various toxic, potentially explosive or unstable radical initiators. Recently, visible-light photocatalysis has emerged as an attractive tool for the catalytic formation of N-centred radicals, but the pre-incorporation of a photolabile groups at the nitrogen atom largely limited the reaction scope. Here, we present a visible-light photocatalytic oxidative deprotonation electron transfer/2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO)-mediation strategy for catalytic N-radical cascade reaction of unsaturated hydrazones. This mild protocol provides a broadly applicable synthesis of 1,6-dihydropyradazines with complete regioselectivity and good yields. The 1,6-dihydropyradazines can be easily transformed into diazinium salts that showed promising in vitro antifungal activities against fungal pathogens. DFT calculations are conducted to explain the mechanism.
Synthetic chemists continuously strive for fast, selective and high yielding reactions under mild conditions. Radical reactions, especially the radical cascades, provide a potential access to such ideal transformations and have attracted considerable attention of synthetic community because of their typically mild conditions, short reaction times and high efficiency. Although various carbon radicals have been widely used in catalytic radical-based cascade reactions, the chemistry of N-centred radicals in this regard remains largely unexplored because of a lack of convenient and general methods for their generation. Known methods for their generation typically require the use of N-functionalized precursors or various toxic, potentially explosive or unstable radical initiators. Pioneered by Nicolaou’s discovery of the o-iodoxybenzoic acid-mediated conversion of N-aryl amides and carbamates into the corresponding nitrogen radicals, the groups of Chiba and Lei, respectively, developed two efficient methods for the generation of 1,3-diazaallyl and amidyl radicals by Cu- and Ni-catalyzed oxidative cleavage of N-H bonds of amides and N-alkoxamides using O2 and di-tertiary butyl peroxide as terminal oxidants at high temperatures. Recently, Li and Chemler also independently reported the Cu- and Ag-catalyzed oxidative formation of amidyl radicals in the presence of stoichiometric MnO2 and Selectfluor reagents as oxidants. Despite these impressive advancements, the search for new efficient protocols for direct catalytic conversion of the N–H bonds into the corresponding N-centred radicals under mild conditions has become an increasingly significant, yet challenging priority in the development of new N-radical cascade reactions.

In recent years, the visible-light photocatalysis has been established as a powerful technique that facilitates selectively activating organic molecules and chemical bonds to indentify new chemical reactions under mild conditions. As the notable early studies by MacMillan and Sanford on neutral N-centred radical-mediated photocatalytic C–H amination of aldehydes and (hetero)arenes, several promising visible-light photocatalytic protocols have been developed by other groups for generating N-centred radicals and C–N bond formation. Despite their advantages, these methods require the introduction of a photolabile substituent at the nitrogen atom as a handle for photo-activation. The use of the visible-light photocatalysis in initiating strong N–H bond activation and application in neutral N-centred radical-mediated catalytic cascade reactions have been, until recently, very limited. The Knowles’ group recently reported an elegant combination of iridium photocatalyst and phosphate base for a direct homolytic cleavage of strong N–H bonds of N-aryl amides to access amidyl radicals by a concerted proton-coupled electron transfer, which allowed an efficient radical cascade reaction towards N-heterocycle synthesis. Exploring new reactivity of N-containing compounds in the field of visible-light photocatalysis is an integral part of our recent ongoing research endeavours. For example, our group has recently developed a direct catalytic conversion of the N–H bonds of β,γ-unsaturated hydrazones into N-centred hydrazonyl radicals by visible-light-induced photoredox catalysis, which enables an efficient and mild approach to intramolecular alkene hydroamination and oxyamination for synthesis of 4,5-dihydroprazole derivatives. In this reaction, a highly regioselective 5-exo radical cyclization of an N-centred radical was observed. It should be noted that the groups of Han and Chiba have also independently reported stoichiometric amounts of tetramethylpiperidine-1-oxyl (TEMPO)-mediated intramolecular cyclization of hydrazonyl radicals for pyrazoline synthesis. Inspired by these studies, we considered exploration of the reactivity of hydrazones in catalytic N-radical cascade reactions to assemble biologically and synthetically important dihydroprazadine scaffolds, inaccessible using other thermal methods or our own previous protocols.

To this end, herein, we report an oxidative deprotonation electron transfer (ODET)/TEMPO-mediation strategy for direct N–H bond activation and catalytic N-radical cascade reactions of unsaturated hydrazones (Fig. 1b). This mild protocol represents the first, to our knowledge, broadly applicable synthesis of 1,6-dihydroprazadines with good regioselectivity and yield, achieved by merge of visible-light photocatalysis and TEMPO mediation.

**Results**

**Reaction design.** To realize the target catalytic N-radical cascade reaction of unsaturated hydrazones as shown in Fig. 1b, several

---

**Figure 1 | Reaction design.** (a) Visible-light-induced photocatalytic generation of N-centred radicals from N-functionalized precursors. (b) Our blueprint for catalytic N-radical cascade reaction of hydrazones: merge of oxidative deprotonation electron transfer (ODET) activation of N–H bond with TEMPO mediation.
major challenges would probably be encountered, such as the controlled formal homolysis of the recalcitrant N–H bond for the formation of the neutral N-centred hydrazone radical, regioselectivity of the N-radical cyclization step (for example, 6-endo and 5-exo, path a versus path b)\textsuperscript{3,34,35} and selective homolytic activation of aza-allylic C–H bond in C-centred radical intermediate. Notably, it has been recently documented by MacMillan\textsuperscript{36,37}, Knowles\textsuperscript{34,38,39} and our group\textsuperscript{37,40} that the addition of a suitable Bronsted acid, Lewis acid or base could facilitate some otherwise inaccessible photocatalytic event by weakening chemical bonds of reactants and co-catalysts or modulating their redox potential. It has also been demonstrated by López and Gómez that complete 6-endo-selectivity over 5-exo ring closure in radical cyclization of C-centred radicals can be controlled by the radical property, substitution pattern at C-5 or ring strain of substrate\textsuperscript{3,34,35}. Quite recently, the MacMillan group also first integrated elementary hydrogen atom transfer (HAT) process into H-bond catalysis, and achieved a highly selective photoredox α-alkylation/lactonization cascade of acids\textsuperscript{41}. Based on these inspiring studies, we hypothesized that the aforementioned regioselective N-radical cascade reaction could possibly be achieved by merging visible-light photoredox with TEMPO-mediated HAT process wherein the N–H bond might be directly converted into the corresponding N-centred hydrazone radical through an ODET and the aza-allylic C–H bond can probably be homolytically cleaved by a suitable H-atom acceptor such as TEMPO\textsuperscript{42}.

To test the feasibility of this strategy, we initially conducted density functional theory (DFT) calculations on the cyclization step of N-centred radical intermediates 1a-A, 1b-A and 1c-A with sterically and electronically diverse substituents at the 2-position of the alkene (Fig. 2a; see Supplementary Note 1–3 for details). The energies given in this work are N\textsubscript{12}-6/311+G(d, p)/B3 LYP/6-31G(d) calculated Gibbs free energies in chloroform. See the Supplementary Information for more computational details.\textsuperscript{43} As expected, both 5-exo and 6-endo N-radical-mediated radical cyclizations are possible pathways. For example, the study showed that the 5-exo-trig radical cyclization of 1a-A with an activation free energy of only 8.8 kcal mol\textsuperscript{-1} via 1a-TS1 is much more favoured than its 6-endo-trig variant (activation free energy of 13.5 kcal mol\textsuperscript{-1}; Fig. 1b). It was also found that 1b-A would undergo 5-exo cyclization through 1b-TS1 more feasibly than its 6-endo cyclization via 1b-TS2, as shown by their activation free energy (Fig. 1c, 7.5 versus 11.2 kcal mol\textsuperscript{-1}). Interestingly, the 6-endo cyclization of 1c-A with a phenyl group at the 2-position of the alkene moiety proved to be easier to accomplish through 1c-TS2, with a relatively low activation free energy of 8.7 kcal mol\textsuperscript{-1}, to give the C-centred radical intermediate 1c-C (Fig. 1d). Encouraged by these computational results, we proceeded to perform experimental studies with these substrates to explore the feasibility of the desired 6-endo radical cyclization.

Under our previously developed visible-light photocatalytic conditions for hydroamination of β,γ-unsaturated hydrazones\textsuperscript{28}, substrates 1a and 1b indeed underwent 5-exo radical cyclization reactions smoothly to give the corresponding products 2a and 2b in 68% and 81% yields, respectively (Fig. 3a). These results also provided a solid support for the above computational investigations into these substrates. Interestingly, the reaction of 1c resulted in the formation of a complex mixture with a complete conversion (Fig. 3b). Careful analysis of the reaction mixture revealed that an inseparable mixture of products 2c and 3 can be obtained in 21% yield with a ratio of 1:0.9. Meanwhile, product 4 was also isolated in 16% yield, which might be formed through another radical cascade reaction between 1c and the reaction solvent CHCl\textsubscript{3} via radical intermediate 1c-B. The structures of 2a-2c, 3 and 4 were fully characterized by their \textsuperscript{1}H and \textsuperscript{13}C NMR spectra and mass data, and compound 4 was further characterized by single-crystal X-ray analysis (see Supplementary Fig. 79 for details). Note that the biologically significant 1,6-dihydropyridazines of type 2c cannot be easily prepared using traditional methods\textsuperscript{43}. These observations suggested that further optimization of reaction parameters might result in the exclusive formation of the desired 1,6-dihydropyridazines.

**Optimization of reaction conditions.** Encouraged by these initial results, we continued to optimize the reaction conditions with 1c as a model substrate to further improve the selectivity and yield (Table 1). Inspired by the recently demonstrated wide applicability of nitroxides in organic synthesis and their unique properties\textsuperscript{44,45}, we initially focused on nitroxides as potential additives. Surprisingly, it was found that the addition of TEMPO (1.0 equiv.) did not quench the reaction; instead, it resulted in a clean reaction and gave the desired 1,6-dihydropyridazine 2c in 89% yield (entry 1). Based on our blueprint of the reaction, we postulated that TEMPO might serve as a H-atom acceptor to abstract aza-allylic H-atom by an HAT process\textsuperscript{41}. Then, we simply screened inorganic bases such as NaOH, Na\textsubscript{2}CO\textsubscript{3} and Na\textsubscript{2}HPO\textsubscript{4}, and established that the base also played an important role in the reaction, with K\textsubscript{2}CO\textsubscript{3} identified as the best choice (entries 2–4). With K\textsubscript{2}CO\textsubscript{3} as the base, we also briefly examined several other common solvents and CHCl\textsubscript{3} proved to be the best reaction media with tetrahydrofuran, MeOH, dimethylformamide and CH\textsubscript{2}CN giving relatively low yields (entries 5–8). Then, we evaluated the effect of photocatalysts on the reaction under otherwise identical conditions. Interestingly, the use of Ir(ppy)\textsubscript{3}(dbbbpy)PF\textsubscript{6} as a photocatalyst provided comparable results, whereas organic photocatalyst Eosin Y was ineffective for the reaction (entries 9–10). It has been well documented that TEMPO can serve not only as a radical scavenger but also as an oxidant in transition-metal catalysis\textsuperscript{44,45}. Thus, we continued to test several other oxidants, such as K\textsubscript{2}S\textsubscript{2}O\textsubscript{8} and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (see Supplementary Table 1 for details). However, all the reactions with these oxidants resulted in a complex mixture without formation of any desired product, suggesting that TEMPO might act as a radical trap to abstract the α-hydrogen atom from intermediate 1c-C to facilitate the target N-radical cascade reaction pathway (entries 11–12). In the control experiments with CH\textsubscript{2}Cl\textsubscript{2} or CH\textsubscript{3}CN as the solvent, only very little or no desired products were detected in the absence of photocatalyst, base, TEMPO or light; large amounts of starting materials remained intact, highlighting the critical role of all the parameters in the reaction (entries 13–16; see Supplementary Table 2 for details).

**Substrate scope.** Under the optimized conditions, we then evaluated the substrate scope of this transformation with a variety of β,γ-unsaturated hydrazones (Fig. 4). First, we examined the effects of arene substitution using a wide range of β,γ-unsaturated hydrazones 1c-1i. It was found that the reaction with various β,γ-unsaturated hydrazones bearing electron-neutral, electron-poor (for example, Cl, Br, CF\textsubscript{3}) or electron-rich (for example, Me) substituents at the 2-, 3- or 4-position of the aromatic ring proceeded well to deliver the corresponding products 2c-2i with yields ranging from 61 to 85%. Notably, those aryl bromides are aminable to further synthetic elaborations through transition-metal-catalyzed C–C coupling reactions. Product 2f was also characterized by single-crystal X-ray analysis (see Supplementary Fig. 79 for details). Moreover, 2-naphthyl substituted hydrazone 1j reacted well to afford product 2j in 86% yield. Considering the

known medicinal chemistry, it is noteworthy that various heterocycles can be incorporated into the hydrazone substrates with no apparent deleterious effect on the reaction efficiency. For example, 2-thiophenyl and 3-indolyl substituted hydrazones were tolerated well to give the desired products 2k and 2l in 59% and 53% yields, respectively. More importantly, the substrate scope of

afford the products standard conditions, although with prolonged reaction times, to can undergo the radical cascade reaction smoothly under

The current protocol can be successfully extended to aliphatic β,γ-unsaturated hydrazones. Thus, the reaction with a series of linear and branched aliphatic β,γ-unsaturated hydrazones 1m-1r can undergo the radical cascade reaction smoothly under standard conditions, although with prolonged reaction times, to afford the products 2m-2r in 63–83% yield. The β,γ-unsaturated hydrazone 1s bearing a styryl group also appeared to be viable for the reaction, producing a 70% yield of 2s. Remarkably, cyclic substituents, such as cyclopropyl, cyclopentyl and cyclohexyl groups, could also be easily incorporated into the 1,6-dihydropyridazine scaffold with high yields (2t-2v, 83–96%).

Encouraged by these results, we proceeded to examine the scope of alkene moieties by incorporation of various substituents into the phenyl ring. As highlighted in Fig. 4c, the substitution patterns and electronic properties of the aromatic ring showed no apparent effect on the reaction efficiency either. For example, all the electron-releasing (for example, 4-Me, 2-Me and 4-MeO) and electron-withdrawing (for example, 4-F, 4-Cl, 4-Br, 2,4-2Cl) groups were well tolerated under the standard conditions, furnishing the expected products 6a-6g in 51–81% yield.

Interestingly, during our subsequent biological studies with 1,6-dihydropyridazines 2- and 6-derived diazinium salts, it was found that such aromatic substituents at the 2-position of the alkene are critical to their antifungal in vitro activities. It should be noted that we did not detect any 5-exo cyclization products in all cases29,30.

Mechanistic investigations. To gain additional insights into the reaction mechanism, several control experiments were conducted with model substrate 1c (Fig. 5; see Supplementary Discussion for details). To further confirm the formation of C-centred intermediate of type 1c-C during the reaction, common radical trapping agents (PhSeSePh or 2,6-di-tert-butyl-4-methylphenol, BHT) were added to the reaction system to capture the radical intermediate (Fig. 5a). However, no trapping products were observed; instead, only the 1,6-dihydropyridazine 2c was produced and isolated in 85% and 83% yields, respectively. In contrast, without addition of TEMPO, the reaction with PhSeSePh as a radical trapping agent furnished a mixture of desired 2c and selenide-adduct 7 (61% yield, 1:4 ratio; see Supplementary Fig. 78).

Figure 4 | Reaction scope of unsaturated hydrazones. (a) Investigation of the effects of arene substitution of hydrazones. (b) Substrate scope of aliphatic unsaturated hydrazones. (c) Substrate scope of alkene moieties. Unless otherwise noted, reactions were run with 1 or 5 (0.3 mmol), Ru(bpy)3Cl2·6H2O (0.006 mmol, 2.0 mol%), K2CO3 (0.45 mmol), TEMPO (0.3 mmol) and CHCl3 (6.0 ml) at rt for 5–24 h under irradiation with 3 W blue light-emitting diodes (450–460 nm).
for details), and compound 7 should be formed from radical intermediate 1c-C and PhSeSePh (Fig. 5b). Then, we obtained the pure selenide-adduct 7 by semi-preparative high-performance liquid chromatography purification and re-subjected it to the standard reaction conditions without TEMPO (Fig. 5c). However, we did not detect any desired product 2c even after 24 h and compound 7 remained intact, suggesting that selenide-adduct 7 should not be the possible intermediate for the formation of 1,6-dihydropyridazine 2c.

To further determine the role of TEMPO, we also calculated the free energy of the subsequent transformation of C-centred radical intermediate 1c-C into the final product 2c via the minimum energy crossing point (MECP; Fig. 6)\textsuperscript{43}. As shown in Fig. 6a, the computational results showed that the TEMPO might facilitate the conversion of the intermediate 1c-C into the final product 2c through a TEMPO-mediated HAT process, because the calculated energy barrier ($\Delta E$) for the aza-allylic hydrogen atom abstraction via MECP-I is only 18.8 kcal mol$^{-1}$. Moreover,
the generation of product 2c is exergonic by 20.0 kcal mol$^{-1}$ compared with the intermediate 1c-C. Recently, a similar trapping of carbon radical and elimination of TEMPO-H process in the presence of base has been identified by Chiba’s group as the possible pathway in TEMPO-mediated C–H bond oxygenation of oximes and hydrazones. Inspired by this work, another possible pathway involving carbon radical trapping/elimination sequence of 1c-C in the presence of base was also considered in calculation. As shown in Fig. 6b, the combination of radical 1c-C with TEMPO occurs through MECP-II, and the energy barrier ($\Delta$E) of which is 18.4 kcal mol$^{-1}$. Although this energy barrier is close to that of MECP-I formation (Fig. 6a), the formation of TEMPO-adduct 8 is endergonic by 19.3 kcal mol$^{-1}$ compared with 1c-C. Moreover, the activation energy of subsequent deprotonation, which occurs via transition state 9-TS, reaches as high as 43.3 kcal mol$^{-1}$. According to these results, the sequential combination of carbon radical 1c-C with TEMPO and elimination process appears to be thermodynamically unfavourable. Moreover, we also intended to isolate the possible intermediate 8 upon ~50% conversion of model substrate 1c. Unfortunately, all the attempts met failure, although a trace amount of intermediate 8 was detected by the high-resolution mass spectrometry analysis of the the reaction mixture (see Supplementary Information). Another possible pathway for base-free elimination of TEMPO-H from 8 by direct radical elimination with C–O bond homolysis is not considered as the stoichiometric base is necessary in our reaction system. Taken together, although the calculation studies support the TEMPO-mediated HAT process as the likely mechanism for the transformation of C-centred radical intermediate 1c-C into the final product 2c, at present we cannot rule out the carbon radical recombination/elimination pathway (see Supplementary Figs 80 and 81 and Supplementary Notes 1-3 for details). More detailed mechanistic studies are currently underway in our laboratory.

According to our blueprint for ODET activation of N–H bond, the addition of K$_2$CO$_3$ proved to be critical for the reaction as a base and this phenomenon was indeed observed during the optimization study (Table 1, entry 14). To further evaluate the role of base in these reactions, we continue to study the mechanism of N-centred hydrazonyl radical formation by luminescence quenching experiments, NMR and electrochemical analysis with 1c as a model substrate (see Supplementary Figs 82–86 for details). Stern–Volmer analysis demonstrated that hydrazone 1c alone is unable to quench the excited state of [*Ru(bpy)$_3$]$^{2+}$ in dimethylformamide at 25°C, implying that the excited state ruthenium complex does not oxidize the hydrazone 1c directly. However, upon addition of K$_2$CO$_3$ as a base, a significant decrease of luminescence emission intensity was observed. In addition, the 1H NMR analysis of a solution containing both 1c and K$_2$CO$_3$ exhibited that the addition of K$_2$CO$_3$ resulted in complete disappearance of the signal of N–H, suggesting that K$_2$CO$_3$ serve to abstract the proton of N–H bond to generate nitrogen anion intermediate 1c’ (Fig. 7 and Supplementary Information). Moreover, cyclic voltammetry data confirmed that the excited photocatalyst [*Ru(bpy)$_3$]$^{2+}$ ($E_{1/2}$ = +0.77 V versus SCE in CH$_3$CN) is likely to be sufficiently oxidizing to oxidize the nitrogen anion 1c’ ($E_{1/2}^{red}$ = −0.56 V versus SCE) to generate the corresponding N-centred radical intermediate 1c-A (Fig. 7). Under these conditions, the key intermediate 1c-A undergoes a 6-endo radical cyclization to afford the C-centred benzylic radical intermediate 1c-C, which can be conveniently transformed into the final product 2c.

**Figure 7 | Proposed catalytic cycle.** The plausible mechanism involves oxidative deprotonation electron transfer (ODET) activation of N–H bond into N-centred radical by visible light photoredox catalysis and TEMPO-mediated N-radical cyclization.
product 2c by an HAT process in the presence of TEMPO (path c). However, as for the transformation of C-centred radical intermediate 1c-C into the final product 2c, at the current stage, we cannot rule out the carbon radical recombination/elimination pathway that involves TEMPO-adduct 8 as the key intermediate (path f, see Supplementary Information). In the absence of TEMPO, the intermediate 1c-C can abstract a hydrogen atom directly from CHCl₃ to give 1,4,5,6-tetrahydropyridazine 3.
derivatives, such as diazinium salts bearing a dihydroxyacetophenone core, showed promising biological activities against a variety of microorganisms (germs and fungi).

2. We further attempted to transform a range of representative pyridazines into the corresponding diazinium salts and preliminarily explored their potential structure–activity relationships. By refluxing a mixture of pyridazines and 2-chloro-3', 4'-dihydroxyacetophenone in acetonitrile for 12 hours, a series of diazinium salts were easily obtained in 63–85% yield after a simple filtration.

Synthetic application. To further demonstrate the synthetic potential of this method, a gram-scale reaction of β,γ-unsaturated hydrazide was conducted in the presence of 1 mol% of photocatalyst under standard reaction conditions, and the desired product was successfully obtained in 74% yield after 48 hours.

Moreover, the desired 1,6-dihydropyridazine was obtained in 67% overall yield. Recently, heteroaromatic N-oxides have been widely employed in transition-metal-catalyzed aromatic C–H activation/functionali zation reactions to access various valuable heterocyclic molecules. We found that the present method could provide a new approach to the synthesis of pyridazine N-oxides. For example, treatment of with m-CPBA as the oxidant resulted in the facile formation of pyridazine N-oxide in a 70% yield that was also clearly determined by X-ray analysis.

Moreover, it was then established that the 1,6-dihydropyridazine products can also be easily transformed into the corresponding biologically important pyridazines under mild conditions. A key benefit of this photocatalytic radical cyclization strategy is that the β,γ-unsaturated hydrazide starting materials are easily accessed from the corresponding β,γ-unsaturated ketones and tosyl hydrazine. Thus, we examined the photocatalytic radical cyclization with β,γ-unsaturated ketone and tosyl hydrazine in a two-step one-pot process.

Discussion

We have developed a novel ODE/T/HAT strategy, which we used to directly convert the N–H bond of β,γ-unsaturated hydrazones to the N-centred radical, and developed an efficient catalytic N-radical cascade reaction. This mild protocol represents the first, to our knowledge, broadly applicable synthesis of 1,6-dihydropyridazines with good regioselectivity and yield, achieved by the mere of visible-light photocatalysis and TEMPO mediation. The 1,6-dihydropyridazines could also be conveniently transformed into biologically important diazinium salts bearing dihydroxyacetophenone core, which showed promising antifungal in vitro activities against various fungal pathogens.

Control experiments and DFT calculations have been performed to help explain the mechanism. Owing to the wide occurrence of various N–H bonds, we believe that this strategy may find wide use for generation of other various N-centred radicals and new reaction developments with these reactive species.

Methods

Materials. Unless otherwise noted, materials were purchased from commercial suppliers and used without further purification. All the solvents were treated according to general methods. Flash column chromatography was performed using 200–300 mesh silica gel. The manipulations for photocatalytic N-centred radical reactions were carried out with standard Schlenk techniques under Ar by visible-light irradiation. See Supplementary Methods for experimental details.

General methods. 1H NMR spectra were recorded on 400 or 600 MHz spectrophotometers. Chemical shifts are reported in delta (δ) units in parts per million (p.p.m.) relative to the singlet (0 p.p.m.) for tetramethylsilane. Data are reported as follows: chemical shift, multiplicity (s = singlet, d = doublet, t = triplet, dd = doublet of doublets, m = multiplet), coupling constants (Hz) and integration.

13C NMR spectra were recorded on 100 or 150 MHz with complete proton-decoupling spectrophotometers (CDCl3: 77.0 p.p.m. or DMSO-d6: 39.5 p.p.m.).

19F NMR spectra were recorded on 376 MHz with complete proton-decoupling spectrophotometers. Mass spectra were measured on MS spectrometer (EI) or liquid chromatography–mass spectrometry (LC/MS), or electrospray ionization mass spectrometry (ESI–MS). High-resolution mass spectrometry was recorded on Bruker ultrafleXtreme matrix-assisted laser desorption/ionization–time-of-flight (TOF)/TOF mass spectrometer. 1H NMR, 13C NMR and 19F NMR spectra are supplied for all compounds: see Supplementary Figs 1–77.

General procedure for catalytic nitrogen radical cascade reaction of hydrazones.

In a flame-dried Schlenk tube under Ar, 1c (117.0 mg, 0.3 mmol), Ru(bpy)3Cl2·6H2O...
(0.006 mmol), TEMPO (46.9 mg, 0.3 mmol) and K2CO3 (61.2 mg, 0.45 mmol) were dissolved in CHCl3 (60.0 ml). Then, the resulting mixture was degassed via freeze-pump-thaw procedure (three times). After that, the solution was stirred at a distance of ~5 cm from a 3-W blue light-emitting diodes (450–460 nm) at room temperature ~5 h until the reaction was completed as monitored by thin-layer chromatography analysis. The crude product was purified by flash chromatography on silica gel (petroleum ether/ethyl acetate 20:1) directly to give the desired product in 90% yield as a white solid. Full experimental details and characterization of new compounds can be found in the Supplementary Methods.

Acknowledgements
We are grateful to the National Science Foundation of China (NO. 21272087, 21472058, 21472057 and 21232003), and the Youth Chen-Guang Project of Wuhan University (No. 2015070404010180). This work was also financially supported by the self-determined research funds of CCNU from the colleges' basic research and operation of MOE (No. CCNU15A02009). X.Q. and Y.L. are grateful to the National Science Foundation of China (NO. 21372266 and 51302327) for financial support. We also thank the anonymous referees for helpful suggestions.

Author contributions
X.-Q.H., J.-R.C., Q.-Q.Z. and Q.W. are responsible for the plan and implementation of the experimental work. X.Q. and Y.L. are responsible for the calculation study. J.-R.C. and W.-J.X. designed and guided this project and co-wrote the manuscript. All authors discussed the results and commented on the manuscript.
