Abstract—In fault-tolerant quantum computation and quantum error-correction one is interested on Pauli matrices that commute with a circuit/unitary. We provide a fast algorithm that decomposes any Clifford gate as a minimal product of Clifford transvections. The algorithm can be directly used for finding all Pauli matrices that commute with any given Clifford gate. To achieve this goal, we exploit the structure of the symplectic group with a novel graphical approach.

I. INTRODUCTION

The Clifford group is of central importance in quantum information and computation. This paper is primarily motivated by its importance in fault-tolerant quantum computation and quantum error-correction [11, 2]. Traditionally, the Clifford group is studied via its connection with the binary symplectic group [3] and the associated decompositions of the latter. The Bruhat decomposition of the symplectic group [4] gives a standard generating set made of qubit permutation [16], diagonal gates [17], and partial Hadamard gates [18]. Alternatively, the Clifford group can be studied via the transvection decomposition of the symplectic group, which we briefly describe in Section II. It is well-known [5, 6] that the symplectic group is generated by symplectic transvections [19]. Although these references give a constructive proof, the decomposition primarily relies on exhaustive search. In this paper we give a simple and fast algorithm that decomposes any symplectic matrix as a minimal product of symplectic transvections. On the other hand, the Clifford gates [20] correspond to symplectic transvections, and for this reason we will refer to them as Clifford transvections. By definition, Clifford transvections are sparse (in fact, they are the most sparse Cliifords other than Paulis and diagonal Cliifords), and given their simple conjugation action, they are also easy to implement. This yields directly a decomposition of any m-qubit Clifford gate as a minimal product of Clifford transvections.

We exploit the structure of symplectic matrices with a novel graphical approach. We associate to a symplectic matrix, written as a minimal product of transvections, a (binary, symmetric) Gram-type matrix [20] that captures the commutativity relations of the defining transvections. Viewed as an adjacency matrix, it yields a graph whose directed paths completely determine the given symplectic matrix; see Theorem 1. These directed paths can be counted with an invertible upper-triangular matrix [20], and this allows us to reduce the decomposition problem to a matrix triangulation problem over the binary field. For the latter we make use of the results of [7].

In [8], the authors studied the Clifford group via the support [4] of a unitary matrix. In that language, Clifford transvections are precisely those Cliifords that have a support of size two, which is smallest support among non-Pauli Cliifords. On top of being a useful algebraic tool, the support of a unitary encodes valuable information about the Paulis that commute with the given unitary. In [8] Prop. 9, the authors compute the support of standard Clifford gates [15-18]. The results of this paper provide a fast algorithm for computing the support of any Clifford gate. Heuristically, we expect our results to have applications in designing flag gadgets [9, 10] for stabilizer circuits.

II. PRELIMINARIES

A. The binary symplectic group

The binary symplectic group, denoted $\text{Sp}(2m;2)$, consists of $2m \times 2m$ matrices over the binary field $\mathbb{F}_2$ that preserve the symplectic inner product [1] under congruence. That is, $F \in \text{Sp}(2m;2)$ iff $\Omega F^T \Omega = \Omega$. Equivalently, symplectic matrices are precisely those matrices that preserve the symplectic inner product over $\mathbb{F}_2^m$:

$$\{ (a,b)| (c,d) \}_{s} = \text{ad}^T + bc^T = (a,b)\Omega(c,d)^T. \quad (2)$$

We will denote by $\text{GL}(n;2)$ and $\text{Sym}(n;2)$ the groups of $n \times n$ invertible and symmetric matrices over the binary field $\mathbb{F}_2$, respectively. A matrix $F = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \in \text{Sp}(2m;2)$ satisfies $F\Omega F^T = \Omega$, which in turn is equivalent with $AB^T, CD^T \in \text{Sym}(m;2)$ and $AD^T + BC^T = I_m$. In $\text{Sp}(2m;2)$ we distinguish two subgroups:

$$\mathcal{F}_D := \{ F_D(P) = \begin{bmatrix} P & 0_m \\ 0_m & P^T \end{bmatrix} \mid P \in \text{GL}(m;2) \}, \quad (3)$$

$$\mathcal{F}_U := \{ F_U(S) = \begin{bmatrix} I_m & S \\ 0_m & I_m \end{bmatrix} \mid S \in \text{Sym}(m;2) \}. \quad (4)$$

Above, $(\cdot)^T$ denotes the inverse transposed, and directly by definition we have $\mathcal{F}_D \cong \text{GL}(m;2)$ and $\mathcal{F}_U \cong \text{Sym}(m;2)$. Together with matrices

$$F_{\Omega}(r) = \begin{bmatrix} I_{m|-r} & I_{m|r} \\ I_{m|\bar{r}} & I_{m|-\bar{r}} \end{bmatrix}, \quad (5)$$

with $I_{m|\bar{r}}$ being the block matrix with $I_r$ in upper left corner and 0 elsewhere, and $I_{m|-\bar{r}} = I_{m} - I_{m|\bar{r}}$, these two groups are the building blocks of the Bruhat decomposition with many applications in quantum computation [4, 11]. A symplectic matrix $F \in \text{Sp}(2m;2)$ is said to be an involution if $F^2 = I_{2m}$ and is said to be hyperbolic if $(v|vF) = 0$ for all $v \in \mathbb{F}_2^m$.

It is straightforward to verify that a hyperbolic map is also an involution. We will denote

$$\text{Fix}(F) := \ker(I + F) := \{ v \in \mathbb{F}_2^m \mid v = vF \}, \quad (6)$$

$$\text{Res}(F) := \text{rs}(I + F) := \{ v + vF \mid v \in \mathbb{F}_2^m \}, \quad (7)$$
where \( \ker(\cdot) \) and \( \text{rs}(\cdot) \) denote the null space and the row space of a matrix, respectively. By definition, these spaces satisfy
\[
\dim \text{Res}(F) + \dim \text{Fix}(F) = 2m. \tag{8}
\]

Involution have the nice property that \( \text{Res}(F) \subseteq \text{Fix}(F) \). Additionally, for an involution we have \( \langle x | yF \rangle_s = \langle xF | y \rangle_s \), and thus \( \langle x + xF | y + yF \rangle_s = 0 \) for all \( x, y \in F_2^m \). This means that \( \text{Res}(F) \) is self-orthogonal (or self-dual if \( \dim \text{Res}(F) = m \) with respect to \( Z \).)

### B. The Heisenberg-Weyl group

The bit-flip and the phase-flip gates are given by
\[
X := \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad Z := \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, \tag{9}
\]
respectively. For vectors \( a, b \in F_2^n \) we will denote
\[
D(a, b) := X^a Z^b \cdots X^a Z^b. \tag{10}
\]

The Heisenberg-Weyl group is defined as
\[
\mathcal{H}_N := \{ e^i D(a, b) \mid a, b \in F_2^n, i \in \mathbb{Z}_4 \} \subseteq \mathcal{U}(N), \tag{11}
\]
where \( N = 2^m \). We will denote by \( \mathcal{P}\mathcal{H}_N := \mathcal{H}_N / \{ \pm I_N, \pm I_X \} \) the projective Heisenberg-Weyl group. Hermitian elements of \( \mathcal{H}_N \) are given (and denoted) by \( E(a, b) := i^{ab} D(a, b) \).

### C. The Clifford group

The Clifford group \( \text{Cliff}_N \) is defined to be the normalizer of \( \mathcal{H}_N \) in \( \mathcal{U}(N) \), that is,
\[
\text{Cliff}_N := \{ G \in \mathcal{U}(N) \mid G \mathcal{H}_N G^\dagger \subseteq \mathcal{H}_N \}. \tag{12}
\]

In order to obtain a finite group, \( \text{Cliff}_N \) is meant modulo \( \mathcal{U}(1) \).

Let \( \{ e_1, \ldots, e_{2^m} \} \) be the standard basis of \( F_2^n \), and consider \( G \in \text{Cliff}_N \). Let \( c_i \in F_2^{2^m} \) be such that
\[
GE(e_i)G^\dagger = \pm E(c_i). \tag{13}
\]

Then the matrix \( FG \) whose \( i \)th row is \( c_i \) is a symplectic matrix such that
\[
GE(c)G^\dagger = \pm E(cFG) \tag{14}
\]
for all \( c \in F_2^{2^m} \). We thus have a group homomorphism
\[
\Phi : \text{Cliff}_N \rightarrow \text{Sp}(2m; 2), \quad G \mapsto FG. \tag{15}
\]

In addition, \( \Phi \) is surjective with kernel \( \ker \Phi = \mathcal{P}\mathcal{H}_N \) \( \mathcal{U}(1) \), and thus \( \text{Cliff}_N / \mathcal{P}\mathcal{H}_N = \text{Sp}(2m; 2) \). It follows that \( \text{Cliff}_N \) is generated by preimages of symplectic matrices \( \mathcal{F}, \mathcal{H}, \mathcal{I} \). Here a preimage \( \Phi^{-1}(F) \) is meant up to \( \mathcal{H}_N \). These preimages are, respectively,
\[
G_D(P) := \langle v \rangle \mapsto |vP\rangle, \tag{16}
\]
\[
G_U(S) := \text{diag}(i^{\langle ySv \rangle_4} \mod 4)_{v \in F_2^m}, \tag{17}
\]
\[
\Omega(r) := (H_2)^{\otimes r} \otimes I_{2m-r}, \tag{18}
\]
where \( H_2 \) is the Hadamard gate.

Since \( \Phi \) is a homomorphism we have that \( \Phi(G^\dagger) = G_F^\dagger \). It follows that if \( G \in \text{Cliff}_N \) is Hermitian then \( G_F \) is a symplectic involution. Conversely, if \( F \) is a symplectic involution then \( G = \Phi^{-1}(F) \) satisfies \( G^2 \in \mathcal{H}_N \). As mentioned, a special class of involutions are the hyperbolic maps. If \( G \in \text{Cliff}_N \) corresponds to a hyperbolic \( F \in \text{Sp}(2m; 2) \) then \( \Phi \) implies that \( \mathcal{G}^\dagger \) commutes with \( E \) for all \( E \).

### III. Transvection Decomposition of Symplectic Matrices

A symplectic transvection is a symplectic map with one-dimensional residue space. It is easily seen that if \( \text{Res}(F) = \langle v \rangle \) then the matrix \( F \in \text{Sp}(2m; 2) \) must act as
\[
T_v := I + \Omega^T v, \quad x \mapsto x + \langle x | v \rangle v. \tag{19}
\]

We will call two transvections \( T_v, T_w \) independent if the defining \( v, w \) are independent. Otherwise, we will call the transvections dependent. Note also that \( T_v, T_w \) commute, that is, \( T_v \cdot T_w = T_w \cdot T_v \) iff \( \langle v | w \rangle = 0 \), that is, iff \( v, w \) are orthogonal (with respect to \( Z \) of course).

It is well-known that \( \text{Sp}(2m; 2) \) is generated by transvections. It is shown in \( \mathcal{F}, \mathcal{H} \) that a non-hyperbolic map \( F \) can be written as a product of \( r \) independent transvections \( T_{v_1}, \ldots, T_{v_r} \), where \( r = r(F) := \dim \text{Res}(F) = 2m - \dim \text{Fix}(F) \) and \( \text{Res}(F) = \langle v_1, \ldots, v_r \rangle \). The strategy of \( \mathcal{F} \) is to find \( v \) such that \( \langle x | xF \rangle_s = 1 \) (which exists for non-hyperbolic), and consider \( FT_{v}, v = x + xF \in \text{Res}(F) \), for which \( r(FT_v) = r(F) - 1 \). One then repeats the process accordingly until a one-dimensional residue space is reached.

The following result will enable us to restrict without loss of generality to non-hyperbolic maps.

**Lemma 1** \( \mathcal{F}, 2.1.8 \). Let \( F \in \text{Sp}(2m; 2) \) be hyperbolic. Then there exists \( v \in F_2^m \) such that \( FT_v \) is non-hyperbolic and \( \text{Res}(F) = \text{Res}(FT_v) \).

**Proof.** Fix any \( 0 \neq v = x + xF \in \text{Res}(F) \). Then any \( y \) such that \( \langle y | v \rangle_s = 1 = \langle yF | v \rangle_s \) (which of course exists) satisfies \( \langle y | yFT_v \rangle_s = 1 \), and thus \( FT_v \) is non-hyperbolic. Next, by the choice of \( v \), \( \text{Res}(FT_v) \subseteq \text{Res}(F) \) holds trivially, and equality is due to equal cardinalities.

It follows from Lemma 1 that a hyperbolic map \( F \) is a product of \( r + 1 \) transvections, \( r \) of which form a basis for \( \text{Res}(F) \), and the additional transvection is dependent of the first \( r \).

For involutions (hyperbolic or not) we have the following nicer result.

**Proposition 1.** Any involution is a product of commuting transvections. The converse is also true, that is, any product of commuting transvections yields and involution.

**Proof.** The result follows immediately by the fact that two transvections commute iff their defining vectors are orthogonal, along with the fact that the residue space of an involution is self-orthogonal.

### A. A Gram-type matrix

In this section \( F \) will be a generic symplectic matrix. We associate to a minimal transvection decomposition \( F = T_{v_1} \cdots T_{v_r} \), a Gram-type matrix
\[
A(v_1, \ldots, v_r) := \langle (v_i | v_j) \rangle_{i,j} = \mathbf{V} \mathbf{O} \mathbf{V}^T, \tag{20}
\]
where $V$ is the $r \times 2m$ matrix formed by stacking $v_1, \ldots, v_r$. Obviously, $A$ is symmetric and has zero diagonal. Since a minimal transvection decomposition is given by some basis of the residue space, we will assume that $v_i \in \text{Res}(F)$. Note that $A = 0$ iff $F$ is an involution iff $V$ is self-orthogonal. On the other hand,

\begin{align}
(v_i | v_j)_s &= (x_i + x_j F | x_j + x_j F)_s \\
&= (x_i F | x_j)_s + (x_i | x_j F)_s \\
&= x_i F \Omega x_j^T + x_j \Omega F^T x_j^T \\
&= x_i (F + F^T) \Omega x_j^T \\
&= (x_i (F + F^{-1}) | x_j)_s.
\end{align}

Obviously, $F$ is an involution iff $F = F^{-1}$, and thus $A$ also captures how far is $F$ from being an involution, or equivalently, how far is $V$ from being self-orthogonal. In what follows we will denote $A_u := \text{tri}u(A)$ the upper triangular part of $A$ and

$$B(v_1, \ldots, v_r) := \sum_{\ell=0}^{r-1} A_{u}^{\ell}.$$  

By definition, it follows that $B$ is upper triangular with all-ones diagonal for any symplectic $A$ and will be presented in future work.

As for the matrix $B$, By definition, it follows that

$$1 1 0 0 0 1 1 1 0 0 1 0$$

is upper triangular with all-zero diagonal. This yields $A_u = 0$, and thus

$$B = (I_r + A_u)^{-1} = I_r + B^{-1}.$$  

The matrices $A$ and $B$ have a natural graphical interpretation. Let us start with $A$, which can be thought as the adjacency matrix of the graph with vertices $v_i$ and edges $(v_i, v_j)$ iff $(v_i | v_j)_s = 1$. On the other hand, its upper triangular part $A_u$ can be thought as the adjacency matrix of the corresponding directed graph with edges $(v_i, v_j)$ iff $(v_i | v_j)_s = 1$ and $i < j$. As for the matrix $B$, note first that entry $(i, j)$ of $A_u$ counts directed paths from $v_i$ to $v_j$ of length $\ell$. Thus, entry $(i, j)$ (always for $i < j$) counts the number of directed paths from $v_i$ to $v_j$.

Before providing an example of the notions introduced, we point out that the matrix $B$ also captures the number of distinct transvection decompositions of a given symplectic matrix $F$. However, this treatment goes beyond the scope of this paper and will be presented in future work.

**Example 1.** Let us consider an example with $m = 5$ and $F = T_{v_1} T_{v_2} T_{v_3} T_{v_4} T_{v_5}$, where

$$V = \begin{bmatrix} v_1 \\ v_2 \\ v_3 \\ v_4 \\ v_5 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 1 & 0 \\ 1 & 1 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 & 1 & 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 & 1 \end{bmatrix},$$

Then one computes

$$A = \begin{bmatrix} 0 & 1 & 0 & 1 & 0 \\ 1 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 \\ 0 & 0 & 1 & 1 & 0 \end{bmatrix}$$

and $B = \begin{bmatrix} 1 & 1 & 1 & 3 & 4 \\ 0 & 1 & 1 & 2 & 3 \\ 0 & 0 & 0 & 1 & 2 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}$.

The graphical description of this scenario is given in Figure 1.

For instance, entry $b_{1,4} = 3$ and there are precisely three directed paths from $v_1$ to $v_4$, namely, $(v_1, v_3), (v_1, v_2, v_3)$, and $(v_1, v_2, v_3, v_4)$.

![Fig. 1. The directed graph with adjacency matrix $A_u$.](image)

**Theorem 1.** For any symplectic matrix $F = T_{v_1} \cdots T_{v_r}$ we have

$$F = I + \Omega V^T B V.$$  

As a consequence, if $F$ is an involution then $F = I + \Omega V^T V$.

**Proof.** By the definition of transvections, the action of $F$ on $x$ is given by some linear combination of $v_j$ added to $x$, that is

$$x F = x + \sum_{j=1}^{r} w_j v_j,$$

where $w_j$ depends on $(x | v_i)_s$ for $i < j$. We claim that $w_j = x \Omega V^T B_j$ where $B_j$ is the $j$th column of $B$. This in turn will complete the proof. In order to prove the claim, note that the input of $T_{v_j}$ is $x T_{v_1} \cdots T_{v_{j-1}}$. Thus $(x | v_i)_s$ contributes to $w_j$ only if $i < j$ and there is a directed path from $v_i$ to $v_j$, which could be of length $1 \leq \ell \leq j - i$. This information is precisely encoded by $B_j$.

To the best of our knowledge, Theorem 1 constitutes a novel structural result about symplectic matrices, and comparing it with [19], should come as no surprise. This structure is the main building block of what follows. Based on Theorem 1 it is imperative to consider the residue matrix

$$\tilde{F} := \Omega (I + F) = V^T B V = \sum_{i,j} b_{i,j} v_i^T v_j.$$  

The terminology comes from the obvious fact that $\text{rs}(\tilde{F}) = \text{Res}(F)$. Note that $\tilde{F}$ is symmetric iff $B = I$ (recall that $B$ is lower triangular) iff $F$ is an involution. Moreover, since $\tilde{F}^T$ has all-zero diagonal iff $\tilde{F}$ does, and since

$$x \tilde{F}^T x^T = x \Omega (I + F^T) x^T = x \Omega x^T + x \Omega F^T x^T = (x | x F)_s,$$

we conclude that $\tilde{F}$ has all-zero diagonal iff $F$ is hyperbolic.

In such case $F$ is also an involution, and thus $\tilde{F}$ is alternating (that is, symmetric and all-zero diagonal). It follows by Lemma 1 that we may restrict ourselves to non-hyperbolic maps, and thus we will assume that $\tilde{F}$ is not alternating.
B. Decomposition of Symplectic Involutions

In this subsection we will present a simple algorithm for the decomposition of (non-hyperbolic) symplectic involutions, and provide intuition for the much more delicate decomposition of general symplectic matrices.

**Theorem 2** (Transvection Decomposition of Involutions). Let $F$ be a non-hyperbolic involution, so that the residue matrix $F_i$ is non-alternating. Then there exists $P \in GL(2m; 2)$ such that $F = T_{v_1} \cdots T_{v_r}$, where $r = \dim \text{Res}(F)$ and $v_j$ is the $j$th row of $P F_i P^{-\top}$ for $1 \leq j \leq r$.

**Proof.** Let $R$ be the matrix of row operations that transforms $P F_i$ into Row-Reduced Echelon form. Let $E$ be the $r \times r$ upper left block of $R F_i R^{-\top}$, which is invertible by construction. It will also be symmetric and have non-zero diagonal since $F$ is non-hyperbolic involution. Then there exists $Q \in GL(r; 2)$ such that $Q E Q^{-\top} = I_r$; see [8, 2.1.14] for instance. Now put $P = \text{blkdiag}(Q, I_{2m-r}) R$. Then

$$P F_i P^{-\top} = \begin{bmatrix} I_r & 0 \\ 0 & 0 \end{bmatrix}.$$

We will consider the nonzero rows of $P F_i$, that is, $[ Q E Q^{-\top} 0 R^{-\top} ]$. For $1 \leq j \leq r$ let $w_j$ denote the $j$th row of $P F_i$, that is, $w_j = e_j P^{-\top}$, where $e_j \in \mathbb{R}^{2m}$ is the $j$th standard basis vector. Put $F' = T_{w_1} \cdots T_{w_r}$. Since $w_j$’s are linear combinations of $v_j$’s and since $F_i$ is a congruence for such a $F$, it follows that $A(w_1, \ldots, w_r) = A(v_1, \ldots, v_r) = 0$, and $B(w_1, \ldots, w_r) = B(v_1, \ldots, v_r) = I_r$. Then (30) yields

$$F = \sum_{j=1}^{r} w_j^\top w_j = \sum_{j=1}^{r} \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} e_j P^{-\top} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} P^{-\top} = F',$$

and thus $F = F'$.

The strength of Theorem [2] is that, as we will see, it can be generalized to non-involutions. The case of involutions can be dealt separately with an alternate approach, which, however, does not generalize to non-involutions. According to [13, Thm. 4.1], an involution $F$ is conjugate with an involution of form

$$F_U(S) \equiv \begin{bmatrix} 1 & S \\ 0 & 1 \end{bmatrix}, \quad S \in \text{Sym}(m; 2),$$

that is, there exists $M \in \text{Sp}(2m; 2)$ such that $M F M^{-1} = F_U(S)$. On the other hand, the involutions of form (34) are easy to decompose as described in [8, Prop. 9(2)]. So let us assume $F_U(S) = T_{v_1} \cdots T_{v_r}$. It is straightforward to verify that $T_{v_i} M = MT_{v_i} M$ holds for any symplectic $M$. This yields

$$F = M^{-1} F_U(S) M = (M^{-1} T_{v_1} M) \cdots (M^{-1} T_{v_r} M)$$

$$= T_{v_1} \cdots T_{v_r} M.$$  

and consider its residue matrix $F_i$, for which rank $(F_i) = r$. Thus, a transvection decomposition of $F$ is given by some basis of $\text{Res}(F) = \text{res}(F_i)$. The task in hand is how to find such basis. The main idea is to start with some fixed basis and transform it accordingly until we reach the desired result. We will start with a basis of $\text{Res}(F)$ in Row-Reduced Echelon form, that is, let $R$ be a matrix of row operations so that $R F_i = \begin{bmatrix} V \end{bmatrix}$, where $V$ is a $r \times 2m$ basis. This can be done, for instance, via Gauss Elimination over $\mathbb{F}_2$. Then

$$R F_i R^{-\top} = \begin{bmatrix} E \end{bmatrix}, \quad E \in GL(r; 2).$$

As mentioned, the basis $V$ may or may not constitute a transvection decomposition of $F$, and the idea is to consider other bases of form $Q V$ where $Q \in GL(r; 2)$. Let us denote $P = \text{blkdiag}(Q, I_{2m-r})$, and let $B = B(QV)$.

**Lemma 2.** With the same notation as above, the basis $Q V$ constitutes a transvection decomposition of $F$ if and only if $Q E Q^{-\top}$ is upper triangular.

**Proof.** Assume $Q V$ gives a transvection decomposition for $F$. Then, by (30), we have $F = (Q V)^\top \cdot B \cdot (Q V)$. But with the notation above we have $Q V = [ Q E Q^{-\top} 0 ] R^{-\top}$. Thus

$$F = V^\top Q^\top \cdot B \cdot Q V$$

$$= R^{-1} \begin{bmatrix} E^T Q^\top \\ 0 \end{bmatrix} \cdot B \cdot [ Q E Q^{-\top} 0 ] R^{-\top}$$

$$= R^{-1} \begin{bmatrix} E^T Q^\top \cdot B \cdot Q E Q^{-\top} \\ 0 \end{bmatrix} R^{-\top}.$$

It follows by (35) that $E = E^T Q^\top \cdot B \cdot Q E$ and thus $Q E Q^{-\top}$ is upper triangular. The reverse direction follows similarly.

**Lemma 3.** With the same notation as above, if $Q E Q^{-\top}$ is lower triangular, then $Q E Q^{-\top} = B^{-\top}$.

**Proof.** Assume $Q E Q^{-\top}$ is lower triangular and put $E' = E^T Q^\top \cdot B \cdot Q E$. Then

$$Q E Q^{-\top} = (Q E Q^{-\top})^\top \cdot B^{-\top} \cdot Q E' Q^{-\top}.$$  

If $Q E Q^{-\top} = I_r$, the statement is clear because in this case $F$ is symmetric, and therefore $B = I_r$. If $Q E Q^{-\top} = I_r$, then both $Q E Q^{-\top}$ and $(Q E Q^{-\top})^\top \cdot B$ have to be invertible and lower triangular. But $(Q E Q^{-\top})^\top \cdot B$ and $B$ are both invertible and upper triangular, meaning $(Q E Q^{-\top})^\top \cdot B$ is also upper triangular. Thus $(Q E Q^{-\top})^\top \cdot B = I_r$, and $Q E Q^{-\top} = B^{-\top}$.

It follows by Lemmas 2 and 3 that we are seeking for matrices $Q$ that triangularize $E$ from (35) by congruence. For more on triangularizations by congruence and related algorithms we refer the reader to [7]. It also follows by Lemma 2 that $F$ can be triangularized by congruence for any non-hyperbolic $F$ (since for this, one would only need a transvection decomposition of $F$, which we know it always exists). We resume everything to the following theorem.

**Theorem 3** (Transvection Decomposition of Symplectic Matrices). Let $F$ be a generic symplectic matrix. Then there exists
Algorithm 1 Transvection Decomposition of Clifford Gates

Input: A Clifford gate \( G \).

1. Compute \( F \) from (13).
2. Compute \( v, v_1, \ldots, v_r \) from Theorem 3.
3. \( G_0 = G_v \prod_{j \in V} G_{V_j} \).
4. Find \( E_0 = E(v_0) \) such that \( G = E_0 G_0 \).

Output: \( v_0, v_r \).

An algorithm that for any generic symplectic matrix \( F \) outputs a minimal transvection decomposition.

Proof. If the residue matrix \( \hat{F} \) is alternating, that is, if \( F \) is hyperbolic, then pick \( v \) as in Lemma 1 and update the input \( F \) with the non-hyperbolic \( FT_v \), while keeping the residue space intact. Next, perform Gauss Elimination on \( \hat{F} \) with \( R \) as in (38), and let \( Q \) be such that \( QEQ^T \) is lower triangular. Then, by Lemmas 2 and 3, the \( r \) non-zero rows of \( \text{blkdiag}(Q, I_{2m-r})R \hat{F} \), where \( r = \dim \text{Res}(F) \), along with \( v \), yield a minimal transvection decomposition for \( F \).

IV. DECOMPOSITION OF CLIFFORD GATES

In [8], the authors studied the Clifford hierarchy via the support of the underlying gates. Every gate \( U \in \mathbb{U}(N) \) can be written as

\[
U = \frac{1}{N} \sum_{v \in \mathbb{F}_2^m} \text{Tr}(E(v)U)E(v),
\]

and the support of \( U \) consist of the basis terms that appear in (43), that is,

\[
supp(U) = \{ \text{E}(v) \in \mathcal{H} \mathbb{V}_N \mid \text{Tr}(\text{E}(v)U) \neq 0 \}.
\]

Given the isomorphism \( E(v) \leftrightarrow v \), the support can be equivalently though of as a subspace of \( \mathbb{F}_2^{2m} \). On the other hand, (13) assigns \( F \in \text{Sp}(2m; 2) \) to a coset \( \mathcal{H} \mathbb{V}_N G = \Phi^{-1}(F) \) for any \( G \in \text{Cliff}_N \). It is straightforward to verify that the Clifford

\[
G_v := \frac{I_N + iE(v)}{\sqrt{2}} \in \text{Cliff}_N
\]

corresponds to the transvection \( T_v \). Then, since every symplectic is a product of transvections, it follows that

\[
G = E_0 \prod_{n=1}^{k} \frac{I_N + iE_n}{\sqrt{2}} = E_0 \sum_{\alpha \in \mathbb{C}} \alpha E_\alpha,
\]

where \( E_0 \in \mathcal{H} \mathbb{V}_N, S = (E_1, \ldots, E_k) \), and \( \alpha E \in \mathbb{C} \); see [8, Prop. 4]. From earlier discussion, it follows that the support of any \( G \in \Phi^{-1}(F) \) is given by \( \text{Res}(F) \) if \( F \) is non-hyperbolic, and by some subspace of \( \text{Res}(F) \) of index 2 otherwise. In [8, Prop. 9], the authors determined the support of the standard Clifford gates (16)-(18), while the general case remained open. The difficulty arose by the fact that the support of products is hard to compute. This problem can now be solved with the aid of Theorem 3 as resumed in Algorithm 1. It is also worth mentioning that in this process one may lose an eighth root of unity; see Example 3 for instance. We point out here that \( G \) is traceless iff \( E_0 \in S \). Thus the search in Step 4 of Algorithm 1 can be reduced to either outside \( S \) if \( G \) is traceless or in \( S \) otherwise.

Example 2. The Hadamard gate can be written as

\[
H_2 = \frac{1}{\sqrt{2}} (X + Z) = X \frac{I + iY}{\sqrt{2}},
\]

where \( Y = iZX \) as usual. Consider now the \( m \) fold transversal Hadamard gate \( H_N = (H_2)^{\otimes m} \), for which \( \Phi(H_N) = \Omega \).

Additionally \( \Omega = \frac{1}{2} \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix} \) and \( \dim \text{Res}(\Omega) = m \). Then

\[
P = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}
\]

triangulizes \( \Omega \).

The first \( m \) non-zero rows of \( \mathbb{P} \Omega \) are \( \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix} \). We see that the \( n \)th row yields the gate \( Y_n \) with \( Y \) in qubit \( n \) and identity elsewhere. From Step 3. of Algorithm 1 we compute

\[
G_0 = \prod_{n=1}^{m} \begin{bmatrix} I_N + iY_n \\ 0 \end{bmatrix}.
\]

We then find \( H_N = X^{\otimes m} G_0 \). A similar result holds for partial Hadamard gates \( H^{\otimes r} \otimes I_{2m-r} \), to which correspond symplectics of form (5), see also [8, Prop. 9(3)].

Example 3. The symplectic and residue matrices corresponding to the CNOT gate are given by

\[
F = \begin{bmatrix} 1 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}
\]

and \( \hat{F} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \).

From which we see that \( \hat{F} \) is alternating, and thus \( F \) is hyperbolic. So first, we transform \( F \) to a non-hyperbolic map by using the first non-zero row of \( \hat{F} \), that is, \( v = 0010 \). Then we update \( F \leftarrow FT_v \), for which

\[
F = \begin{bmatrix} 1 & 1 & 1 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{bmatrix}
\]

and \( \hat{F} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \).

A matrix that triangulizes \( \hat{F} \) is given by

\[
P = \begin{bmatrix} 1 & 1 & 1 & 0 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}.
\]

The non-zero rows of \( \mathbb{P} \hat{F} \) are \( v_1 = 0100, v_2 = 0110 \). Note that \( v = v_1 + v_2 \), and \( \{v_1 \mid v_2\} = 0 \) as in Proposition 1. Then we compute

\[
G_0 = \left( I + iX \right) \left( I - iZ \right) \left( I + iZ \right) \sqrt{S}
\]

and then we end with the observation that \( \text{CNOT} = \xi G_0 \), where \( \xi = (1 - i)/\sqrt{2} \) is an eighth root of unity.
