It has recently been suggested that two counter-propagating, circularly polarized, ultra-intense lasers can induce a strong electron spin polarization at the magnetic node of the electromagnetic field that they setup. We confirm these results by considering a more sophisticated description that integrates over realistic trajectories. The electron dynamics is weakly affected by the variation of power radiated due to the spin polarization. The degree of spin polarization differs by approximately 5% if considering electrons initially at rest or already in a circular orbit. The instability of trajectories at the magnetic node induces a spin precession associated with the electron migration that establishes an upper temporal limit to the polarization of the electron population of about one laser period.

I. INTRODUCTION

Since the application of chirped pulse amplification to optical laser pulses (2), laser intensities have increased dramatically, surpassing $10^{22}$ W/cm$^2$ (3). The increase in the electromagnetic fields in the laser focus, resulting from the increase in laser intensity, has enabled the investigation of new regimes in laser-produced plasmas. For example, as laser intensities increased beyond $10^{19}$ W/cm$^2$, plasma electrons became relativistic (4–5), paving the way to new applications, such as laser driven particle acceleration (6–9).

Several facilities being constructed as part of the Extreme Light Infrastructure project (ELI) (10) aim to surpass a new laser intensity threshold ($I \geq 5 \times 10^{23}$ W/cm$^2$). At this intensity, strong-field quantum-electrodynamics (QED) effects (11–12) are expected to play an important role in the collective plasma dynamics (13–15). This new regime – so called QED plasma – is inferred to exist also in extreme astrophysical environments, such as the pulsar magnetosphere (16) and the black hole dyadosphere (17).

The important QED effects, expected to play a major role in laser-created QED plasmas, are (13–21): (i) incoherent emission of MeV energy gamma-ray photons by electrons and positrons on acceleration by the macroscopic electromagnetic fields in the plasma (strongly non-linear Compton scattering), with the resulting radiation-reaction (RR) strongly modifying the dynamics of the emitting electron or positron (22–23); (ii) pair creation by the emitted gamma-ray photons, in the macroscopic electromagnetic fields (the multi-photon Breit-Wheeler process (24)). Moreover, processes involving other particles such as muons and pions, but also more exotic particles like axions may appear as well (19–25).

The first steps toward experimental tests of the existing theory (22–27) of quantum RR have been recently performed (28–30) but the role of the fermion spin has received relatively little investigation (11–31–36). While radiating gamma-rays via non-linear Compton scattering, electrons may undergo spin-flip transitions. It is well known that for an electron orbiting in a constant magnetic field, spin-flip transitions where the final projection of the spin onto the axis defined by the magnetic field is antiparallel to the magnetic field are more energetically favorable than the reverse (37). Furthermore, it has been recently shown that the same is true for an electron orbiting with normalized velocity $\beta$ in a rotating electric field $E$, where the vector $E \times \beta$ plays the same role as the magnetic field $\vec{B}$. The latter case is potentially experimentally realizable at the magnetic node of the standing wave formed by two counter-propagating circularly-polarized laser pulses. By considering highly idealized stationary orbits, it has been shown that electrons at the magnetic node should rapidly spin polarize. Similar spin flip transitions can occur when energetic electrons radiate in the strong atomic fields as they pass down the axis of a crystal lattice. It has been shown that spin flip transitions, at the expected rate, are required to reproduce the emitted gamma-ray spectrum measured experimentally (38).

In this article we confirm the predictions of Ref. (1), considering a more detailed description of time-dependent trajectories, obtained by the numerical integration of the electron equations of motion, coupled to the equations that describe the spin dynamics. The influence of different parameters such as the RR force, the initial phase space configuration and the effect of electron migration away from the magnetic node, which is an unconditionally unstable point, are analyzed.

The article is organized as follows. In Sec. (1) the dynamics of spin polarized electrons is described, detailing the equations that have to be numerically solved in order to track the electron trajectory, the spin polarization direction and the probability of spin polarization. In Sec. (11) the influence of electron trajectory on the degree of spin polarization is investigated, considering the effects of the RR force and the effects of the instability of trajectories at the magnetic node. In Sec. (14) the derived results and their implications are discussed. Finally, in
This form of RR gives a good approximation to the average energy loss by an ensemble of electrons [27, 45]. Another quantum aspect of radiation is that during emission of a gamma-ray photon the electron’s spin may flip. To describe the evolution of the electron’s spin, we consider the spin expectation value vector $S$.

The classical evolution of $S$ can be described by the Bargmann-Michel-Telegdi (BMT) equation [46, 47]
population of electrons are no longer possible) and, consequently, the Gaunt factor. Here we fit the spin dependent Gaunt factor \(g^s(\eta)\) for \(s = \pm 1\) as

\[
g^s(\eta) \approx \left[ 1 + 2.54(\eta^2 - 1.28\eta) 
+ (4.34 + 2.58\eta)(1 + \eta) \ln(1 + (1.98 + 0.11s)\eta) \right]^{-2/3},
\]

which in the case where \(s = 0\) gives a more precise fit of the spin-independent Gaunt factor to that given in equation (6). We may therefore include the effect of spin in the RR force as

\[
F_{RR} = -\frac{[P^x g^x(\eta) + P^y g^y(\eta)] \mathbf{p} \cdot \mathbf{p}}{\|\mathbf{p}\|}, \quad \text{(10)}
\]

This description of spin dynamics relies on the existence of a globally non-precessing spin basis and, therefore, is limited to particular field configurations. In more general electromagnetic field configurations it is usually not possible to identify a globally non-precessing spin basis and there is as yet no way to describe the spin dynamics during multiple photon emissions.

In this article, we focus on a particular laser configuration\(^2\): counter-propagating, circularly polarized plane-waves which produce a standing wave of the form

\[
E = \frac{a_0 m_e c \omega}{e} \begin{pmatrix} \cos(kz) \cos(\omega t) \\
\cos(kz) \sin(\omega t) \\
0 \\
\end{pmatrix},
\]

\[
B = \frac{a_0 m_e c \omega}{e} \begin{pmatrix} \sin(kz) \cos(\omega t) \\
\sin(kz) \sin(\omega t) \\
0 \\
\end{pmatrix},
\]

where the electromagnetic waves propagate parallel and antiparallel to the z-direction, \(\omega = 2\pi c/\lambda\) is the laser frequency, \(k = \omega/c\) is the magnitude of the laser wavevector and \(a_0 \approx 85.5\lambda/\mu m\sqrt{I/(10^{22} \text{ W/cm}^2)}\) is the laser’s strength parameter, (where \(I\) and \(\lambda\) are the intensity and wavelength of each laser and equal in this case). Typically, for high intensity lasers, \(\lambda \approx 1 \mu m\) and the laser period is \(T = \lambda/c \approx 3.33\ \text{fs}\).

In the plane of the magnetic nodes, i.e. where \(kz\) is an integer multiple of \(2\pi\), the electromagnetic fields given in Eq. (11) reduce to a rotating electric field. In this particular plane, the spin polarization direction (non-precessing spin basis) is \(\mathbf{\zeta} = \mathbf{E} \times \mathbf{\beta}/\|\mathbf{E} \times \mathbf{\beta}\| = \mathbf{e}_z\), where \(\mathbf{e}_z = (0, 0, 1)^T\). We are going to show that electrons tend to spin polarize antiparallel to \(\mathbf{\zeta}\), as shown schematically in Fig. 1. Outside the magnetic node plane, it is not possible to identify a non-precessing spin basis. Therefore, beyond the magnetic node plane it is not possible to perform any prediction of electron spin polarization using the current model.

The standing wave set up by two counter-propagating circularly polarized lasers is a configuration favorable for the observation of strong-field QED effects\(^13\)\(^,\)\(^43\)\(^,\)\(^53\)\(^,\)\(^54\). Moreover, it is a simple case because there exists a globally non-precessing spin basis.

**III. REALISTIC TRAJECTORIES & SPIN POLARIZATION**

We have numerically solved Eq. (11) in order to track the electron trajectory in the particular laser configuration considered (the magnetic node of two circularly polarized counter-propagating lasers). As the electron moves along its trajectory, we estimate its spin polarization probability, by solving Eq. (8).

The solution of Eq. (11) is performed using different definitions of the RR force. We will refer to the ‘noRR’ trajectory as the solution of Eq. (11) with \(F_{RR} = 0\), the ‘RR’ trajectory as that when \(F_{RR}\) is be provided by Eq. (5) and the ‘SRR’ trajectory when the equation of motion is Eq. (10).

We will also consider three different field strengths: \(a_0 = 200, 600 & 2000\), corresponding to laser intensities \(I \approx 5 \times 10^{22}, 5 \times 10^{23} & 5 \times 10^{24}\ \text{W/cm}^2\) for each beam, assuming \(1 \mu m\) wavelength. For these intensities, the scaling laws in Ref. (1) predict the degrees of spin polarization antiparallel to \(\mathbf{\zeta}\) of: \(\lesssim 10, \sim 50 \& \gtrsim 70\%\) respectively.

Finally we will study the robustness of the spin polarization when accounting for the instability of an electron trajectory initially displaced from the magnetic node in

---

\(^2\) In Ref. (52), a correction for gamma-ray emission rates in the rotating electric field configuration was proposed. However, the latter is derived for scalar fields (spin-0 electrons) and does not apply to ultra-relativistic particles, as considered in this article.
the z-direction.

### A. Influence of radiation-reaction on the electron orbits

Let us consider an electron initially at rest at the position \( x = (0, 0, 0) \), subject to the electromagnetic field in Eq. (11), with \( \alpha_0 = 600 \). This laser field can be obtained from counter-propagating 1 \( \mu \)m wavelength laser pulses, each of intensity \( I \approx 5 \times 10^{23} \text{ W/cm}^2 \).

Figure 2a shows the electron noRR, RR and SRR trajectories in the magnetic node plane. As the laser accelerates the electron from rest, it very rapidly achieves ultra-relativistic velocity. Since the electric field is entirely in the \( xy \) plane, no drift outside magnetic node is induced. In the noRR trajectory, the electron dynamics is characterized by a secular drift in the \( y \) direction. On the contrary, when the electron energy loss due to radiation emission is considered (RR and SRR trajectories), the radiative losses due to gamma-ray emissions rapidly (in one laser period) balance the Lorentz acceleration, settling the electron in a circular orbit. The effect of electron spin polarization on the trajectory, i.e. the difference between the RR and SRR trajectories, is small.

The noRR trajectory is characterized by impulses at each half-period that are responsible for the secular drift. This can be seen more clearly in Figs. 2b and 2c that show \( \gamma \) and \( \eta \) as functions of time, for the different trajectories. At each impulse, the kinetic energy \( \left( x \gamma \right) \) reaches its maximum before decreasing. Consequently, \( \eta \) oscillates between 0 and 1.8. When \( \eta \) is comparable to or greater than one, spin flip induced by gamma-ray emission becomes more likely and the probability of spin polarization increases more rapidly. As is shown in Fig. 2d, which shows the time evolution of \( \Delta P^\parallel \), where

\[
\Delta P^\parallel = P^\parallel - P^\parallel_0. \tag{12}
\]

In the case of the RR and SRR trajectories a steady state is reached rapidly where \( \gamma \) and \( \eta \) stabilize to constant values with consequences on the particle degree of spin polarization antiparallel to \( \zeta \). Fig. 2e shows that in these cases \( \Delta P^\parallel \) increases steadily, in contrast to the noRR case that alternates rapidly increases and then plateaus due to the oscillation in \( \eta \). Despite the fact that RR and SRR trajectories are characterized by a lower \( \eta \) than the maximum reached in the noRR trajectory, they reach higher spin polarization \( \Delta P^\parallel \) after little more than half of the laser period, due to the steady increase in the RR and SRR cases. Note that, if we had considered a different initial condition, such as \( \gamma \beta_y = \alpha_0 \), then the secular drift would also have been absent in the noRR case, suppressing the oscillation in \( \eta \). In this case we may expect the noRR case to reach higher \( \Delta P^\parallel \) than the RR and SRR cases.

Differences between the RR and SRR predictions of the trajectory, \( \gamma \), \( \eta \) and \( \Delta P^\parallel \) never exceed 5\% and are therefore neglected here. We conclude that the RR description of particle dynamics is sufficient and we need not consider spin effects on RR in the cases considered here. For this reason, in the rest of the article we will always solve RR trajectories only, no longer considering SRR trajectories.

### B. Field strength & initial velocity conditions

The probability of electron spin polarization in the orbits considered here is dependent on two parameters: the time and the field strength \( \alpha_0 \). As the electron radiates, the degree of spin polarization increases in time, reaching an asymptotic value after a time which we will call the polarization time. As the field strength increases, both the asymptotic spin polarization and the polarization time decrease. In Ref. 11, the the spin polarization time was estimated for particles initially in circular orbits. Here we consider an electron initially at rest.

Three characteristic laser intensities are discussed in this section: \( \alpha_0 = 200 \) corresponds to the laser intensities expected to be accessible in the near term (two 1 \( \mu \)m wavelength lasers with \( I \approx 5 \times 10^{22} \text{ W/cm}^2 \)); \( \alpha_0 = 600 \), corresponding to the laser intensity which should be readily achievable with ELI 13; \( \alpha_0 = 2000 \), corresponding to \( I \approx 5 \times 10^{24} \text{ W/cm}^2 \).

The RR spatial trajectory of electrons initially at rest and subject to the field strengths \( \alpha_0 = 200, 600 \) and 2000 are shown in Fig. 3a. The trajectory for \( \alpha_0 = 600 \) has already been discussed in Sec. IIIA. For \( \alpha_0 = 200 \), the electron dynamics is characterized by weak radiation emission. For this reason the electron does not settle into the circular orbit in the time considered, after which it is still drifting in the \( y \) direction (although the drift velocity is decreasing in time). On the contrary, for \( \alpha_0 = 2000 \), the RR force is very strong and sufficient to settle the electron in the circular orbit in less than half a period.

In Ref. 11 predictions of the spin polarization were made for the three cases described here, with the electrons settled in the circular orbit from the outset. In figure 3b we compare the degree of spin polarization for these predictions to the case where the electron starts at rest, i.e. the three trajectories considered in figure 3a. For \( \alpha_0 = 200 \), the degree of spin polarization antiparallel to \( \zeta \) is small (\( \Delta P^\parallel \leq 20\% \)) because \( \eta \) is small (\( \eta < 0.18 \)). Therefore the probability of emission and therefore spin flip is reduced. In the case of electrons initially in the circular orbit, \( \Delta P^\parallel \) increases linearly with time as the time-scale considered is much shorter than the time for the spin polarization to saturate -- the polarization time. If the electron is initially at rest, the growth of \( \Delta P^\parallel \) is characterized by the alternation of relatively rapid growth and then a plateau due to the periodicity in \( \eta \) caused by the drift in the \( y \)-direction, as shown in Sec. IIIA. Nevertheless the difference in \( \Delta P^\parallel \) between the cases where the electron is initially in the circular orbit and where it starts from rest is small.
FIG. 2. (a) Electron spatial trajectory in the magnetic node plane. (b) Its Lorentz factor, (c) non-linear quantum parameter and (d) degree of spin polarization antiparallel as functions of the time (normalized to the laser period). Three trajectories are compared: noRR (in green) RR (in red) and SRR (in blue), for $a_0 = 600$. The legend is shared among the four figures.

FIG. 3. Spatial trajectory (a) and relative degree of spin polarization antiparallel (b) for electrons at the magnetic node of two counter-propagating laser fields with $a_0 = 200, 600 & 2000$. Continuous lines refer to electrons initially at rest and dashed lines to electrons settled in the circular trajectory from the outset. The legend is shared among the figures and the simulation time is $4T$.

For $a_0 = 600$, $\Delta P^\downarrow$ increases linearly for approximately $0.5T$ and then begins to saturate as the polarization time (which is shorter for $a_0 = 600$ than for $a_0 = 200$) is approached. For this laser intensity, the difference in $\Delta P^\downarrow$ between electrons initially at rest and those initially in the circular orbit is small and decreases in time. The difference is due to the fact the the electron initially settled in the circular orbit is initially more energetic than the electron initially at rest, so it has a higher probability of radiating and therefore of spin flip. For $a_0 = 2000$, after one laser period, $\Delta P^\downarrow$ reaches its asymptotic value. The electron initially at rest very quickly reaches the circular orbit and therefore, differences between electrons initially at rest or already in their circular trajectory are even smaller than in the case with $a_0 = 600$.

In this section we have shown that the spin polariza-
FIG. 4. Spin precession time as a function of the electron initial position (off the magnetic node $z = 0$). As color-plot, also the degree of spin polarization as a function of time is shown. Each point represents a different simulation.

C. Trajectory instability & spin precession

At present, we do not have a good model to describe the spin flips (radiative polarization) and the classical spin precession simultaneously. Therefore, the theory for electron spin polarization discussed in this article and in Ref. 10 relies on the choice of a globally non-precessing spin basis. Such a basis is represented by the vector parallel to the magnetic field in the electron’s instantaneous rest frame. For the laser configuration discussed, a globally non-precessing spin basis can only be found if the electron’s motion is confined to the magnetic node: the vector $\zeta = e_z$.

In Ref. 14, the stability of the trajectory at the magnetic node has been discussed in detail. It has been shown that it is an unstable trajectory: any small perturbation from that position giving an irreversible deviation from the position of the node. This deviation happens in a timescale of the same order as the laser period. We now aim to determine the consequences, for the degree of spin polarization, of a small deviation from the magnetic node. We consider the case of an electron initially at rest, in the standing wave created by lasers with $a_0 = 600$ at a position a few percent of a laser wavelength away from the magnetic node.

As the electron migrates away from the magnetic node plane, $\zeta = e_z$ is no longer a non-precessing spin basis. Classically, the spin expectation value starts to precess, according to Eq. 7. In Fig. 4, we plot the time for the spin expectation value to undergo significant precession – the precession time. Note that we do not include the additional radiative spin polarization resulting from spin flip transitions, only the classical spin precession, due to the lack of an appropriate model. The spin is assumed initially parallel to $e_z$ and the precession time is defined as the time the expectation value of the spin takes to differ by 50% from its initial value. This value is computed considering the spin in the particle instantaneous rest frame, related to its laboratory counterpart by the transformation

$$S_{RF} = S - \frac{\gamma}{\gamma + 1} S \cdot \beta \beta.$$  (13)

The precession time is plotted as a function of the initial position $kz_0$ (off the magnetic node $kz = 0$).

The spin precession time represents an upper limit for the validity of our theory, i.e. we consider the predictions of the simple model presented here to be valid only on a timescale shorter than this. This gives an upper limit on the spin polarization for electrons off the magnetic node which is shown by the color map in Fig. 4. This shows that we can expect a degree of spin polarization higher than 30%, for $a_0 = 600$, for electrons initially $\lesssim 1\%$ of a laser wavelength off the magnetic node. Analogously, for $a_0 = 2000$, we expect a 70% degree of spin polarization for electrons initially $\lesssim 1\%$ of a laser wavelength off the magnetic node.

The electron migration from the magnetic node will quickly suppress spin flip transitions, due to the decrease in $\eta$ caused by the decrease in the electric field away from the node. This suggests that away from the magnetic node the spin polarization achieved before migration may be preserved. On the contrary, the electron’s trajectory is chaotic as it migrates and therefore the spin expectation value would be expected to precess chaotically, causing a depolarization.

IV. DISCUSSION

Recent progress in the study of RR in experiments with high intensity lasers 28-30 motivates the need to recognize signatures of quantum effects on RR. The spin polarization of electron beams may be one of the clearest, because it has no classical counterpart. However, further work is needed to accurately model the spin polarization dynamics for realistic experimental conditions.

The model we used in this article to describe electron spin polarization is based on a deterministic description of the particle trajectory and on a stochastic description of spin flip transitions along a non-precessing polarization direction. Using this approach we have examined the robustness of electron spin polarization induced by ultra-intense lasers to effects such as the instability of the magnetic node and variations in the initial velocity of the electron.
We have seen that the electron dynamics is weakly affected (≤ 5%) by the polarized nature of the particle. On the contrary the RR force plays an important role because it settles electrons in a stationary orbit, such that η is constant and ∼ 1. In this case, electrons radiate continuously in time, decreasing the polarization time. The RR force also helps to confine the electron in the magnetic node. In particular, this second statement could be important when considering lasers with a realistic focal spot size.

One major limitation of this analysis is our inability to deal with spin precession and spin flip simultaneously as the electron migrates away from the magnetic node (an effect of far greater importance that variations in the initial velocity of the electron – which causes the spin polarization to vary by ≤5%). However, classical tracking of the spin precession indicates that the spin polarization time is shorter than the time electrons take to migrate from the magnetic node: we expect a systematic polarization of the magnetic node plane region, due to the quick polarization of incoming electrons. The spin polarization should be preserved for electrons within 0.01 laser wavelengths of the magnetic node suggesting that thin targets may be advantageous. Multi-dimensional effects such as laser focusing will further complicate this picture and have not been considered here. We may be able to find additional configurations where spin precession is suppressed by considering more complex field configurations where the electrons may be trapped in a rotating field.

In this article we have used a deterministic model for the radiation reaction force (as described in [27]). In the quantum regime the emission is a stochastic process, and these can play a crucial role in next generation laser-plasma interactions [53, 56] and these can play a crucial role in next generation laser matter interactions [53, 56].

V. CONCLUSIONS

In this article we have discussed the possibility of electron spin polarization in realistic trajectories around the magnetic node of the standing wave set up by two circularly polarized, counter-propagating, ultra-intense lasers. We have characterized the conditions in which we can confidently expect an important degree of electron spin polarization. A significant degree (>5%) of spin polarization can be expected for a0 ≥ 200 and that the instability of the electron trajectories at the magnetic node gives an upper limit to the achievable spin polarization as the spin precesses as the electrons migrate from this unstable point. The possibility of producing spin-polarized electrons with ultra-intense lasers paves the way for new applications. Polarized electrons are fundamental for the study of particle physics and are used in the spin polarized electron spectroscopy.

The data required to reproduce the results in this article are available from the University of York at DOI 10.15124/b25e6428-ae40-43fb-b91d-f2785a09b5bc.
