(Dated: November 21, 2018)

We report nuclear magnetic resonance studies on the low-doped n-type copper-oxide $\text{Pr}_{0.91}\text{LaCe}_{0.09}\text{CuO}_{4-y}$ ($T_c=24$ K) in the superconducting state and in the normal state uncovered by the application of a strong magnetic field. We find that when the superconductivity is removed, the underlying ground state is the Fermi liquid state. This result is at variance with that inferred from previous thermal conductivity measurement and contrast with that in p-type copper-oxides with a similar doping level where high-$T_c$ superconductivity sets in within the pseudogap phase. The data in the superconducting state are consistent with the line-nodes gap model.

PACS numbers: 74.25.Jb, 74.72.Jt, 76.60.-k

The underlying ground state from which superconductivity evolves is closely related to, and may even determine, the nature of the superconductivity. In conventional metals, BCS type of superconductivity develops out of a ground state described by Landau's Fermi-liquid theory in which electrons, even interact with each other, can be treated as dressed fermions called quasi-particles. By contrast, the normal state above the transition temperature ($T_c$) in the p-type (hole-doped) copper-oxide superconductors deviates from the Fermi liquid. One of the emerging pictures is that high-$T_c$ superconductivity evolves out of a new state of matter. Meanwhile, the n-type (electron-doped) copper-oxide superconductors $\text{Re}_{2-x}\text{Ce}_x\text{CuO}_{4-y}$ ($\text{Re}=\text{Nd, Pr, Eu or Sm}$) show a substantially lower $T_c$ than their p-type counterparts. It is therefore an outstanding important question of what is the difference in the underlying ground state between these two classes of materials. Early experiments found that the electrical conductivity in $\text{Re}_{2-x}\text{Ce}_x\text{CuO}_{4-y}$ ($\text{Re}=\text{Nd, Pr}$) is strikingly different from that in the p-type copper-oxides, but it is recently suggested that the ground state in $\text{Pr}_{1.85}\text{Ce}_{0.15}\text{CuO}_{4-y}$ is a "spin-charge separated" state, as the case thought to occur in the p-type materials, where electrons have different capability to transport heat and charge.

In this study, we suppress superconductivity in the n-type $\text{Pr}_{0.91}\text{LaCe}_{0.09}\text{CuO}_{4-y}$ ($T_c=24$ K) with a strong magnetic field and evaluate the normal state using $^{63}\text{Cu}$ nuclear magnetic resonance (NMR). We find that the ground state hidden behind superconductivity is the Fermi liquid. When the superconductivity is removed, the spin lattice relaxation rate ($1/T_1$) was found to follow the $T_1 T=\text{constant}$ relation, known as Korringa law, down to a very low temperature of $T=0.2$ K. The NMR data in the superconducting state, which were obtained for the first time in $\text{Re}_{2-x}\text{Ce}_x\text{CuO}_4$, are rather consistent with line-nodes gap model.

High quality single crystal of $\text{Pr}_{1-x}\text{Ce}_x\text{LaCuO}_{4-y}$ used in this study was grown by the traveling-solvent-floating-zone method. Here half of Pr was replaced by La that helps stabilizing crystallization to obtain large-size single crystals. More crucially, it helps eliminating the magnetic moment due to the rare earth element that has been the main cause for preventing the understanding of this class of superconductors. Substituting $x$ tetravalent Ce for trivalent Pr adds $x$ electron to the CuO$_2$ plane. Upon doping Ce, superconductivity appears at $x=0.09$ with $T_c$ as high as 26 K, then $T_c$ decreases monotonically with increasing $x$. A crystal of $5 \times 2 \times 0.5 \text{ mm}^3$ of $\text{Pr}_{0.91}\text{LaCe}_{0.09}\text{CuO}_{4-y}$ was used for NMR and ac magnetic susceptibility measurements. Figure 1 shows the critical field necessary to destroy superconductivity, $H_{c2}$, determined from the ac-susceptibility measured at high frequency of $f=175$ MHz (left inset of Fig. 1). The value of $H_{c2}(T=0)$ for the magnetic field applied perpendicular to the CuO$_2$ plane ($H \parallel c$-axis) is estimated to be less than 10 T, indicating a substantially longer superconducting-coherence-length than that in the p-type cuprates. This low $H_{c2}$ makes it possible to access the "normal" ground state by applying a laboratory magnetic field to suppress the superconductivity. Note that in typical p-type superconductors, the highest static field of ~30 T using Bitter magnets can only reduce $T_c$ to its half value.

Taking full advantage of the large anisotropy of $H_{c2}$, we study the nature of the superconductivity by applying a magnetic field of 6.2 T along the CuO$_2$ plane ($T_c(6.2T)=19$ K) and we explore the ground state by applying a field of 15.3 T perpendicular to the plane to suppress the superconductivity. A single $^{63}\text{Cu}$ NMR line was observed for both $H \parallel c$-axis and $H \parallel a$-axis. The full width at half maximum of the linewidth at $T=300 \text{ K}$ is ~150 Oe (~300 Oe) at $H=6.2$ T (15.3 T) $\parallel c$-axis and ~75 Oe at $H=6.2$ T $\parallel a$-axis, which indicate that the nuclear quadrupolar frequency $\nu_Q$ is very small ($\nu_Q \lesssim 0.5$ MHz, if any), as the case in $\text{Nd}_{1.85}\text{Ce}_{0.15}\text{CuO}_3$. This is understood as due to electron doping into the Cu 3d-orbit whose hole is the main contribution to $\nu_Q$. The $1/T_1$ of $^{63}\text{Cu}$ was...
measured by the saturation-recovery method. A small RF field was used in order to avoid possible heating by the RF pulse. The value of 1/T$_1$ was determined from an excellent fitting of the nuclear magnetization $M(t)$ to $M(t) = 0.1e^{-t/T_1} + 0.9e^{-6t/T_1}$. The key results of this study were obtained by measuring 1/T$_1$ in the zero-temperature limit "normal state" when the superconductivity is suppressed. A criterion for judging an electronic state being a Fermi liquid or a "strange metal" is to see whether or not 1/T$_1$ obeys the Korringa law [8]. In a Fermi liquid, those quasiparticles that participate in the nuclear spin-lattice relaxation are the quasiparticles near $E_F$ whose population is $\sim k_BT$. Therefore 1/T$_1$ is proportional to $T$ in such a state (see below for a broader definition of the Korringa law). As seen in Fig. 2, for $H$ along the CuO$_2$ plane of Pr$_{0.91}$LaCe$_{0.09}$CuO$_{4-y}$, there appears a signature of 1/T$_1$ becoming proportional to $T$ below a temperature above $T_c$, but only in a narrow temperature range because superconductivity sets in (see Fig. 2, circles) [10]. It is unclear whether or not this is in the middle of crossing over to a more exotic state at lower temperatures as seen in p-type cuprate superconductors. We therefore applied a strong magnetic field of 15.3 T perpendicular to the CuO$_2$ plane to suppress the superconductivity and thereby to reveal the ground state hidden behind the superconductivity. There, it is seen that the $T_1T$=constant relation indeed holds, persisting down to a very low temperature $T=0.2$ K (also see the inset of Fig. 3). Namely, the hallmark of the Fermi liquid is unambiguously observed over more than two decades in temperature.

In order to examine in more detail how the electron-electron correlations evolve with temperature, it is instructive to plot the quantity of 1/T$_1T$ as a function of $T$. In Fig. 3, one sees that upon lowering temperature from 300 K, 1/T$_1T$ increases with decreasing $T$, but is saturated around $T=70$ K. The most important feature is that 1/T$_1T$ becomes a constant below $T=55$ K which persists down to $T=0.2$ K (see the inset), as mentioned already. Note that 1/T$_1T$ probes the imaginary part of the low-frequency ($\omega \rightarrow 0$) dynamical susceptibility ($\chi(q,\omega)$) averaged over the momentum ($q$) space: $1/T_1T = \frac{3k_B}{\mu_B^2}\sum_{k'}A_q A_{-q}\frac{\chi(q,\omega)}{\omega}$, where $A_q$ is the hyperfine coupling constant [17]. For conventional metals described by the Fermi liquid theory, $\sum_q\chi(q,\omega) = \pi\sum_{k,k'}\delta(E_k-E_{k'}-\omega)(f(E_{k'})-f(E_k))$, thus one recovers the Korringa law of $1/T_1T = \sum A^2N(E_F)k_B = \frac{A^2N(E_F)}{\gamma_{\epsilon(n)}}K_s^2$, where $\gamma_{\epsilon(n)}$ is the Gyromagnetic ratio of electron (nucleus) and $K_s$ is the spin Knight shift. By contrary, when $\chi(q)$ has a peak at the antiferromagnetic wave vector $Q = (\pi, \pi)$ as seen in the p-type cuprates, 1/T$_1T$ becomes to be proportional to $\chi(Q)$ [18] [19]. The increase of 1/T$_1T$ upon decreasing temperature in Pr$_{0.91}$LaCe$_{0.09}$CuO$_{4-y}$ can therefore be attributed to the
increase of $\chi(Q)$, namely, to the development of antiferromagnetic spin correlations. But the increase of $1/T_1T$ is weak, resembling that in high-doped (overdoped) p-type materials[23], which may be due to the electron-doping into the Cu-3d orbit that reduces the size of the spin moment. More importantly, for the low-doped p-type copper-oxides with carrier density usually less than 0.2, with further lowering $T$, $1/T_1T$ starts to decrease at a temperature $T^*$ that is far above $T_c \sim 100$ K. This phenomenon of the loss of low-energy spectral weight or DOS is ascribed to be due to a pseudogap opening[2], which has been a subject of intensive studies over the last decade. However, the pseudogap behavior is not seen in $1/T_1T$ in Pr$_{0.91}$LaCe$_{0.09}$CuO$_{4-y}$ even though it is low-doped. Its low-$T$ ($T \leq 55$ K) spin dynamics is renormalized to well conform to the prediction for the Fermi liquid that persists as the ground state when the superconductivity is removed.

That the present compound is a low carrier-doped sample is supported by the Knight shift result. The spin susceptibility $\chi(q = 0)$ of the present sample shares a property commonly seen in low-doped p-type cuprate superconductors[20], namely, $\chi(q = 0)$ decreases with lowering $T$, although its $T_c$ is the highest among its class. In Fig. 4, the Knight shift, which is a sum of the orbital contribution $K_{orb}$ and the spin contribution $K_s = A_{hf} \chi(q = 0)$, are shown for both $a$-direction ($K_a$) and $c$-direction ($K_c$). $K_s$ is less $T$-dependent, probably because of smaller hyperfine interaction $A_{hf}$ in this direction, namely, $K_c$ is predominantly orbital origin. As seen in the lower panel of Fig. 4 and the inset to it, the decrease of $K_a$ as $T$ is reduced ceases below $T \sim 55$ K, namely, $K_a$ becomes $T$-independent within the experimental error below $T \sim 55$ K, until superconductivity sets in. We have applied a high field of 28 T along the $a$-direction to reduce the $T_c$ to $\sim 10$ K and confirmed that the $T$-independence of $K_a$ persists down to 10 K. Thus, the criterion for the Fermi liquid in a broader sense, the requirement of $T_1T K^2_a$-constant, is also fulfilled for $T \leq 55$ K. Taking $K_{orb,a}=0.155\%$ from Fig. 4 we obtain $T_1T K_s^2=7.5\times10^{-8}$Sec·K, which is smaller by a factor of 50 than the value for non-interacting electrons of $3.75\times10^{-8}$Sec·K. The difference primarily arises from the enhancement of $1/T_1T$ due to the antiferromagnetic spin correlation. Hence, the low-$T$ normal state is a strongly-correlated Landau Fermi liquid. The inplane resistivity $\rho_a$, as shown in the right inset of Fig. 1, can be fitted to $\rho_a = \rho_0 + AT^2$ with $\rho_0=92\mu\Omega cm$ and $A=3.75\times10^{-3}\mu\Omega cm K^{-2}$, which is consistent with such Fermi liquid state but inconsistent with other liquids[24]. Our conclusion is different from that inferred from a recent low-$T$ thermal conductivity measurement that suggested a break-down of the Fermi liquid theory in the n-type Pr$_{1.85}$Ce$_{0.15}$CuO$_4$[7]. Also note that in p-type cuprates, the pseudogap persists in the $H$-induced normal state below $T_c(H=0)$[12,23]. Thus, our results suggest that the physics of the ground state in the n-type copper-oxide superconductors differs from that in the p-type counterparts, which may be responsible for the strikingly different $T_c$ they generated.
Finally, we discuss the nature of the superconducting (SC) state for $H$ parallel to the CuO$_2$-plane ($H \parallel \sigma$-axis) is reduced sharply just below $T_c$, and decreases in proportion to $T^n$ upon further lowering $T$, with the exponent $n = 3$ for $6 \text{ K} \leq T \leq 13 \text{ K}$. As elaborated below, this is consistent with the existence of line-nodes in the SC order parameter. In terms of density of states (DOS), $T_1$ in the SC state is expressed as $\frac{T_1}{T} = \frac{2}{3} \frac{1}{k_B T} \int \frac{1}{N_s(E)} N_s(E) f(E) [1 - f(E)] \delta(E - E') dE dE'$, where $N_s(E)$ is the DOS in the SC state, $f(E)$ is the Fermi function, $\Delta$ is the energy gap. For an s-wave gap, $1/T_1$ should show a peak just below $T_c$ due to the divergence of $N_s$ at $E = \Delta$, and then decrease as $\sim \exp(-\Delta/k_B T)$. The broken curve in Fig. 2 is the calculated $T$-dependence of $1/T_1$ for the simple BCS gap which was applied previously to several n-type cuprates $\cite{24, 25, 26, 27}$. By contrary, for a line-nodes gap such as d-wave gap, the peak just below $T_c$ is removed $\cite{28}$, and a $N_s(E) \propto E$ at low $E$ results in the $1/T_1 \propto T^3$ behavior at low temperatures. In the present case, the deviation of $1/T_1$ from $T^3$ at $T \leq 6 \text{ K}$ is explained as due to the presence of impurity (disorder) scattering which brings about a residual DOS $(N_{res})$ at the Fermi level $(E_F)$ in the case of line-nodes gap $\cite{29, 31}$. Note that an anisotropic (or extended) s-wave gap model can not explain the $T$-linear behavior of $1/T_1$ at low $T$ $\cite{31}$. To demonstrate the result of line-nodes gap, we applied the $d_{x^2-y^2}$ gap model, $\Delta(\theta) = \Delta_0 \cos(2\theta)$, in the presence of disorder $\cite{24}$. The calculation finds excellent agreement with the experimental data as seen in Fig. 2, with $2\Delta_0 = 3.8 k_B T_c$ and $N_{res} = 0.15 N(E_F)$. The same model can also consistently explain the Knight shift below $T_c$, for a choice of $K_{orb}=0.155\%$, but the difference between the d-wave and the s-wave cases in the Knight shift result is generally small, which is also true in the present case. In summary, our results in the SC state are compatible with the photoemission and scanning SQUID experiments that found d-wave-like gap in Nd$_{1.85}$Ce$_{0.15}$CuO$_4$ $\cite{32, 33, 34}$. In conclusion, from $^{63}$Cu NMR measurements in an electron low-doped copper oxide superconductor Pr$_{0.91}$LaCe$_{0.09}$CuO$_{4-y}$, we find that no pseudogap shows up and that the low-$T$ ($T \leq 55 \text{ K}$) spin dynamics is renormalized to well conform to the prediction for the Fermi liquid that persists as the ground state when the superconductivity is removed. This is the first case in which the normal state in the zero-temperature limit was investigated by a microscopic probe. The NMR data set in the superconducting state, which was obtained for the first time in Re$_{2-\delta}$Ce$_2$CuO$_4$, can be consistently explained by line-node gap model. These results shed light on understanding doped Mott insulators and superconductivity derived from them.

We thank H. Kohno, K. Miyake, M. Ogata, Z.-X. Shen, T. Tofyama, C. M. Varma, and T. Xiang for useful discussions, and Y. Okita for assistance in some of the measurements. Support by MEXT grants Nos. 11640350, 14540338 (G.-q.Z), 13740216 (M.F) and 12046239 (Y.K and K.Y) is acknowledged.

\bibitem{22} This $K_{orb,a}$ and $K_{orb,c}=0.92\%$ are both smaller than the respective values in p-type cuprates (see for example Ref. $\cite{12}$). This is consistent with the result of the very small $\nu_q$ that indicates a reduced hole number in the Cu3d orbit. Namely, $K_{orb,c} = n_{g_{x^2-y^2}} \frac{\gamma g_y}{2 g_y - \gamma_g - \gamma_x}$, where $n_{g_{x^2-y^2}}$ is the hole number in the $3d_{x^2-y^2}$-orbit and the denominator is the energy difference between the two designated orbits $\cite{14}$.
