Article
The Diminishing Role of the Nucleation Rate as Crystallization Develops in Avrami-Type Models

Fernando C. Pérez-Cárdenas

Abstract: By making use of an isothermal crystallization kinetics formulation in which growth and nucleation rates are functions of the degree of crystallization, we describe a process consisting of birth and growth of spherical crystalline domains. It is found that beyond the early stages of crystallization, the role played by the nucleation rate becomes quite insignificant as compared to the role of the crystalline domain growth rate. This is in contrast to what we would expect from the simplified Avrami exponential equation, where both rates play a symmetrical role. We argue that the asymmetric roles of the growth and nucleation rates greatly contribute to the wide applicability of Avrami-type expressions. A geometric explanation of the diminishing role of nucleation in the later stages of transformation is given. Future theoretical developments might benefit from the arguments and results presented.

Keywords: crystallization; Avrami equation; KJMA model; nucleation rate

1. Introduction
The isothermal, isotropic transformation from an amorphous to a crystalline phase, consisting of nucleation and growth of spherical domains, is usually well described by the Kolmogorov–Johnson–Mehl–Avrami (KJMA) model [1–3]:

$$X(t) = 1 - \exp \left( - \int_0^t \tau I(\tau) v(t, \tau) \right),$$

where $X$ is the fraction of material that has crystallized, $t$ is the time that has elapsed from the start of the process, $v(t, \tau)$ is the volume corresponding to the crystalline domains that were born at the nucleation time $\tau$, and $I(\tau)$ is the nucleation rate at $t = \tau$. If we assume a constant nucleation rate, $N_R$, and a constant linear growth rate, $k$, Equation (1) reduces to what we will simply call the Avrami exponential expression:

$$X(t) = 1 - \exp \left( - \frac{4\pi}{3} N_R k^3 t^4 \right).$$

Though these two expressions were introduced about 80 years ago, they are still widely used to fit a great variety of experimental data, spanning metals and alloys [1,4], polymers [2,5], growth of cancerous cells [6], etc. A few examples of critical reviews and/or alternatives to Avrami-like formulations are given in Refs. [7–17].

The rate of transformation in Equation (2) is dictated by the product $N_R k^3$. This suggests that increasing the growth rate, $k^3$, by a factor of 10 is the same as increasing the nucleation rate, $N_R$, by a factor of 10. Notice that the product $N_R k^3$ can be achieved in innumerable ways: we could have a nucleation rate of $1000 N_R$ times a growth rate of $k^3/1000$ or $N_R/1000$ times $1000 k^3$. In Equation (2), this is irrelevant due to the assumption that both rates remain constant along the transformation process. Nevertheless, we know that in reality, these two rates vary as crystallization progresses. Consider the process in
which the domain growth rate is slowed by the proximity of other domains (phenomenon
known as impingement). To some extent, it matters if for a given value of $X$, we have a few
large crystalline domains or a large number of small ones. When morphological details
affect these two rates to a significant extent, Equation (1) would be better suited to deal with
a crystallization kinetics involving time-dependent rates. We will follow a slightly different
approach in order to study the roles of variations in these two rates. We will make use of
an integral equation describing the isothermal crystallization kinetics that was introduced
previously by the author to assess the relevance of phantom nuclei [18]. In it, nucleation
and growth rates explicitly depend on the degree of crystallization. It will be shown that
varying the expression describing the growth rate as a function of $X$ has a much greater
effect than varying the expression describing the nucleation rate as a function of $X$, in clear
contrast to the situation described for Equation (2) above in this paragraph. The reason for
this is of a geometric nature, and we explain it in Section 4.

To put our results in context, in Appendix A, we show under which circumstances our
integral equation transforms into three well-known models of isothermal crystallization,
including Equations (1) and (2). To some extent, this lends support to our assertion that
the asymmetry between the nucleation and growth rates contributes to the great success of
Equations (1) and (2) in describing a wide range of experimental data.

2. Crystallization Kinetics Integral Equation

In developing our model, it is important to distinguish between two time variables:

1. The time elapsed since the overall crystallization process started, beginning from a
state of zero crystallization, is indicated by $t$.

2. The nucleation time, $\tau$, indicates the time at which a particular spherical crystalline
domain, originating from a nucleus, begins its growth process. This way, we say that,
at a time $t$, the growth interval for a spherical crystalline domain born at a nucleation
time $\tau$ is $(t-\tau)$.

Let $V_{tot}$ be the total volume of a sample and $V_x(t)$ be the volume of material trans-
formed at time $t$. Thus, we can define the crystallized fraction at time $t$ as
$X(t) = \frac{V_x(t)}{V_{tot}}$, with $X(t = 0) = 0$ and $X(t = \infty) = 1$. For simplicity, assume that the densities of non-
crystallized (amorphous) and crystallized phases are the same.

Let us assume that at time $\tau$, a spherical domain initializes its growth with a constant
and isotropic radial growth rate, given by

$$k = \frac{dr}{dt},$$

where $r$ is the radius. That is, if growth is unimpeded, the radius at time $t$ will be given by:

$$r(t, \tau) = k(t - \tau).$$

This is the kind of growth that is expected in the early stages of crystallization, when
the spherical domains have little, if any, influence over each other. As the initial unimpeded
growth continues, the volume of a crystalline domain born at time $\tau$ will be given by

$$v(t, \tau) = \frac{4}{3}\pi k^3 (t - \tau)^3.$$  

We assume that, as the number and volume of spherical domains increase with time,
growth will be increasingly diminished by the presence of close neighbors. In our formulation,
this will be taken into account by the introduction of a growth factor $G[X]$, with $0 \leq G[X] \leq 1$,
such that now $k^3 G[X]$ is an instantaneous (volumetric) growth rate ($G[X = 0] = 1$ and $G[X = 1] = 0$).
Thus, the volume of a crystalline domain born at a time $\tau$ is now given by

$$v(t, \tau) = 4\pi \int_{\tau}^{t} r^2 (t', \tau) G[X(t')] k dt' = 4\pi k^3 \int_{\tau}^{t} G[X(t')] (t' - \tau)^2 dt'.$$  

In developing our model, it is important to distinguish between two time variables:

1. The time elapsed since the overall crystallization process started, beginning from a
state of zero crystallization, is indicated by $t$.

2. The nucleation time, $\tau$, indicates the time at which a particular spherical crystalline
domain, originating from a nucleus, begins its growth process. This way, we say that,
at a time $t$, the growth interval for a spherical crystalline domain born at a nucleation
time $\tau$ is $(t-\tau)$.
For early stages of crystallization, we can consider that the nucleation rate is a constant, \( N_R \), such that the number of nuclei born between time \( t \) and \( t + dt \) is given by \( N_R dt \). However, as in the case of the growth rate for later stages, we assume that the nucleation rate decreases as crystallinity increases. Thus, we propose an instantaneous nucleation rate given by a function \( N_R[I(x)] \), with \( 0 \leq I[X] \leq 1 \), \( I[X = 0] = 1 \), and \( I[X = 1] = 0 \). Thus, the number of crystalline domains born up to time \( t \) is given by

\[
N(t) = N_R \int_0^t I[X(t')] dt'.
\]  

(7)

We define \( x(t, \tau) d\tau \) as the fraction of the volume occupied by all the spherical domains born during the time interval from \( \tau \) to \( \tau + d\tau \). Since the number of spherical domains born during this time interval is given by \( I[X(\tau)]N_R d\tau \), we have

\[
x(t, \tau) d\tau = \frac{I[X(t)]N_R v(t, \tau) d\tau}{V_{tot}}.
\]  

(8)

\( X \) can be found by summing up the contributions from all spherical domains that have initiated growth within the time interval from 0 to \( t \):

\[
X(t) = \int_0^t x(t, \tau) d\tau = \frac{1}{V_{tot}} \int_0^t N(\tau) v(t, \tau) d\tau = \frac{1}{V_{tot}} \int_0^t I[X(\tau)]N_R v(t, \tau) d\tau.
\]  

(9)

Inserting Equation (6) into Equation (9):

\[
X(t; G, I) = 12\kappa \int_0^t I[X(\tau)] \left\{ \int_\tau^t G[X(t')] (t' - \tau)^2 dt' \right\} d\tau,
\]  

(10)

\( \kappa = \frac{4\pi d^3 N_R}{V_{tot}} \). In Ref. [18], the author made use of this integral equation to study the negligible contributions from phantom nuclei within the Avrami theory. In this paper, we use it to assess the relative importance of the growth and nucleation rates during the early and late stages of crystallization.

We assume that the evolution of \( G \) and \( I \) over time depends on the morphological properties of the system. Thus, we propose that \( G \) and \( I \) are functions that depend explicitly on \( X \) and that they decrease monotonically from 1 to 0 as \( X \) increases from 0 to 1. The following expressions will be used:

\[
G[X(t)] = (1 - X(t))^\gamma
\]  

(11)

and

\[
I[X(t)] = (1 - X(t))^\nu.
\]  

(12)

where \( \gamma \) and \( \nu \) are the growth and nucleation exponents, respectively. By changing the values of these exponents, we can control how fast growth and nucleation rates decrease as \( X \) increases.

3. Dependence of the Evolution of \( X \) on \( \gamma \) and \( \nu \)

First, we consider the case in which \( G \) and \( I \) are proportional to \( 1 - X \), the untransformed fraction. This approximation is made by setting \( \gamma = 1 \) and \( \nu = 1 \) in Equations (10)–(12). The + symbols in black in Figure 1 show the time dependence of \( X \). Recalling that \( x(t, \tau) d\tau \) represents the fraction of volume occupied by all the spherical domains born during the time interval from \( \tau \) to \( \tau + d\tau \), in Figure 2 we show the relative values of \( x(t, \tau) \) versus time for crystalline domains born at different nucleation times \( \tau \). As expected, the volume occupied by crystalline domains born in the early stages (\( \kappa^{1/4} = 0.001 \)) is significantly larger than that of late comers (\( \kappa^{1/4} = 1 \)). This point will turn out to be important for the discussions given below. Figure 3 shows the rates \( dx(t, \tau)/dt \) corresponding to the same \( \tau \) values. Again, we see the predominance of domains born in the early stages.
Figure 1. $X(t)$ as predicted by Equation (10) using two sets of data. When $\gamma = 1$ and $\nu = 0$, Equation (10) transforms into Equation (2), as shown in Appendix A.

Figure 2. $x(t, \tau)$ for different nucleation times $\tau$, for $\gamma = 1$ and $\nu = 1$.

Figure 3. $dx(t, \tau)/dt$ for different nucleation times $\tau$, for $\gamma = 1$ and $\nu = 1$. 
Next, we study the case for a time-independent $I$ (i.e., $\nu = 0$), keeping the same growth exponent, $\gamma = 1$. This case is important because it corresponds to the Avrami exponential expression, Equation (2) [18]. Remarkably, $X(t)$ is similar to one of the previous cases, as is shown by the red curve in Figure 1. The curves shown in Figures 4 and 5, corresponding to $x(t, \tau)$ and $dx(t, \tau)/dt$, respectively, are practically the same as those shown in Figures 2 and 3. At first thought, this might seem remarkable, considering that for $\nu = 1$, nucleation decreases significantly for the late stages as $X$ increases, while it remains constant for $\nu = 0$. In the next section, we show that the reason is that, when referring to crystalline spherical domains, early-born domains easily win the battle for volume. Even if we increase the exponent $\nu$ further, let us say to 5 or 10, we still observe the same behavior as that depicted in Figure 1. For two-dimensional crystallization, the difference between the $\nu = 0$ and $\nu = 1$ cases is larger, but still small [18]. The conclusions drawn from the similarities between Figures 2 and 3, on the one hand, and Figures 4 and 5, on the other, are crucial in understanding the irrelevance of phantom nuclei [18], a topic that we do not touch here.

![Figure 4](image1.png)

**Figure 4.** $x(t, \tau)$ for different nucleation times $\tau$, for $\gamma = 1$ and $\nu = 0$.

![Figure 5](image2.png)

**Figure 5.** $dx(t, \tau)/dt$ for different nucleation times $\tau$, for $\gamma = 1$ and $\nu = 0$.

Now, let us study the effect of the variations in the growth exponent $\gamma$ on $X(t)$. Having seen that the variations in the nucleation exponent $\nu$ have a rather small effect on the crystallization rate, we choose to keep $\nu = 0$. The left-most curve in Figure 6 corresponds to...
\( \gamma = 1 \) (the Avrami exponential expression of Figure 1, with \( \gamma = 1 \) and \( \nu = 0 \)), for which the growth rate is proportional to the untransformed fraction \((1 - X)\). For \( \gamma = 3 \) and 5, there is a noticeable slowdown of the growth rate for \( X \geq 0.1 \). This is in contrast to the similarity of the two curves in Figure 1. The slow approach to the completion of the transformation, for \( \gamma = 3 \) and 5, is what is known as a long tail. It is shown in Appendix A that for \( \gamma \neq 1 \) and \( \nu = 0 \), Equation (10) transforms into an expression proposed by Lee and Kim to study the transformation kinetics of Cu–Zn–Al shape memory alloys [11].

In Figures 7 and 8, we show \( x(t, \tau) \) and \( dx(t, \tau)/d\tau \), respectively, as a function of time, for \( \gamma = 3 \) and \( \nu = 0 \). Since the growth rate now diminishes faster than when \( \gamma = 1 \) (Figures 1–5), we see that the relative contributions to crystalline volume from domains born at \( \kappa^{1/4} = 0.1, 0.5, \) and 1 are now larger than for \( \gamma = 1 \) (see Figures 2–5).

**Figure 6.** \( X(t) \) as predicted by Equation (10), when \( \nu = 0 \). For \( \gamma = 1 \) (equivalent Avrami model, Equation (2)), for \( \gamma = 3 \), and for \( \gamma = 5 \). For these last two cases, Equation (10) is equivalent to Equation (A6) in Appendix A.

**Figure 7.** \( x(t, \tau) \) for different nucleation times \( \tau \), for \( \gamma = 3 \) and \( \nu = 0 \).
Figure 8. $dx(t, \tau)/dt$ for different nucleation times $\tau$, for $\gamma = 3$ and $\nu = 0$.

Figure 9 shows the domain volumes after completion of the crystallization process, $x(t = \infty, \tau)$, as a function of birth time $\tau$, with $\nu = 0$. For the Avrami case ($\gamma = 1$), the domains born after $\kappa^{1/4} \tau = 1.0$ have a negligible contribution. This is not the case for $\gamma = 3$ and 5, in which case, at time $\kappa^{1/4} \tau = 1.0$, the old domains are smaller than for $\gamma = 1$, leaving more room for new domains to grow.

Figure 9. $x(t = \infty, \tau)$, as a function of birth time $\tau$, with $\nu = 0$, for $\gamma = 1, 3, \text{ and } 5$.

In these last two sections, we have considered a crystallization process consisting of nucleation and spherical growth, where growth and nucleation rates depend explicitly on $X$: $G(X)$ and $I(X)$. We found that, as would be expected, in its early stages, crystallization is governed by the product of both rates. However, as the transformation develops, the role of $I(X)$ becomes quite insignificant compared to the role of $G(X)$. This is clear if one notes that a change in the function $G(X)$ has a much larger effect on the evolution of $X(t)$ than a similar change in $I(X)$. The reason for this is given in Section 4.
4. A geometric Explanation

Consider some growth and nucleation rate functions, \( G(X) \) and \( I(X) \), that decrease as \( X \) increases. In early stages, the crystalline domains grow from nuclei that randomly emerged along the amorphous phase that initially dominates the volume of a sample. Once a domain is born, its radius grows due to the transformation (from an amorphous to a crystalline phase) that occurs at its surface. Thus, the increase in the volume of a spherical crystalline domain at a given time interval is proportional to the square of its radius. That is the simple reason why the volume of the older (bigger) domains grows much faster than the volume of the younger (smaller) domains. Once a certain number of domains are born, within a given volume, the volume gain produced by older domains overwhelmingly dominates the overall crystallization, regardless of the future changes in \( I(X) \). In contrast, changes in the growth rate function \( G(X) \) have a direct, and noticeable, effect on the evolution of \( X(t) \).

5. Conclusions

We have studied the roles played by the crystalline domain growth rate and the nucleation rate in the calculations of the crystallized fraction, \( X(t) \), for systems that initially are characterized by an amorphous phase. We found that beyond the early stages of transformation, the role played by the domain growth rate is much more relevant than that played by the nucleation rate. As explained above, this contradicts Equation (2), which is a simplification of the KJMA model. To address this issue, we have made use of a formulation that considers crystallization as a process consisting of nucleation and growth of spherical crystalline domains and assumes that the nucleation and domain growth might be a function of the level of crystallization. It allowed us not just to calculate the overall level of crystallization but also to quantify the volume fraction corresponding to crystalline domains born at different nucleation times and levels of crystallization. This gave us a clear picture of the geometric factors responsible for the diminishing role of the nucleation rate as compared to that of the domain growth rate.

Within the framework of our integral formulation, we argue that the great success of Equations (1) and (2) in describing a wide range of experimental data is due, in part, to two features of the crystallization kinetics: (1) a growth rate \( G \) proportional to the amount of untransformed fraction \((1 - X)\) is often a sound assumption, and (2) kinetics corresponding to different nucleation rate modes \( I(X) \) are described by similar expressions for cases of similar growth rates \( G(X) \). Future theoretical developments in the field of crystallization might benefit from taking into account the arguments and results presented above.

Appendix A

Here, we show that under certain assumptions, Equation (10) transforms into three well-known expressions:

(1). If \( \gamma = 1 \) (that is, the growth rate factor \( G \) is proportional to the untransformed fraction \((1 - X)\)) and if \( I(\tau) \) is not an explicit function of \( X \), then we obtain the KJMA model, Equation (1).

(2). For \( \gamma = 1 \) and a constant nucleation rate \((\nu = 0)\), we obtain Equation (2).

(3). If \( \gamma \neq 1 \) and \( \nu = 0 \), a simple mathematical expression proposed by Lee and Kim to study the transformation kinetics of Cu-Zn-Al shape memory alloys is obtained [11].

We have seen that in our formulation, the transformed fraction as a function of time is given by:

\[
X(t) = 12\kappa \int_0^t \frac{I(\tau)}{G(1 - X(t')) \gamma (t' - \tau)^2} dt' d\tau. \tag{A1}
\]
Differentiating it with respect to $t$:

$$\frac{dX}{dt} = 12\kappa (1-X)^7 \int_0^t I[\tau] \left\{ (t' - \tau)^2 \right\} d\tau. \quad (A2)$$

Separating variables:

$$\frac{dX}{(1-X)^\gamma} = 12\kappa \int_0^t I[\tau] \left\{ (t' - \tau)^2 \right\} dt d\tau. \quad (A3)$$

If $\gamma = 1$ (that is, assuming that the growth rate factor $G$ is proportional to the untransformed fraction, $(1-X)$), the integration gives us:

$$\ln(1-X) = -\int_0^t I[\tau] v(\tau, t) d\tau, \quad (A4)$$

where we have made use of Equation (6). This finally gives us the KJMA equation, Equation (1):

$$X(t) = 1 - \exp\left(-\int_0^t d\tau I(\tau) v(t, \tau) \right). \quad (A5)$$

As is well known, this transforms into Equation (2), the simplified Avrami exponential equation, if $I$ is a constant.

We have also studied crystallization for $\gamma \neq 1$, when $I$ is a constant ($v = 0$). In this case, by requiring that $X(t = 0) = 0$, the integration of Equation (A3) results in:

$$X(t) = 1 - \left( \frac{1}{\kappa(\gamma - 1)t^4 + 1} \right)^{1/(\gamma-1)}, \quad (A6)$$

which is equivalent to an expression proposed by Lee and Kim [11].
