Abstract

We construct the first examples of complete, properly embedded minimal surfaces in $\mathbb{H}^2 \times \mathbb{R}$ with finite total curvature and positive genus. These are constructed by gluing copies of horizontal catenoids or other nondegenerate summands. We also establish that every horizontal catenoid is nondegenerate.

1 Introduction

Amidst the great activity in the past several years concerning the existence and nature of complete minimal surfaces in homogeneous three-manifolds, the study of minimal surfaces in $\mathbb{H}^2 \times \mathbb{R}$ has witnessed particular success. The central problem is the solvability of the asymptotic Dirichlet problem, i.e. the existence of complete surfaces asymptotic to a given embedded curve $\gamma$ in the boundary of the compactification of this space $B^2 \times I$, where $B^2$ is the closure of the Poincaré ball model of $\mathbb{H}^2$ in $\mathbb{R}^2$ and the interval $I$ is the stereographic compactification of $\mathbb{R}$.

There have been three main approaches to this problem. The first is based on the method of Anderson [1] for the analogous problem in $\mathbb{H}^3$: one defines a sequence of curves $\gamma_R$ lying on the geodesic sphere of radius $R$ around some point, solves the Plateau problem for each of these curves, then attempts to take a limit as $R \to \infty$. The main points are to show that the sequence of minimal surfaces with boundary does not drift off to infinity and that the limit has $\gamma$ as its asymptotic boundary curve; both of these are accomplished using suitable barrier surfaces, the existence and nature of which depends upon the convexity of $\mathbb{H}^3$ at infinity. This approach has also been used successfully for the analogous asymptotic Plateau problem in higher dimensions and codimensions for various classes of nonpositively curved spaces. The second approach generalizes the classical method of Jenkins and Serrin [6] for minimal graphs in $\mathbb{R}^3$, and was developed in this setting by Nelli and Rosenberg [20], Collin and Rosenberg [2] and Mazet, Rosenberg and the third author [10]. This involves finding a minimal graph...
over domains of $\mathbb{H}^2$ with prescribed boundary data, possibly $\pm \infty$. The third approach is by an analytic gluing construction, and this is the method we follow here.

Before describing our work, let us draw attention to the issue of obtaining surfaces with finite total curvature. (We recall that the total curvature of a surface is defined as the integral on the surface of its Gauss curvature.) It turns out to be far easier to obtain complete minimal surfaces of finite topology in $\mathbb{H}^2 \times \mathbb{R}$ with infinite total curvature, and we refer to some of the papers above for a good (but not yet definitive) existence theory. The simplest example is the slice $\mathbb{H}^2 \times \{0\}$, but more generally there exist minimal surfaces asymptotic to a vertical graph $\{(\theta, f(\theta)) : \theta \in S^1\} \subset \partial B^2 \times \mathbb{R}$ for any $f \in C^1(S^1)$. Other examples include the one-parameter family of Costa-Hoffman-Meeks type surfaces, each asymptotic to three parallel horizontal copies of $\mathbb{H}^2$. These have positive genus and were constructed by Morabito [17] also using a gluing method.

On the other hand, surfaces of finite total curvature have proved more elusive. The basic examples are the vertical plane $\gamma \times \mathbb{R}$, where $\gamma$ is a complete geodesic in $\mathbb{H}^2$, and the Scherk minimal graphs over ideal polygon constructed by Nelli and Rosenberg [20], and Collin and Rosenberg [2]. There is also a family of horizontal catenoids $K_\eta$, each consisting of a catenoidal handle which is orthogonal to the vertical direction, and asymptotic to two disjoint vertical planes which are neither asymptotic nor too widely separated. The recent paper [5] shows that these are the unique complete minimal surfaces with finite total curvature and two ends. A large number of new examples of genus zero have been constructed recently by Pyo [23], and Morabito and the third author [18], independently. Both papers use the conjugate surface method. The theory of conjugate minimal surfaces in $\mathbb{H}^2 \times \mathbb{R}$ was elaborated by Daniel [3] and Hauswirth, Sa Earp and Toubiana [4]. The surfaces in [18] are shown to have total curvature $-4\pi(k-1)$, where $k$ is the number of ends, and each end is asymptotic to a vertical plane. The horizontal catenoids, which have total curvature $-4\pi$, are a special case.

Despite all this progress, it has remained open whether there exist complete, properly embedded minimal surfaces in $\mathbb{H}^2 \times \mathbb{R}$ with finite total curvature and positive genus. The aim of this paper is to construct such surfaces, which we do by gluing together certain configurations of horizontal catenoids. There is a dichotomy in the types of configurations one may glue together. The ones for which the horizontal catenoid components have “necksize” bounded away from zero are simpler to handle, and the gluing construction in this case is quite elementary; the trade-off is that the minimal surfaces obtained using only this type of component have a very large number of ends relative to the genus. Alternatively, one may glue together horizontal catenoids with very small necksizes, which allows one to obtain viable configurations with relatively few ends for a given genus. Unfortunately this turns out to involve more analytic details because these the horizontal catenoids with very small necks are ‘nearly degenerate’, and because of this we will address this second case in a sequel to this paper.

Our main result here is the

**Theorem 1.1.** For each $g \geq 0$, there is a $k_0 = k_0(g)$ such that if $k \geq k_0$, then there exists a properly embedded minimal surface with finite total curvature in $\mathbb{H}^2 \times \mathbb{R}$, with genus $g$ and $k$ ends, each asymptotic to a vertical plane.

The proof involves gluing together component minimal surfaces which are nondegenerate in the sense that they have no decaying Jacobi fields. Unfortunately, every
minimal surface in $\mathbb{H}^2 \times \mathbb{R}$ with each end asymptotic to a vertical plane is degenerate since vertical translation (i.e. in the $\mathbb{R}$ direction) always generates such a Jacobi field. Because of this we shall work within the class of surfaces which are symmetric with respect to a fixed horizontal plane $\mathbb{H}^2 \times \{0\}$ and then it suffices to work with surfaces which are \emph{horizontally nondegenerate} in the sense that they possess no decaying Jacobi fields which are even with respect to the reflection across this horizontal plane. The surfaces obtained in Theorem 1.1 are all even with respect to the vertical reflection, and all are horizontally nondegenerate as well.

This leads to the problem of showing that there are component minimal surfaces which satisfy this condition, and our second main result guarantees that many such surfaces exist.

\textbf{Theorem 1.2.} Each horizontal catenoid $K_\eta$ is horizontally nondegenerate.

Our final result concerns the deformation theory of this class of surfaces.

\textbf{Theorem 1.3.} Let $\mathcal{M}_k$ denote the space of all complete, properly embedded minimal surfaces with finite total curvature in $\mathbb{H}^2 \times \mathbb{R}$ with each end asymptotic to an entire vertical plane. If $\Sigma \in \mathcal{M}_k$ is horizontally nondegenerate, then the component of this moduli space containing $\Sigma$ is a real analytic space of dimension $2k$, and $\Sigma$ is a smooth point in this moduli space. In any case, even without this nondegeneracy assumption, $\mathcal{M}_k$ is a real analytic space of virtual dimension $2k$.

We make two remarks on this. First, this dimension count coincides with the dimension of the family constructed by our gluing methods, and also with the dimension of the family of genus 0 surfaces constructed in [18, 23]. The fact that the dimension does not depend on the genus may be surprising at first, but this is also the case for the space of complete Alexandrov-embedded minimal or CMC surfaces of finite topology in $\mathbb{R}^3$, see [7] and [21]. As is the case in these other theories, it turns out to be very hard to construct surfaces which are actually degenerate, and we leave this as an interesting open problem here as well. The second remark is that it would also be quite interesting to know whether the vertical symmetry condition we are imposing is anything more than a technical convenience. More specifically, we ask whether there exist finite total curvature minimal surfaces in $\mathbb{H}^2 \times \mathbb{R}$ which do not have a horizontal plane of symmetry.

Our results show that the existence theory for these properly embedded minimal surfaces of finite total curvature in $\mathbb{H}^2 \times \mathbb{R}$ is in some ways opposite to that in $\mathbb{R}^3$. Indeed, Meeks, Perez and Ros [15] have proved that there is an upper bound, depending only on the genus, for the number of ends of a properly embedded minimal surface of finite topology in $\mathbb{R}^3$. This is a significant step toward resolving the conjecture of Hoffman and Meeks that a connected minimal surface of finite topology, genus $g$ and $k > 2$ ends can be properly minimally embedded in $\mathbb{R}^3$ if and only if $k \leq g + 2$. By contrast, our result gives some indication that a connected surface of finite topology and finite total curvature can be properly minimally embedded in $\mathbb{H}^2 \times \mathbb{R}$ only if the number of ends $k$ has a specific lower bound in terms of the genus $g$. Going out on a limb, we conjecture that the correct bound for the surfaces constructed by gluing horizontal catenoids with small necks is $k \geq 2g + 1$. Note also that our construction
shows that if there exists a surface of this type of genus $g$ and $k$ ends, then we can construct such surfaces with genus $g$ and any larger number of ends, so there definitely is no upper bound as in the Euclidean space to the number of ends that a surface of fixed genus may have.

The plan of this paper is as follows: In §2 we describe the horizontal catenoids in more detail, reviewing known properties and developing some new ones as well. This is where we prove Theorem 1.2. Next in §3 we describe the configurations of approximate minimal surfaces formed by patching together horizontal catenoids. The actual gluing, i.e. the perturbation of these approximately minimal surfaces to actual minimal surfaces, which is possible when some parameter in the construction is sufficiently large, is carried out in §4. The analytic steps involve a parametrix construction which is perhaps not so well known in the minimal surface literature but fairly standard elsewhere; we refer to the recent paper [13] which uses a similar method to construct multi-layer solutions of the Allen-Cahn equation in $H^n$. In §5 the general construction is given for gluing together any two nondegenerate properly embedded minimal surfaces of finite total curvature; this is a simple variant of the proof of the main result. Finally, in §6, we study the deformation theory.

2 Horizontal catenoids

We now describe the fundamental building block in our gluing construction, which is the family of horizontal catenoids $K_\eta$ in $\mathbb{H}^2 \times \mathbb{R}$, originally constructed by Morabito and the third author [18] and by Pyo [23]. Each $K_\eta$ has genus zero and two ends asymptotic to vertical geodesic planes. The parameter $\eta$ is the hyperbolic distance between these two planes; it varies in an open interval $(0, \eta_0)$, where the upper bound $\eta_0$ corresponds to the distance between two opposite sides of an ideal regular quadrilateral. These catenoids have total curvature $-4\pi$, and have “axes” orthogonal to the $\mathbb{R}$ direction, whence the moniker horizontal.

The horizontal catenoid as a vertical bigraph: The initial construction of $K_\eta$ in the papers above describes it as a bigraph over a region $\Omega_\eta \subset \mathbb{H}^2$ with a reflection symmetry across the central $\mathbb{H}^2 \times \{0\}$. This means the following: first, there is a nonnegative function $u$ defined in $\Omega_\eta$ such that

$$K_\eta = \{(z, u(z)) : z \in \Omega_\eta\} \cup \{(z, -u(z)) : z \in \Omega_\eta\}.$$ 

The domain $\Omega_\eta$ is bounded by four smooth curves of infinite length which intersect only at infinity; two of these are hyperparallel geodesics, denoted $\gamma_{-1}$ and $\gamma_1$, and the parameter $\eta$ equals the hyperbolic distance between them; the other two curves, denoted $C_{-1}$ and $C_1$, connect the adjacent pairs of endpoints of $\gamma_{\pm 1}$. The function $u$ is strictly positive in the interior of $K_\eta$, vanishes and has infinite gradient on $C_{-1} \cup C_1$, and tends to $+\infty$ along $\gamma_{-1} \cup \gamma_1$. We also let $C_{-1}'$ and $C_1'$ be the geodesic lines with the
same endpoints as $C_{-1}$ and $C_1$, respectively, and $\Omega'_\eta$ the ideal geodesic quadrilateral bounded by $\gamma_{-1} \cup \gamma_1 \cup C'_{-1} \cup C'_1$. Using vertical planes (which are minimal) as barriers, we see that $C_{-1}$ and $C_1$ are strictly concave with respect to $\Omega'_\eta$. In particular, they lie in the interior of $\Omega'_\eta$. For later reference, we identify a few other curves which will enter the discussion. First, let $\Gamma$ denote the unique geodesic which is orthogonal to both $\gamma_{\pm 1}$; next, let $\gamma_0$ be the geodesic perpendicular to $\Gamma$ and midway between $\gamma_{\pm 1}$; finally, denote by $\tilde{\gamma}_{\pm 1}$ the two geodesics which connect the opposite ideal vertices of $\Omega_\eta$. Observe that $\gamma_0$ is perpendicular to both $C'_{\pm 1}$; in addition the points of intersection $\gamma_0 \cap \Gamma$ and $\tilde{\gamma}_{-1} \cap \tilde{\gamma}_1$ are the same, and we denote this centerpoint by $Q$.

![Figure 1: The boundary of the region $\Omega_\eta$.](image)

**The extremal surface:** The family of catenoids $K_\eta$ exists only for $0 < \eta < \eta_0$. This critical value $\eta_0$ corresponds to the case where the pairs of geodesics $\tilde{\gamma}_{\pm 1}$ intersect orthogonally at $Q$. The limiting domain $\Omega'_{\eta_0}$ is the same as $\Omega'_{\eta}$ (so $C'_{-1} = C''_{-1}$ and $C_1 = C'_1$ in this limit). Furthermore, as $\eta \nearrow \eta_0$, the value $u(Q)$ tends to $+\infty$. In fact, recentering $K_\eta$ by translating down by $-u(Q)$, there is a limiting surface which is a graph over $\Omega'_{\eta_0}$ with boundary values $\pm \infty$ disposed alternately. It is planar of genus zero with one end. This surface is qualitatively similar to the classical Scherk surface of $\mathbb{R}^3$, and so we also call it Scherk surface.

**Further symmetries:** Unlike the Euclidean case, or even the case of vertical catenoids in $\mathbb{H}^2 \times \mathbb{R}$, the horizontal catenoid $K_\eta$ has only a discrete isometry group, isomorphic to $\mathbb{Z}_2 \times \mathbb{Z}_2 \times \mathbb{Z}_2$. Each $\mathbb{Z}_2$ corresponds to a reflection: the first reflection, which we call $R_t$, sends $(z, t)$ to $(z, -t)$, and thus interchanges the top and bottom halves of $K_\eta$; the
second, $R_s$, is the reflection across $\Gamma \times \mathbb{R}$, it interchanges the ‘left’ and ‘right’ sides of each asymptotic end; the final one, $R_o$, is the reflection across $\gamma_0 \times \mathbb{R}$ and interchanges the two ends of $K_\eta$ and has fixed point set a loop around the neck.

Figure 2: A horizontal catenoid $K_\eta$.

**Graphical representation of the ends of $K_\eta$:** Each end of $K_\eta$ is asymptotic to one of the totally geodesic vertical planes $P_j = \gamma_j \times \mathbb{R}$, $j = \pm 1$. The intermediate vertical plane $\gamma_0 \times \mathbb{R}$ fixed by $R_o$ bisects $K_\eta$, decomposing it into two pieces, $K_\eta^1 \cup K_\eta^{-1}$, which are interchanged by this reflection. Each $K_j^k$ is a smooth manifold with compact boundary and one end, which is asymptotic to the vertical plane $P_j$. Outside of some compact set, $K_j^k$ is a normal graph over $P_j$, with graph function $v^j$ which is strictly positive and defined on an exterior region $E^j_\eta = P_j \setminus O_\eta$.

The two ends are equivalent, so let us fix one and drop the sub- and superscripts $j$ for the time being. Use parameters $(s,t)$ on $P$, where $t$ is the vertical coordinate and $s$ is the signed distance function along the geodesic $\gamma$, as measured from $\gamma \cap \Gamma$. The restrictions of $R_s$ and $R_t$ to the plane $P$ correspond to $(s,t) \mapsto (-s,t)$ and $(s,t) \mapsto (s,-t)$, respectively. We assume that the domain $E_\eta$ is invariant under both these
reflections.

The parameter $\eta$, strictly speaking, measures the distance between the asymptotic vertical planes of $K_\eta$, but also measures the size of the neck of $K_\eta$, which we take, for example, as the length of the closed curve $K_\eta \cap (\gamma_0 \times \mathbb{R})$. This function, which we denote by $n(\eta)$, has $n(\eta) \to 0$ as $\eta \to 0$ and $n(\eta) \to \infty$ as $\eta \to \eta_0$. This can be thought as the original parameter for this family used in [18, 23].

We now describe the asymptotic decay profile of the graphical representation of $K_\eta$ over $P$. Introduce polar coordinates $(r, \theta)$ in the $(s, t)$ plane, so $s = r \cos \theta$ and $t = r \sin \theta$.

**Proposition 2.1.** For each $\eta \in (0, \eta_0)$, as $r \to \infty$, the graph function $v$ has the asymptotic expansion

$$v(r, \theta) = A_\eta(\theta)e^{-r^{\frac{1}{2}}} + O(r^{\frac{3}{2}}e^{-r}),$$

where $A_\eta(\theta)$ is some strictly positive smooth function on $S^1$. This decay profile is essentially a linear phenomenon and corresponds to the known asymptotic properties of homogeneous solutions of the Jacobi operator on $P$. Recall that for any minimal surface $\Sigma$, its Jacobi operator (for the minimal surface equation) is the elliptic operator

$$L_\Sigma := \Delta_\Sigma + |A_\Sigma|^2 + \text{Ric}(N, N);$$

here $\Delta_\Sigma$ is the Laplacian on $\Sigma$, $A_\Sigma$ the second fundamental form of the surface, $N$ its unit normal, and $\text{Ric}$ the Ricci tensor of the ambient space. When $\Sigma = P$ is a vertical plane, this simplifies substantially. Indeed, $A_P \equiv 0$ and $N$ has no vertical component, so that $\text{Ric}(N, N) \equiv -1$, hence

$$L_P = \Delta_{\mathbb{R}^2} - 1.$$  

We now deduce Proposition 2.1 from a slightly more general result.

**Proposition 2.2.** Let $E \subset P$ be an unbounded region with complement $P \setminus E$ smoothly bounded and compact. Let $K \subset \mathbb{H}^2 \times \mathbb{R}$ be a minimal surface which is a normal graph over $E$ with compact boundary over $\partial E$, and denote by $v : E \to \mathbb{R}$ the graph function. Suppose that $v \to 0$ at infinity in $P$. Then there exists $A \in C^\infty(S^1)$, such that

$$v(r, \theta) = A(\theta)e^{-r^{\frac{1}{2}}} + O(r^{\frac{3}{2}}e^{-r}).$$

Furthermore, if $K$ lies on one side of $P$ at infinity, then $A$ is either strictly positive or strictly negative.

**Proof.** The minimal surface equation for a horizontal graph over $P$ is a quasilinear elliptic equation $\mathcal{N}(v, \nabla v, \nabla^2 v) = 0$, the linearization of which at $v = 0$ is just $L_P$. Let $p_j$ be any sequence of points in $P$ tending to infinity, and consider the restriction of $v$ to the unit ball $B_1(p_j)$ around $p_j$. Recenter this ball at the origin and write the translated function as $v_j$. We are assuming that $v_j \to 0$, and it follows from standard regularity theory for the minimal surface equation that

$$||v_j||_{L^{2,\infty};B_1(0)} \to 0 \quad \text{as} \quad j \to \infty.$$
This means that we can write
\[ \mathcal{N}(v, \nabla v, \nabla^2 v) = L_P v + Q(v), \] (2.6)
where \( Q \) is quadratic in \( v, \nabla v \) and \( \nabla^2 v \), and has the property that if \( \|v\|_{2,\mu} \) is small, then
\[ \|Q(v)\|_{0,\mu} \leq C\|v\|_{2,\mu}^2. \] (2.7)
Now, rewriting \( \mathcal{N}(v, \nabla v, \nabla^2 v) = 0 \) using (2.6) gives
\[ v = G_P(-Q(v)), \] (2.8)
where \( G_P = (\Delta_{\mathbb{R}^2} - 1)^{-1} \) is the Green function of the Jacobi operator.

We assume initially only that \( v \to 0 \) at infinity in \( P \), but without any particular rate. We first show that \( v \) decays at some exponential rate; this is done using the maximum principle. The second and final step is to obtain the asymptotic formula (2.4).

To begin, using (2.5) and (2.7), the following is true: there exists a constant \( C_1 > 0 \) such that, given any \( \delta_0 > 0 \) sufficiently small, there exists \( R_0 \geq 1 \) so that if \( \delta < \delta_0 \), \( R > R_0 \) and \( |v| < \delta \) for all \( r \geq R \) then \( \sup |Q(v)| \leq C_1 \delta^2 \).

Now, define \( w = ae^{-r} + b \). This satisfies \( L_P w = -ar^{-1}e^{-r} - b \). Suppose that \( \delta < \delta_0,1 \) and \( R > R_0 \) are such that \( \sup_{r \geq R} |v| = \delta \) is attained at \( r = R \), and choose the coefficients \( a \) and \( b \) so that \( ae^{-R} + b \geq \delta \) and \( b \geq C_1 \delta^2 \); to be specific, we take \( b = C_1 \delta^2 \) and \( a = \delta(1 - C_1 \delta)e^R \). Then \( v - w \leq 0 \) when \( r = R \), and furthermore (taking \( \delta \leq 1/C_1 \)),
\[ L_P(v - w) = -Q(v) + ar^{-1}e^{-r} + b \geq -Q(v) + C_1 \delta^2 \geq 0, \]
where we drop the middle term since \( ar^{-1}e^{-r} > 0 \). Thus \( v - w \) is a subsolution of the equation which is negative at \( r = R \) and is bounded as \( r \geq R \), hence \( v - w \leq 0 \) for all \( r \geq R \). This implies that
\[ v(R+1,\theta) \leq w(R+1) = \delta(1 - C_1 \delta)e^Re^{-R-1} + C_1 \delta^2 = \delta \left( (1 - C_1 \delta)e^{-1} + C_1 \delta \right). \]
Since \( C_1 \) is independent of \( \delta \), we can choose \( \delta \) so small that \( (1 - C_1 \delta)e^{-1} + C_1 \delta < \frac{1}{2} \), and hence \( v(R+1,\theta) \leq \frac{1}{2} \delta \). In other words, we see that
\[ \sup_{r=R+1} |v| \leq \frac{1}{2} \sup_{r=R} |v|, \]
for all \( R \geq R_0 \), or equivalently \( |v(r,\theta)| \leq Ce^{-mr} \) for some \( m > 0 \). This completes the first step.

Now, by local a priori estimates, if \( A(\rho) \) is the annulus \( \{ \rho \leq r \leq \rho + 1 \} \), then
\[ ||v||_{2,\mu; A(\rho)} \leq Ce^{-m\rho}, \] and hence \( |Q(v)| \leq C_2 e^{-2m\rho} \) for all \( r \geq R_0 \). Assuming that \( m < 1 \), we use the maximum principle again, this time with \( w = e^{-\beta r} \) for some \( \beta \in (m, \min \{1,2m\}) \). Since
\[ L_P w = (\beta^2 - r^{-1} \beta - 1)e^{-\beta r} < (\beta^2 - 1)e^{-\beta r}, \]
we obtain $L_P(v - C_3 w) \geq -Q(v) + C_3(1 - \beta^2)e^{-\beta r} \geq 0$ for all $r \geq R_0$; in addition
$v - C_3 w \leq 0$ along $r = \rho$ for $C_3$ sufficiently large, and $v - C_3 w \to 0$ as $r \to \infty$. We conclude that $v \leq C_3 e^{-\beta r}$ for $r \geq R_0$.

This argument can be iterated until we conclude that $v \leq C_4 e^{-(1-c)r}$ for some very small $\epsilon > 0$, and hence $|Q(v)| \leq C_5 e^{-2(1-c)r}$, and then that $||Q(v)||_{0,\nu;A(0)} \leq C_6 e^{-2(1-c)\rho}$ as well.

Now write $v = G_P(-Q(v))$ as in (2.8). We use the explicit formula

$$G_P((s, t), (s', t')) = \frac{1}{4\pi}K_0(\sqrt{|s - s'|^2 + |t - t'|^2}).$$

(2.9)

Here $K_0(r)$ is the Bessel function of imaginary argument, see [3], which has the well-known asymptotics

$$K_0(r) \sim \log r \text{ as } r \searrow 0,$$

$$K_0(r) \sim r^{-\frac{1}{2}}e^{-r} + O(r^{-\frac{3}{2}}e^{-r}) \text{ as } r \nearrow \infty$$

(2.10)

(we are omitting the normalizing constant $(4\pi)^{-\frac{1}{2}}$ for simplicity.) It is a straightforward exercise to check that if $f$ is continuous and $|f| \leq Ce^{-2(1-c)r}$, then

$$v = G_P f = \int_{\mathbb{R}^2} G_P((s, t), (s', t')) f(s', t') \, ds' \, dt'$$

$$= A(\theta) e^{-r/2}e^{-r} + O(r^{-3/2}e^{-r}),$$

and if $f \in C^\infty$, then $A \in C^\infty(S^1)$. We refer to [16] for an explanation of the linear mapping $f(s, t) \mapsto A(\theta)$ (it is the adjoint of the Poisson operator and is closely related to the scattering operator for $L_P$).

To complete the argument, suppose that $v > 0$. Since $A(\theta)e^{-r/2}e^{-r}$ dominates the expansion for $r$ large, clearly $A(\theta) > 0$.

\begin{flushright}
$\square$
\end{flushright}

**Geometric Jacobi fields:** We now describe the special family of global Jacobi fields on the horizontal catenoid $K_\eta$ generated by the ‘integrable’, or geometric, deformations of $K_\eta$. In other words, these Jacobi fields are tangent at $K_\eta$ to families of horizontal catenoids.

We have already described the space $\mathcal{M}_K$ of all horizontal catenoids which are symmetric about the plane $t = 0$. Indeed, there is a unique such catenoid associated to any two geodesics $\gamma_\pm$ in $\mathbb{H}^2$ with $0 < \text{dist}(\gamma_+, \gamma_-) = \eta < \eta_0$. Thus $\mathcal{M}_K$ is identified with an open subset of the space of distinct four-tuples of points on $S^1$: writing any such four-tuple in consecutive order around $S^1$ as $(\zeta_{-1}, \zeta_{-2}, \zeta_{+1}, \zeta_{+2})$, then we let $\gamma_{\pm}$ be the unique geodesic connecting $\zeta_{\pm,1}$ to $\zeta_{\pm,2}$. Note that we do not allow arbitrary four-tuples simply because the distances between these geodesics must be less than $\eta_0$. In any case, $\dim \mathcal{M}_K = 4$.

There are a few different ways to describe the complete family of horizontal catenoids (symmetric about $\{t = 0\}$). First we can vary the points $\zeta_{\pm, \ell}$ independently. Second, we can transform $K_\eta$ using the three-dimensional space of isometries of $\mathbb{H}^2$, and then, to obtain the entire four-dimensional family, we augment this by the extra deformation
ample, if we vary only one end of one of the geodesics. The corresponding Jacobi field decays exponentially in all directions but one. For example, if we vary only \( \zeta_{+,2} \), then this Jacobi field decays exponentially in all directions at infinity on \( P_- \), while on \( P_+ \), it decays exponentially as \( s \to -\infty \) but grows exponentially as \( s \to +\infty \) (we assume that \( s \) increases as we move along \( \gamma_+ \) from \( \zeta_{+,1} \) to \( \zeta_{+,2} \)).

In computing the infinitesimal variations here, note that if \( K_\eta(\epsilon) \) is a one-parameter family of horizontal catenoids as described here, with \( K_\eta(0) = K_\eta \), then for \( \epsilon \neq 0 \) we can write \( K_\eta(\epsilon) \) as a normal graph over some proper subset of \( K_\eta \). However, as \( \epsilon \to 0 \), this proper subset fills out all of \( K_\eta \), and hence the derivative of the normal graph function at \( \epsilon = 0 \) is defined on the entire surface.

Denote by \( \Phi_{\pm,\ell} \) the Jacobi field generated by varying only the one point \( \zeta_{\pm,\ell} \), and note that each \( \Phi_{\pm,\ell} \sim e^{r \cos \theta} \). For any four real numbers \( E_{\pm,\ell} , \ell = 1, 2 \), we define

\[
\Phi_E = \sum_{\pm,\ell} E_{\pm,\ell} \Phi_{\pm,\ell},
\]

**\( K_\eta \) as a horizontal bigraph:** The geometric Jacobi fields can be used to show that \( K_\eta \) is a horizontal bigraph in two distinct directions: over the vertical plane \( \gamma_0 \times \mathbb{R} \) and also over the vertical plane \( \Gamma \times \mathbb{R} \). These two new graphical representations were also obtained in the recent paper [5] using an Alexandrov reflection argument. We present a separate argument using these Jacobi fields since it is somewhat less technical. Note that the assertion about horizontal graphicality must be clarified first since there are two geometrically natural ways of writing a surface with a vertical end in \( \mathbb{H}^2 \times \mathbb{R} \) as a horizontal graph over a vertical plane. Indeed, let \( \gamma(s) \) be an arclength parametrized geodesic in \( \mathbb{H}^2 \). We can then coordinatize \( \mathbb{H}^2 \) using Fermi coordinates off of \( \gamma \), i.e. \((s, \sigma) \mapsto \exp_{\gamma(s)}(s\nu(s))\) (where \( \nu \) is the unit normal), or else by \((s, \sigma) \mapsto D_{\sigma}(\gamma(s))\), where \( D_{\sigma} \) is the one-parameter family of isometries of \( \mathbb{H}^2 \) which are dilations along the geodesic \( \gamma^\perp \) orthogonal to \( \gamma \) and meeting \( \gamma \) at \( \gamma(0) \). We use the latter, and then say that a curve is a graph over \( \gamma \) in the direction of \( \gamma^\perp \) if \( \sigma = f(s) \). Hence \( f \equiv \text{const.} \) corresponds to a geodesic \( \gamma' \) which is hyperparallel to \( \gamma \) and perpendicular to \( \gamma^\perp \). This transfers immediately to the notion of a horizontal graph over \( \gamma \times \mathbb{R} \) in the direction of \( \gamma^\perp \) in \( \mathbb{H}^2 \times \mathbb{R} \).

Now, recall the two orthogonal geodesics \( \Gamma \) and \( \gamma_0 \) (see Figure 1). The vertical plane \( \gamma \times \mathbb{R} \) fixed by \( R_\alpha \) (resp. \( R_\beta \)) bisects \( K_\eta \), decomposing it into two pieces denoted by \( K_\eta^{\alpha^+} \) and \( K_\eta^{\beta^+} \), which are interchanged by this reflection. The result of Hauswirth, Nelli, Sa Earp and Toubiana [5] Lemmas 3.1 and 3.2] is the following:

**Proposition 2.3.** For each \( \eta \in (0, \eta_0) \), the surface \( K_\eta \) decomposes as \( K_\eta^{\alpha^+} \cup K_\eta^{\alpha^-} \) and \( K_\eta^{\beta^+} \cup K_\eta^{\beta^-} \), with each half interchanged by \( R_\alpha \) and \( R_\beta \), respectively, and where \( K_\eta^{\alpha^+} \) is a horizontal graph in the direction of \( \Gamma \) over some portion of the vertical plane \( \gamma_0 \times \mathbb{R} \) while \( K_\eta^{\beta^+} \) is a horizontal graph in the direction of \( \gamma_0 \) over some portion of the vertical plane \( \Gamma \times \mathbb{R} \).
As noted, we sketch an independent proof of this.

**Proof.** First, notice that the first assertion in Proposition 2.3 is equivalent to the fact that the Jacobi field $\Phi_\eta$ generated by dilations along $\Gamma$ is strictly positive on $K^{\eta, +}_\eta$ and vanishes along the fixed point set of $R_\eta$; similarly, the second assertion is equivalent to claiming that the Jacobi field $\Phi_s$ generated by dilations along $\gamma_0$ is strictly positive on $K^{\eta, +}_\eta$ and vanishes along the fixed point set of $R_s$.

The proof has two steps. We first show that these Jacobi fields have the required positivity property when $\eta$ is very close to the upper limit $\eta_0$. We then show that as we vary $\eta$ from $\eta_0$ down to $0$, they maintain this positivity.

We begin by asserting that the limiting Scherk surface $K_{\eta_0}$ is a horizontal graph over $\Gamma \times \mathbb{R}$ and also over $\gamma_0 \times \mathbb{R}$. In fact, this surface has a symmetry obtained by rotating by $\pi/2$ and flipping $t \mapsto -t$; this interchanges these two graphical representations. This can be proved by a simple Alexandrov reflection argument: Consider the family of geodesics $\gamma_\sigma$ perpendicular to $\Gamma$ and intersecting it at $\Gamma(\sigma)$ (where $\Gamma(0) = \Gamma \cap \gamma_0$). The plane $\gamma_\sigma \cap \mathbb{R}$ only intersects $K_{\eta_0}$ when $\sigma < \eta_0/2$, and for $\sigma$ just slightly smaller, the reflection of the ‘smaller’ portion of $K_{\eta_0}$ across this vertical plane does not intersect the other component. Pushing $\sigma$ lower, it is standard to see that these two half-surfaces do not intersect until $\sigma = 0$, in which case they coincide. These planes of reflection are the images of $\gamma_\eta \times \mathbb{R}$ with respect to dilation along $\Gamma$, so we deduce that the vector field $X$ generated by this dilation is everywhere transverse to the component $K^{\eta, +}_\eta$ of $K_{\eta_0}$ on one side of this plane of symmetry. Note finally that the angle between $X$ and $K^{+, \eta}_\eta$ is bounded below by a positive constant if we remain a bounded distance away from $\partial K^{+, \eta}_\eta$.

Now recall that an appropriate vertical translate of $K_\eta$ converges locally uniformly in $C^\infty$ to $K_{\eta_0}$, and indeed this convergence is uniform in the half-plane $t \geq -C$ for any fixed $C$. It is then clear that the angle between $X$ and $K^{\eta, +}_\eta \cap \{t \geq -C\}$ is also positive everywhere when $\eta$ is sufficiently close to $\eta_0$. Since $K_\eta$ is invariant by $R_\eta$, this finishes the first step.

For the second step, to be definite consider $\Phi_\eta$, and let us study what happens as $\eta$ varies in the interval $(0, \eta_0)$. We use that $L_\eta \Phi_\eta = 0$ and $\Phi_\eta$ is nonnegative on $K^{\eta, +}_\eta$ for $\eta$ close to $\eta_0$, vanishing only on the boundary, and by the Hopf boundary point lemma, has strictly positive normal derivative there. As $\eta$ decreases, $\Phi_\eta$ must remain strictly positive in the interior; the alternative would be that it develops some interior zeroes or else its normal derivative vanishes at the boundary while the function still remains nonnegative in the interior, and both contradict the maximum principle. Note that we are using two additional facts: first, we use the form of the maximum principle which states that a nonnegative solution of $(\Delta + V)u = 0$ cannot have an interior zero, regardless of the sign of $V$; we also use that because of the graphical representation of the ends, it is clear that $\Phi_\eta$ is bounded away from $0$ outside a compact set. This proves that $\Phi_\eta > 0$ on $K^{\eta, +}_\eta$ for all $\eta \in (0, \eta_0)$, which shows that this half remains graphical.

The case of the Jacobi field $\Phi_s$ is quite similar. Taking into account the asymptotic behavior of $K_{\gamma_0}$, it is not hard to see that there exists a constant $T \gg 0$ so that $K_{\eta} \cap \{|t| > T\}$ is a horizontal graph over the vertical plane $\Gamma \times \mathbb{R}$, $\forall \eta \in (0, \eta_0)$. We can then apply the same argument as in the previous paragraphs to $K_\eta \cap \{|t| \leq T\}$. □
Fluxes Closely related to the geometry in the last subsection is the computation of the flux homomorphism. We recall that if $\Sigma$ is an oriented minimal surface in an ambient space $(Z, g)$, then its flux is a linear mapping $F : H_1(\Sigma) \times K(Z, g) \to \mathbb{R}$, where $K(Z, g)$ is the space of Killing vector fields on $Z$, i.e. infinitesimal generators of one-parameter families of isometries. The definition is simple: if $c \in H_1(\Sigma)$ is a homology class represented by a smooth oriented closed curve $\gamma$ and if $X \in K(Z, g)$, then $F(c, X) = \int_{\gamma} X \cdot \nu ds$, where $\nu$ is the unit normal to $\gamma$ in $\Sigma$. This is only interesting when the ambient space $Z$ admits Killing fields, but this is certainly the case in our setting. Indeed, $K(\mathbb{H}^2 \times \mathbb{R})$ (with the product metric) is four-dimensional: there is one Killing field $X_t$ generated by vertical translation, and a three-dimensional space of Jacobi fields on $\mathbb{H}^2$ which lift to the product to act trivially on the $\mathbb{R}$ factor. If $K_\eta$ is a horizontal catenoid and if $o = \gamma_0 \cap \Gamma \in \mathbb{H}^2$ is its 'center', then this three-dimensional space is generated by the infinitesimal rotation $X_R$ around $o$, and the infinitesimal dilations $X_{\gamma_0}$ and $X_{\Gamma}$ along $\gamma_0$ and $\Gamma$, respectively.

The first homology (with real coefficients), $H_1(K_\eta)$, is one-dimensional and is generated by the loop $(\gamma_0 \times \mathbb{R}) \cap K_\eta$. Thus it suffices to consider $F([\gamma], X_j)$ where $X_j = X_t$, $X_R$, $X_{\gamma_0}$ or $X_{\Gamma}$.

**Proposition 2.4.** The quantity $F([\gamma], X_j)$ vanishes when $X = X_t$, $X_R$ or $X_{\gamma_0}$, and is nonzero when $X = X_{\Gamma}$.

**Proof.** The vector field $X_t$ is odd with respect to the reflection $R_t$; similarly, $X_R$ and $X_{\gamma_0}$ are odd with respect to one or more of the reflections $R_o$, $R_s$. Since the choice of generator $\gamma$ for $H_1$ is invariant under all three reflections, it is easy to see that $F([\gamma], X) = 0$ when $X$ is any one of these three vector fields. However, $X_{\Gamma}$ is a positive multiple of $\nu$ at every point of $\gamma$, so that $F([\gamma], X_{\Gamma}) > 0$, as claimed.

We do not actually compute the value of this one nonvanishing flux. \[\square\]

Unlike many other gluing constructions for minimal surfaces, these fluxes turn out to play no interesting role in the analysis below. This traces, ultimately, to the fact that we will be gluing together copies of horizontal catenoids and these are already ‘balanced’. We explain this point further at the end of \S 5.

**Spectrum of the Jacobi operator:** We now study the $L^2$ spectrum of the Jacobi operator $L_\eta$. By the general considerations described above,

$$\text{spec}(-L_\eta) = \{\lambda_j(\eta)\}_{j=1}^N \cup [1, \infty).$$

This ray consists of absolutely continuous spectrum, while the discrete spectrum all lies in $(-\infty, 1)$; note that, even counted according to multiplicity, the number of eigenvalues may depend on $\eta$.

Our main result is the following:
**Proposition 2.5.** For each $\eta \in (0, \eta_0)$, the only one of the eigenvalues of $-L_\eta$ which is negative is $\lambda_0(\eta)$, and only $\lambda_1(\eta) = 0$. All the remaining eigenvalues are strictly positive. The ground-state eigenfunction $\phi_0 = \phi_0(\eta)$ is even with respect to all three reflections, $R_t$, $R_s$ and $R_o$; the eigenfunction $\phi_1$, which is the unique $L^2$ Jacobi field, is generated by vertical translations and is odd with respect to $R_t$ but even with respect to $R_s$ and $R_o$. In particular, if we restrict $-L_\eta$ to functions which are even with respect to $R_t$, then $L_\eta$ is nondegenerate.

**Proof.** We can decompose the spectrum of $-L_\eta$ into the parts which are either even or odd with respect to each of the isometric reflections $R_t$, $R_s$ and $R_o$. Indeed, for each such reflection, there is an even/odd decomposition

$$L^2(K_\eta) = L^2(K_\eta)_{j\text{-ev}} \oplus L^2(K_\eta)_{j\text{-odd}}, \quad j = t, s, o.$$ 

The reduction of $-L_\eta$ to the odd part of any one of these decompositions corresponds to this operator acting on functions on the appropriate half $K_\eta^{j+, -}$ of $K_\eta$ with Dirichlet boundary conditions.

Our first claim is that the restriction of $-L_\eta$ to $L^2(K_\eta)_{j\text{-odd}}$ with $j = s, o$ is strictly positive, and is nonnegative if $j = t$, with one-dimensional nullspace spanned by the Jacobi field $\Phi_t$ generated by vertical translations.

To prove this, note first that since $\Phi_t \in L^2(K_\eta)_{t\text{-odd}}$ and $\Phi_t$ is strictly positive on $K_\eta^{t+}$, it must be the ground state eigenfunction for this reduction and is thus necessarily simple, with all the other eigenvalues strictly positive.

On the other hand, we have proved above that $\Phi_s$ and $\Phi_o$ are strictly positive solutions of this operator on the appropriate halves of $K_\eta$, vanishing on the boundary, but of course do not lie in $L^2$. We shall invoke the following Lemma.

**Lemma 2.6.** Consider the operator $-L = -\Delta + V$ on a Riemannian manifold $M$, where $V$ is smooth and bounded. Assume either that $M$ is complete, or else, if it has boundary, then we consider $-L$ with Dirichlet boundary conditions at $\partial M$. Suppose that there exists an $L^2$ solution $u_0$ of $Lu_0 = 0$ such that $u_0 > 0$, at least away from $\partial M$. If $v$ is any other solution of $Lv = 0$ with $v > 0$ in $M$ and $v = 0$ on $\partial M$, then $v = c u_0$ for some constant $c$.

**Remark 2.7.** We can certainly relax the hypotheses on $V$. The proof below is from the paper of Murata [19]; the result appears in earlier work by Agmon, and is proved by different methods in [24, Theorem 2.8] and [22, Ch. 4, Theorem 3.4].

**Proof.** It is technically simpler to work on a compact manifold with smooth boundary, so let $\Omega_j$ be a sequence of nested, compact smoothly bounded domains which exhaust $M$, and in the case where $\partial M \neq \emptyset$, assume that $\overline{\Omega_j} \cap \partial M = \emptyset$ for all $j$. The last condition is imposed since it is convenient to have that $v$ is strictly positive on the closure of each $\Omega_j$.

It is well-known that the lowest eigenvalue $\lambda_j^0$ of $-L$ with Dirichlet boundary conditions on $\Omega_j$ converges to the lowest Dirichlet eigenvalue $\lambda_0$ of $-L$ on all of $M$ (indeed, this follows from the Rayleigh quotient characterization of the lowest eigenvalue). We are assuming that $\lambda_0 = 0$, so by domain monotonicity, $\lambda_j^0 \searrow 0$. 

13
Now choose a nonnegative (and not identically vanishing) function \( \psi \in C^\infty_0(\Omega_0) \) and define \(-L_k = -L - \frac{1}{k} \psi \) for any \( k \in \mathbb{R}^+ \). Denoting the lowest eigenvalue of this operator on \( \Omega_j \) by \( \lambda_0^{j,k} \), then by the same Rayleigh quotient characterization, we have that \( \lambda_0^{j,k} \leq \langle -L_k u, u \rangle \) for any fixed \( u \in H_0^1(\Omega_j) \). In particular, inserting the ground state eigenfunction \( \tilde{u}_0 \) for \(-L \) on \( \Omega_j \), we obtain

\[
\lambda_0^{j,k} \leq \lambda_0^j - \frac{1}{k} \int_{\Omega_j} \psi |\tilde{u}_0|^2 \, dV_g.
\]

In particular, fixing \( k > 0 \), then since the first term on the right can be made arbitrarily close to 0 by assumption, we can choose \( j \) so that \( \lambda_0^{j-1,k} > 0 \) and \( \lambda_0^{j,k} \leq 0 \). This is because the integral in the second term on the right is bounded away from zero, which holds because \( \tilde{u}_0^j \leq \tilde{u}_0^{j+1} \) on the support of \( \psi \) (this can be proved using the maximum principle for \(-L - \lambda_0^{j+1} \lambda \) to compare \( \tilde{u}_0^j \) and \( \tilde{u}_0^{j+1} \) on the smaller domain \( \Omega_j \)). If we recall also that the eigenvalue \( \lambda_0^{j,k} \) depends continuously (in fact, analytically) on \( k \), then we can adjust the value of \( k \) slightly to a nearby value \( k_j \) so that \( \lambda_0^{j,k_j} = 0 \). Clearly \( k_j \to \infty \). We have thus obtained a solution \( u_0^j > 0 \) of \(-L_{k_j} u_0^j = 0 \) on \( \Omega_j \) with \( u_0^j = 0 \) on \( \partial\Omega_j \).

Since the solution \( v \) is strictly positive, we have that \( \Delta \log v = V - |\nabla \log v|^2 \). Now, using that \( u_0^j \) vanishes on \( \partial\Omega_j \), we compute that

\[
\int_{\Omega_j} |\nabla \left( u_0^j/v \right)|^2 v^2 \, dV_g = \int_{\Omega_j} |\nabla u_0^j|^2 - \nabla (u_0^j)^2 \cdot \nabla \log v + (u_0^j)^2 |\nabla \log v|^2 \, dV_g
\]

\[
= \int_{\Omega_j} |\nabla u_0^j|^2 + (u_0^j)^2 (V - |\nabla \log v|^2) + (u_0^j)^2 |\nabla \log v|^2 \, dV_g
\]

\[
= \int_{\Omega_j} u_0^j (-\Delta + V) u_0^j \, dV_g = \frac{1}{k_j} \int_{\Omega_j} \psi (u_0^j)^2 \, dV_g.
\]

Normalizing so that \( ||u_0^j||_{L^2} = 1 \), then it is straightforward to show that \( u_0^j \to u_0 \) on any compact subdomain of \( M \). Since the right hand side of this equation tends to 0, so does the left, hence in particular the integral of \( |\nabla (u_0/v)|^2 \) over any fixed \( \Omega_j \), vanishes, i.e. \( v = cu_0 \) as claimed. \( \square \)

This Lemma implies that it is impossible for \(-L_0 \) to have lowest eigenvalue equal to 0 on either of the subspaces \( L^2(K_j)_{s-odd} \), since if this were the case, then we could use the corresponding eigenfunction as \( u_0 \) in Lemma 2.6 and let \( v = \Phi_j \) to get a contradiction since \( \Phi_j \notin L^2 \).

We shall justify below that when \( \eta \) is very close to its maximal value \( \eta_0 \), the lowest eigenvalue of \(-L_0 \) on \( L^2(K_j)_{s-odd} \) is strictly positive. Using the continuity of the ground state eigenvalue as \( \eta \) decreases combined with the argument above, we see that this lowest eigenvalue can never be negative on any one of these odd subspaces, and the only odd \( L^2 \) Jacobi field is \( \Phi_j \). This proves the claim.

We have finally reduced to studying the spectrum of \(-L_0 \) on \( L^2(K_j)_{ev} \), i.e. the subspace which is even with respect to all three reflections (we call this “totally even”). Because of the existence of an \( L^2 \) solution of \( L_0 u = 0 \) which changes signs, namely
As a first step, we first prove that \( \lambda_0(\eta) \not\nearrow 0 \) as \( \eta \nearrow \eta_0 \). Recall that in this limit, \( K_\eta \) converges (once we translate vertically by an appropriate distance) to the limiting Scherk surface \( K_{\eta_0} \). Moreover, \( K_{\eta_0} \) is strictly stable because the Jacobi field \( \Phi_1 \) generated by vertical translation is strictly positive on it.

Now suppose that \( \lambda_0(\eta) \leq -c < 0 \). When \( \eta \) is sufficiently close to \( \eta_0 \), we can construct a cutoff \( \tilde{\phi}_0(\eta) \) of the corresponding eigenfunction \( \phi_0(\eta) \) which is supported in the region \( t > 0 \) (we are still assuming that \( K_\eta \) is centered around \( t = 0 \)); this function lies in \( L^2 \) and regarding it as a function on \( K_{\eta_0} \), it is straightforward to show that

\[
\frac{\int_{K_{\eta_0}} (-L_{\eta_0} \tilde{\phi}_0) \tilde{\phi}_0}{\int_{K_{\eta_0}} |\tilde{\phi}_0|^2} \leq -c/2 < 0.
\]

This contradicts the strict stability of \( K_{\eta_0} \), and hence proves that \( \lambda_0(\eta) \not\nearrow 0 \).

Now suppose that there is some sequence \( \eta^j \not\nearrow \eta_0 \) and a corresponding sequence of eigenvalues \( \lambda^j \in (\lambda_0(\eta^j), 0) \) and eigenfunctions \( \phi^j \in L^2(K_{\eta^j})_{-\text{odd}} \), \( j = s, o \). We know that \( \lambda^j \not\nearrow 0 \). Suppose that the maximum of \( |\phi^j| \) is attained at some point \( p^j \in K_{\eta^j} \). Normalize by setting \( \tilde{\phi}^j = \phi^j / \sup |\phi^j| \) and take the limit as \( \ell \to \infty \). Depending on the limiting location of \( p^j \), we obtain a bounded solution of the limiting equation on the pointed Gromov-Hausdorff limit of the sequence \( (K_{\eta^j}, p^j) \). There are, up to isometries, only two possible such limits: either the limiting Scherk surface \( K_{\eta_0} \) or else a vertical plane \( P = \gamma \times \mathbb{R} \). In the latter case, the limiting function \( \tilde{\phi} \) satisfies \( L_P \tilde{\phi} = 0 \). However, \( L_P = \Delta_P - 1 \) and there are no bounded solutions of this equation, so this case cannot occur. Therefore, we have obtained a function \( \tilde{\phi} \) on \( K_{\eta_0} \) which is a solution of the Jacobi equation there and which is bounded. We now invoke Theorem 2.1 in [15], which is a result very similar to Lemma 2.6 but instead of assuming that \( v \) is positive, we assume instead that \( v \) is bounded, and then conclude that \( v = c u_0 \) where \( u_0 \) is the positive \( L^2 \) solution. The proof proceeds by a somewhat more intricate cutoff argument than the one above. In any case, this proves that \( \tilde{\phi} \) must equal the unique positive \( L^2 \) Jacobi field on \( K_{\eta_0} \), but this is impossible because of the oddness of \( \phi^j \).
with respect to either $R_s$ or $R_o$.

This completes the proof of the main Proposition. \hfill \Box

3 Families of nearly minimal surfaces

We now describe a collection of families of ‘nearly minimal’ surfaces, exhibiting a wide variety of topological types. In the next section we prove that these can be deformed to actual minimal surfaces, at least when certain parameters in the family are sufficiently large. The geometry of each such configuration is encoded by a finite network of geodesic lines and arcs in $\mathbb{H}^2$. Each complete geodesic $\gamma$ in this network corresponds to a vertical plane $P = P_\gamma = \gamma \times \mathbb{R}$. The geodesic segments connecting these geodesic lines correspond to catenoidal necks connecting the associated vertical planes. The approximate minimal surfaces themselves are constructed by gluing together horizontal catenoids. Thus we take advantage of the existence of these components, the existence of which already incorporates some of the nonlinearities of the problem; this is in lieu of working with the more primitive component set comprised of vertical planes and catenoidal necks. The parameter which measures the extent to which each such configuration is uncoupled is the distance between the finite geodesic segments. Once this distance is sufficiently large, we expect that the approximately minimal surface can be perturbed to be exactly minimal. We prove this here under one extra hypothesis, that the catenoidal neck sizes remain bounded away from zero. The more general case will be handled in a subsequent paper. The joint requirement that the distances between geodesic ‘connector’ arcs be large and that the neck sizes are bounded away from zero imposes restrictions which we describe below.

We now describe all of this more carefully.

Geodesic networks

An admissible geodesic network $F$ (see Fig. 3) consists of a finite set of (complete) geodesic lines $\Gamma = \{ \gamma_\alpha \}_{\alpha \in A}$ and geodesic segments $T = \{ \tau_{\alpha\beta} \}_{(\alpha, \beta) \in A'}$ connecting various pairs of elements in $\Gamma$. Here $A$ is some finite index set and $A'$ is a subset of $A \times A \setminus \text{diag}$ which indexes all ‘contiguous’ geodesics, $\gamma_\alpha$ and $\gamma_\beta$ which are joined by some $\tau_{\alpha\beta}$. We now make various assumptions on these data and set notation:

i) If $\alpha \neq \beta$, then $\text{dist}(\gamma_\alpha, \gamma_\beta) := \eta_{\alpha\beta} \in (0, \eta_0)$, where $\eta_0$ is the maximal separation between vertical planes which support a horizontal catenoid.

ii) The segment $\tau_{\alpha\beta}$ realizes the distance $\eta_{\alpha\beta}$ between $\gamma_\alpha$ and $\gamma_\beta$, and hence is perpendicular to both these geodesic lines.

iii) Set $p_\alpha(\beta) = \tau_{\alpha\beta} \cap \gamma_\alpha$ and $p_\beta(\alpha) = \tau_{\alpha\beta} \cap \gamma_\beta$, and then define

$$D_\alpha = \min_{(\alpha\beta), (\alpha', \beta') \in A'} \{ \text{dist}(p_\alpha(\beta), p_\alpha(\beta')) \}, \quad \text{and} \quad D = \min_\alpha D_\alpha.$$  

This number $D$ is called the minimal neck separation of the configuration $F$.

iv) We also write $\eta := \sup \eta_{\alpha\beta}$, and call it the maximal neck parameter.
We shall be considering sequences of geodesic networks $F_j$ for which the minimal neck separation $D_j$ tends to infinity. Such sequences have two distinct types of behaviour: either all of the $(\eta_{\alpha\beta})_j \geq c > 0$, or else at least some of the $(\eta_{\alpha\beta})_j \to 0$. The main analytic construction below turns out to be fairly straightforward for the first type, but unfortunately the simplest geometries (a relatively small number of ends for a given genus) can only happen in the second setting.

**Proposition 3.1.** Let $F_j$ be a sequence of configurations with $D_j \to \infty$, and suppose that no $F_j$ is contractible. If the cardinalities of the index sets $A(F_j)$ and $A'(F_j)$ (i.e. the number of geodesics and geodesic segments) remain bounded independently of $j$, then at least some of the necksizes $(\eta_{\alpha\beta})_j$ must tend to 0.

**Proof.** By hypothesis, for each $j$ the configuration $F_j$ contains a cycle $c_j$. Referring to the geometry of each $F_j$, it is clear that each side of every $c_j$ is a geodesic segment, and moreover, each $c_j$ is a convex hyperbolic polygon. By hypothesis then we have a sequence of such polygons where the number of sides remains bounded, so we may as well assume that each $c_j$ is a $k$-gon for some fixed $k$. Suppose that all $(\eta_{\alpha\beta})_j \geq c > 0$. Then by hypothesis, the alternating sides of $c_j$ are geodesic segments of length at least $D_j$ and geodesic segments of length lying in the interval $[c, \eta_0]$. However, it is a standard fact in hyperbolic geometry that a geodesic polygon with every other side lying in such an interval must have all sidelengths uniformly controlled, which is a contradiction.

In summary, for any sequence of configurations with fixed nontrivial topology and a fixed number of geodesic lines, at least some of the $\eta_{\alpha\beta}$ must converge to 0.
From geodesic networks to nearly minimal surfaces

To each geodesic network \( \mathcal{F} \) satisfying the properties above we now associate an approximately minimal surface \( \Sigma \). The idea is straightforward: each geodesic line \( \gamma_\alpha \) is replaced by the vertical plane \( P_\alpha = \gamma_\alpha \times \mathbb{R} \), and each geodesic segment \( \tau_{\alpha\beta} \) corresponds to a catenoidal neck connecting \( P_\alpha \) and \( P_\beta \) at the points \( p_\alpha(\beta) \) and \( p_\beta(\alpha) \). The resulting surface is denoted \( \Sigma_{\mathcal{F}} \).

The arguments used below to deform \( \Sigma_{\mathcal{F}} \) to an actual minimal surface are perturbative, so we must construct sequences of nearly minimal surfaces for which the error, which is a quantitative measure of how far \( \Sigma_{\mathcal{F}} \) is from being minimal, tends to zero. To make the error term small, it is necessary to consider a sequence of networks \( \mathcal{F}_j \) where the minimum neck separation \( D_j \) tends to infinity. As proved above, if the necksizes stay bounded away from zero, the number of component pieces must grow with \( j \). Because the proof is much cleaner in this case, we assume that \( (\eta_{\alpha\beta})_j \geq c > 0 \) in all the rest of this paper. The more general case can be treated using techniques similar to those in [11], but we shall address this in a separate paper.

The surface \( \Sigma_{\mathcal{F}} \) is constructed by assigning to each \( \tau_{\alpha\beta} \) a vertical strip in the catenoid \( K_{\eta_{\alpha\beta}} \) which contains a very wide neighbourhood around the neck region. Using that none of the necksizes tend to zero, we prove that the Jacobi operator has a uniformly bounded inverse, acting between certain weighted Hölder spaces.

For each \( \mathcal{F} \), we now show how to construct \( \Sigma_{\mathcal{F}} \). Fix a line \( \gamma_\alpha \) in \( \mathcal{F} \), and enumerate the points \( p_\alpha(\beta) \) along this line consecutively as \( p_{\alpha,1}, \ldots, p_{\alpha,N} \). (The number of such points, \( N = N_\alpha \), depends on \( \alpha \), but for the sake of simplicity, the notation does not record this.) Let \( q_{\alpha,j} \) be the midpoint of the geodesic segment from \( p_{\alpha,j} \) to \( p_{\alpha,j+1} \), \( j = 1, \ldots, N - 1 \) and denote the length of such a segment by \( d_{\alpha,j} \). Hence

\[
\text{dist}(p_{\alpha,j}, q_{\alpha,j}) = \frac{1}{2}d_{\alpha,j}, \quad \text{dist}(p_{\alpha,j}, q_{\alpha,j-1}) = \frac{1}{2}d_{\alpha,j-1}.
\]

Note that each \( d_{\alpha,j} \geq D_\alpha > D \). Finally, let \( S_{\alpha,j} \) denote the vertical strip in \( P_\alpha \) bounded by the two lines \( q_{\alpha,j} \times \mathbb{R} \) and \( q_{\alpha,j+1} \times \mathbb{R} \). For the extreme values \( j = 0 \) and \( N \), let \( S_{\alpha,0} \) be the half-plane in \( P_\alpha \) bounded by \( q_{\alpha,1} \) (on the right) and \( q_{\alpha,N} \) (on the left), respectively.

Now, consider a geodesic segment \( \tau_{\alpha\beta} \in \mathcal{F} \), and write its two endpoints as \( p_{\alpha,j} \) and \( p_{\beta,k} \). Let \( K_{\alpha\beta} \) be the horizontal catenoid with vertical ends \( P_\alpha \sqcup P_\beta \) and parameter \( \eta_{\alpha\beta} \). Writing this catenoid as a horizontal normal graph over the relevant portions of the planes \( P_\alpha \) and \( P_\beta \) (i.e. away from the neck regions), we let \( K_{\alpha\beta}^0 \) denote that portion of the catenoid which includes the neck region and which lies over the strips \( S_{\alpha,j} \) and \( S_{\beta,k} \) by \( K_{\alpha\beta}^c \) (this is possible when \( D \) is large enough).

This ensemble is not quite in final form since the edges of the different truncated horizontal catenoids do not quite match up. Write the corresponding portion of \( K_{\alpha\beta} \) over the strip \( S_{\alpha,j} \) as a normal graph with graph function \( v_{\alpha,j} \). Choose a smooth cutoff function \( \chi_{\alpha,j} \geq 0 \) which equals 1 in the interior of \( S_{\alpha,j} \) at all points which are a distance at least 2 from the boundaries, and which vanishes at all points which are distance at most 1 from these boundaries, and such that \( |\nabla \chi_{\alpha,j}| + (\nabla^2 \chi_{\alpha,j}) \leq 2 \) (again this is possible for \( D \) is large enough). We then let \( K_{\alpha\beta}^0 \) be the slightly modified surface which agrees with \( K_{\alpha\beta}^c \) near the neck region and is the graph of \( \chi_{\alpha,j}v_{\alpha,j} \) over the rest.
of $S_{\alpha,j}$. Of course, this is no longer quite minimal where the modifications have been made.

Our final definition of the approximately minimal surface $\Sigma_F$ in this case, where all neck parameters are bounded below by $c$, is

$$\Sigma_F = \bigcup_{(\alpha\beta) \in A'} K_{\alpha\beta}^0.$$  \hfill (3.1)

**Proposition 3.2.** Let $\mathcal{F}$ be a geodesic network which satisfies the properties i), ii) and iii), and let $\Sigma = \Sigma_\mathcal{F}$ be the associated surface in $\mathbb{H}^2 \times \mathbb{R}$ just constructed. Then $\Sigma$ is smooth and has $H \equiv 0$ except in the vertical strips $Q_{\alpha,j}$ of width 2 around the lines $q_{\alpha,j} \times \mathbb{R}$. In the vertical strip $Q_{\alpha,j}$,

$$\sup_{B_t} ||H||_{2,\mu;B_t} \leq Cr^{-\frac{1}{2}}e^{-r};$$

here $r = \min\{\sqrt{(d_{\alpha,j})^2 + t^2}, \sqrt{(d_{\alpha,j+1})^2 + t^2}\}$ and $B_t$ is the square of width 2 and height 2 centered at $(q_{\alpha,j}, t) \in Q_{\alpha,j}$. The constant $C$ is independent of all parameters in the construction provided $D = \min D_\alpha$ is sufficiently large.

The only point which needs to be checked is the decay of the local Hölder norm of the mean curvature. However, this follows directly from the corresponding estimate for the decay of the horizontal graph functions $v_{\alpha,j}$, see (2.4).

**Examples**

It is possible to construct nearly minimal surfaces as sketched above, assuming that all necksizes $\eta_{\alpha\beta}$ are bounded away from 0, with arbitrary genus, though possibly a large number of ends. Since each plane $P_\alpha$ is diffeomorphic to a once-punctured sphere, we see that $\Sigma_\mathcal{F}$ is a connected sum of such spheres, with one connection corresponding to each geodesic segment $\tau_{\alpha\beta}$.

To carry out the perturbation analysis, we must consider sequences of networks $\mathcal{F}_j$ such that $D(\mathcal{F}_j) \to \infty$. As already explained, this imposes various restrictions. For example, to find a sequence of networks $\mathcal{F}_j$ with precisely one loop, and with $D(\mathcal{F}_j) \to \infty$ and all $\eta_{\alpha\beta} \geq c > 0$, standard formulas from hyperbolic trigonometry show that the number of edges must grow with $j$. One construction is to take a hyperideal polygon in $\mathbb{H}^2$ which is invariant with respect to rotation by $2\pi/j$, by which we mean a collection of $j$ disjoint geodesics with a cyclic ordering and such that the minimal distance between any pair of adjacent geodesics is some fixed number $\eta$. If $\eta$ does not tend to zero, then the only way to have the minimal neck separation tend to infinity is if $j \to \infty$. By contrast, we can find sequences of such networks with $j = 3$, for example, if we let $\eta \to 0$.

**4 Perturbation of $\Sigma_\mathcal{F}$ to a minimal surface**

We now complete the perturbation analysis to show how to pass from the nearly minimal surfaces $\Sigma_\mathcal{F}$ to actual minimal surfaces in $\mathbb{H}^2 \times \mathbb{R}$ when $\mathcal{F}$ is a geodesic network.
with minimal neck separation $D$ sufficiently large, and with a uniform lower bound $\eta_{\alpha\beta} \geq c > 0$ on the neck parameters.

Fixing $\mathcal{F}$, let $\Sigma = \Sigma_{\mathcal{F}}$ and let $\nu$ be the unit normal on $\Sigma$ with respect to a fixed orientation. For any $u \in C^{2,\mu}(\Sigma)$, consider the normal graph over $\Sigma$ with graph function $u$, 

$$\Sigma(u) = \{\exp_q(u(q)\nu(q)), \ q \in \Sigma\}.$$ 

Assuming that all $\eta_{\alpha\beta} \geq c > 0$, then there exists $C = C(c) > 0$ such that if $||u||_{2,\mu} < C$, then $\Sigma(u)$ is embedded.

The surface $\Sigma(u)$ is minimal if and only if $u$ satisfies a certain quasilinear elliptic partial differential equation, $\mathcal{N}(u) = 0$, which calculates the mean curvature of $\Sigma(u)$. (A similar argument was considered in the proof of Proposition 2.2 considering the vertical plane $P$ instead of $\Sigma$.) We do not need to know much about $\mathcal{N}$ except the following. If we write $\mathcal{N}(u) = \mathcal{N}(0) + D\mathcal{N}|_0 + \mathcal{Q}(u)$, then

i) $\mathcal{N}(0) = H_\Sigma$;

ii) the linearization at $u = 0$ is the Jacobi operator of $\Sigma$,

$$D\mathcal{N}|_0 = L_\Sigma = \Delta_\Sigma + |A_\Sigma|^2 + \text{Ric}(\nu, \nu);$$

iii) if $\epsilon$ is sufficiently small and $||u||_{2,\mu} < \epsilon$, then

$$||\mathcal{N}(u)||_{0,\mu} \leq C\epsilon \text{ and } ||\mathcal{Q}(u)||_{0,\mu} \leq C\epsilon^2.$$ 

The equation $\mathcal{N}(u) = 0$ is equivalent to

$$L_\Sigma u = -H_\Sigma - \mathcal{Q}(u). \quad (4.1)$$

The strategy is now a standard one: we shall define certain weighted H"older spaces $X$ and $Y$, and first prove that $L_\Sigma : X \rightarrow Y$ is Fredholm. A more careful analysis shows that, at least when the minimal neck separation $D$ is sufficiently large, this map is invertible and moreover its inverse $G_\Sigma : Y \rightarrow X$ has norm which is uniformly bounded by a constant depending only on the lower bounds $D$ for the minimal neck separation and $c$ for the maximal neck parameter. Given these facts, we then rewrite $\mathcal{N}(u) = 0$ as

$$u = -G_\Sigma(H_\Sigma + \mathcal{Q}(u)), \quad (4.2)$$

and solve this equation by a standard contraction mapping argument.

Somewhat remarkably, in this instance, this argument works almost exactly as stated. The only subtlety is that we must restrict to functions which are even with respect to the vertical reflection $t \mapsto -t$, since this subspace avoids the exponentially decaying element of the nullspace of the Jacobi operator on $\Sigma$.

The basic function spaces are standard H"older spaces $C^{k,\mu}(\Sigma)$ defined using the seminorm

$$[u]_{0,\mu} = \sup_{x \neq x', \dist(x,x') \leq 1} \frac{|u(x) - u(x')|}{\dist(x,x')^\mu}. $$
Although the result could be proved using these spaces alone, we can obtain finer results by including a weight factor, which involves the exponential of a piecewise radial function $R$. On each strip $S_{\alpha,j}$, define a radial function $r_{\alpha,j} = \sqrt{s^2 + t^2}$, where $s$ is the arclength parameter along $\gamma_{\alpha}$ and $s = 0$ corresponds to the point $p_{\alpha,j}$. The functions $r_{\alpha,j}$ and $r_{\alpha,j+1}$ match up continuously at $S_{\alpha,j} \cap S_{\alpha,j+1}$. Now define a function $R$ on $\Sigma$ as follows: on each neck region of every horizontal catenoid set $R \equiv 1$; on the portion of $\Sigma$ which is a graph over $S_{\alpha,j} \setminus \mathcal{O}_{\alpha,j}$ (where $\mathcal{O}_{\alpha,j}$ is some ball which is larger than the projection of the neck region), set $R = r_{\alpha,j}$. It is convenient to replace this function with a slightly mollified version which is smooth everywhere, and which is larger than the projection of the neck region), set

$$R = e^{\kappa R} \alpha,j \in \mathbb{R}$$

which has the property that $R \equiv 1$. On each strip $S$, replace this function with a slightly mollified version which is smooth everywhere, and which is larger than the projection of the neck region), set $R = r_{\alpha,j}$. It is convenient to replace this function with a slightly mollified version which is smooth everywhere, and which has the property that $|\nabla R| + |\nabla^2 R| \leq 2$, so we assume this is the case. Finally, define

$$e^{R} C^{k,\mu}(\Sigma) = \{ u = e^{R} v : v \in C^{k,\mu}(\Sigma) \}.$$

**Proposition 4.1.** Fix any $\kappa \in (-1, 1)$ and $\mu \in (0, 1)$. If $\Sigma$ is any nearly minimal surface, as constructed above, then

$$L_\Sigma : e^{R} C^{2,\mu}(\Sigma) \rightarrow e^{R} C^{0,\mu}(\Sigma)$$

is Fredholm.

**Proof.** If the elliptic operator $L_\Sigma$ has local parametrices with compact remainder on each end of $\Sigma$, then we can patch together these local parametrices to obtain a parametrix on all of $\Sigma$ with similarly good properties. Recall that a local parametrix on a bounded open set $U$ in $\Sigma$ is a continuous linear operator $G_U : \mathcal{E}'(U) \rightarrow \mathcal{D}'(U)$, between the spaces of compactly supported and all distributions on $U$, satisfying

$$L G_U = \text{id} - R, \quad G_U L = \text{id} - R,'$$

where $R$ and $R'$ are smoothing of infinite order, and such that

$$G_U : C^{0,\mu} \cap \mathcal{E}'(U) \rightarrow C^{2,\mu}(U).$$

Similarly, if $E$ is any infinite end of $\Sigma$, then a local parametrix on $E$ is a linear operator $G_E$ which is bounded as a map $e^{R} C^{0,\mu}(E) \rightarrow e^{R} C^{2,\mu}(E)$, and satisfies the analogue of (4.3), where $R$ and $R'$ are again smoothing of infinite order and map into some space of (smooth) functions which have a fixed rate of decay at infinity. Note that both on bounded sets $U$ and on infinite ends $E$, these properties of $R$ and $R'$ ensure that they are compact operators on these weighted Hölder spaces.

Since $L_\Sigma$ is uniformly elliptic, the existence of local parametrices on bounded open sets is standard. The construction of parametrices on the ends of $\Sigma$ uses more, namely that $L_\Sigma$ is ‘fully elliptic’ near infinity, which means that it is strongly invertible there in a sense we make precise below.

Each end of $\Sigma$ has the form $P \setminus \mathcal{O}$ where $P$ is a vertical plane and $\mathcal{O}$ is a large ball of finite radius. The restriction of $L$ to each end is a decaying perturbation of the simple operator $\Delta_{\mathbb{R}^2} - 1$. The Green function for (the restriction to the complement of $\mathcal{O}$ of) this operator is expressed in terms of the modified Bessel function

$$G_{\mathbb{R}^2}(z, z') = c K_0(|z - z'|) \sim c |z - z'|^{-\frac{1}{2}} e^{-|z - z'|} , \text{ as } |z - z'| \rightarrow \infty.$$
It is not hard to check (see [14]) that if $|\kappa| < 1$ and $r=|z|$, then

$$G_{R^2} : e^{\kappa r} C^0,\mu(R^2) \longrightarrow e^{\kappa r} C^2,\mu(R^2).$$

Now write $L_{\Sigma} = \Delta_{R^2} - 1 + F$ where $F$ is a second order operator with smooth coefficients which decay like $e^{-r}$. From this we deduce that

$$L_{\Sigma}G_{R^2} - \text{Id} = R : e^{\kappa r} C^0,\mu(R^2 \setminus \mathcal{O}) \longrightarrow e^{(\kappa - 1)r} C^0,\mu(R^2 \setminus \mathcal{O}).$$

This does not yet compactly include into $e^{\kappa r} C^0,\mu$ since there is no gain of regularity. There are two effective ways to overcome this: first, restricting to the complement of an even larger ball, we can make the norm of this remainder term as small as desired, hence $\text{Id} + R$ can be inverted using a Neumann series. Equivalently, we can use a standard elliptic parametrix construction to modify $G_{R^2}$ by an asymptotic series so that the new modified parametrix satisfies $LG = \text{Id} - R$ where $R$ maps into $e^{(\kappa - 1)r} C^\infty(R^2 \setminus \mathcal{O})$. Either of these methods produces a global parametrix for $L_{\Sigma}$ with compact remainder on each end of $\Sigma$.

Now, cover $\Sigma$ by open sets of the form $P_{\alpha} \setminus \mathcal{O}_{\alpha}$ and one relatively compact open set $\mathcal{U}$. Using the standard elliptic parametrix construction on this bounded set and the parametrices constructed above on each $P_{\alpha}$, we may form a global parametrix as follows. Choose a partition of unity for this open cover, $\{\chi_0, \chi_\alpha\}_{\alpha \in A}$, and for each open set here choose another smooth function $\tilde{\chi}_i$ with support in $\mathcal{U}$ for $i = 0$ and in $P_{\alpha} \setminus \mathcal{O}_{\alpha}$ for $i = \alpha$, such that $\tilde{\chi}_i = 1$ on the support of $\chi_\alpha$. Now define

$$\tilde{G}_{\Sigma} = \tilde{\chi}_0 G_0 \chi_0 + \sum_{\alpha \in A} \tilde{\chi}_\alpha G_\alpha \chi_\alpha.$$

We calculate that

$$L_{\Sigma} \tilde{G}_{\Sigma} = \tilde{\chi}_0 L_{\Sigma} G_0 \chi_0 + \sum_{\alpha} \tilde{\chi}_\alpha L_{\Sigma} G_\alpha \chi_\alpha + [L_{\Sigma}, \tilde{\chi}_0] G_0 \chi_0 + \sum_{\alpha} [L_{\Sigma}, \tilde{\chi}_\alpha] G_\alpha \chi_\alpha = \text{Id} + R_{\Sigma}.$$

We use here that $L_{\Sigma}G_i = \text{Id}$ on the support of $\chi_i$ so the first set of terms on the right is equal to $\sum \tilde{\chi}_i \text{Id} \chi_i = \sum \chi_i \text{Id} = \text{Id}$. The remainder $R_{\Sigma}$ is an operator of order $-1$ with image lying in the union of the supports of the $\nabla \tilde{\chi}_i$, which is a compact set. Hence $R_{\Sigma} : e^{\kappa R} C^0,\mu \rightarrow e^{\kappa R} C^0,\mu$ is a compact operator. A similar calculation shows that $\tilde{G}_{\Sigma} L_{\Sigma} = \text{Id} + R'_{\Sigma}$ is also compact.

This proves the proposition. \qed

The next step is to show that $L_{\Sigma}$ is invertible provided the minimal neck separation $D$ is sufficiently large. This fails of course if $L_{\Sigma}$ acts on the entire space $e^{\kappa R} C^2,\mu(\Sigma)$ because of the exponentially decaying Jacobi field generated by vertical translations. To circumvent this issue, we restrict $L_{\Sigma}$ to the subspace $e^{\kappa R} C^2,\mu(\Sigma)$ of even functions with respect to the reflection $t \mapsto -t$. (Note that we can assume that the radial function $R$ is even.)
Proposition 4.2. Let $\Sigma$ be a nearly minimal surface associated to the geodesic network $\mathcal{F}$. There exists a $D_0 > 0$ such that if the minimal neck separation $D$ is greater than $D_0$, then

$$L_{\Sigma} : e^{\kappa R} C_{\text{ev}}^2(\Sigma) \rightarrow e^{\kappa R} C_{\text{even}}^0(\Sigma)$$

is invertible.

Proof. We have already proved that the mapping $L_{\Sigma}$ is Fredholm on the entire weighted Hölder space, and it is clear that this remains true when restricting to the subspace of even functions. We let $G_{\Sigma}$ denote the generalized inverse, and write

$$L_{\Sigma} G_{\Sigma} - \text{Id} = R_{\Sigma}, \quad G_{\Sigma} L_{\Sigma} - \text{Id} = R'_{\Sigma}$$

where $R_{\Sigma}$ and $R'_{\Sigma}$ are finite rank. In fact, $\text{Tr} R'_{\Sigma} - \text{Tr} R_{\Sigma} = \text{Ind} (L_{\Sigma}) = 0$.

To proceed, we sketch a slightly different version of the parametrix construction. Recall that $\Sigma$ is a union of truncated (and slightly perturbed) horizontal catenoids $K_{\alpha \beta}^0$, on the subspace of even functions. These catenoids are joined along the lines $\{q_{\alpha,j}\} \times \mathbb{R}$, which are at distance at least $D/2$ away from each neck region. In fact,

$$\sup e^{-\kappa R} |H_{\Sigma}| \leq C \sup e^{-\kappa R} R^{-1/2} \leq C e^{-(\kappa+1)D/2} D^{-1/2}.$$ 

Now choose an open cover comprised by slightly larger truncations of these catenoids, a partition of unity $\chi_{\alpha \beta}$ associated to this open cover, and smooth cutoff functions $\tilde{\chi}_{\alpha \beta}$ which are supported in these same open sets and which equal 1 on the support of $\chi_{\alpha \beta}$. Then set

$$\tilde{G}_{\Sigma} = \sum_{(\alpha \beta) \in A'} \tilde{\chi}_{\alpha \beta} G_{\alpha \beta} \chi_{\alpha \beta}.$$

Exactly the same computation as above shows that $L_{\Sigma} \tilde{G}_{\Sigma} - \text{Id} = -\tilde{R}_{\Sigma}$ is compact on $e^{\kappa R} C_{\text{ev}}^0(\Sigma)$, but furthermore has norm $||\tilde{R}_{\Sigma}|| \leq C e^{-(\kappa+1)D/2}$, where $C$ is independent of $D$.

Finally, choosing $D$ sufficiently large, then $\text{Id} - \tilde{R}_{\Sigma}$ is invertible on $e^{\kappa R} C_{\text{even}}^0$, and hence $L_{\Sigma} \tilde{G}_{\Sigma} = \text{Id}$ where

$$G_{\Sigma} = \tilde{G}_{\Sigma} \circ (\text{Id} - \tilde{R}_{\Sigma})^{-1}.$$ 

This shows that $L_{\Sigma}$ is surjective. Since its index is zero (by Proposition 2.5), we conclude that it is injective as well, which concludes the proof.

Corollary 4.3. If $\Sigma$ satisfies all the assumptions of the previous proposition, then the norm of the inverse $G_{\Sigma}$ on $e^{\kappa R} C_{\text{even}}^0$ is uniformly bounded as $D \rightarrow \infty$.

The slightly surprising fact is that these estimates are independent of the topology or number of ends of $\mathcal{F}$ and $\Sigma$, but this is due to the character of the function spaces being used.

Theorem 4.4. Let $\mathcal{F}$ be a geodesic network in $\mathbb{H}^2$ and $\Sigma_{\mathcal{F}}$ the nearly minimal surface constructed from it. If the minimal neck separation $D$ is sufficiently large, then there exists a function $u \in e^{\kappa R} C_{\text{ev}}^2(\Sigma_{\mathcal{F}})$ with $||u||_{2,\mu,\kappa} \leq C e^{-(\kappa+1)D/2} D^{-1/2}$ such that $\Sigma_{\mathcal{F}}(u)$ is an embedded minimal surface which is a small normal graph over $\Sigma_{\mathcal{F}}$. 

23
Proof. We solve $\mathcal{N}(u) = 0$ in the function space $e^{\kappa R}c_{\text{even}}^{2,\mu}$ by rewriting this equation as in (4.2). If $\kappa \in (-1,0)$, then

$$
\|Q(u)\|_{0,\mu,\kappa} \leq C_1\|u\|_{2,\mu,\kappa}^2,
$$

and hence if $\|H^\Sigma\|_{0,\mu,\kappa} \leq A$, then

$$
\|G^\Sigma(H^\Sigma + Q(u))\|_{2,\mu,\kappa} \leq C(A + C_1\|u\|_{2,\mu,\kappa}^2).
$$

If $\|u\|_{2,\mu,\kappa} \leq \beta$, then the right hand side here is bounded by $C(A + C_1\beta^2)$, and $C(A + C_1\beta^2) \leq \beta$ provided we choose $\beta = \lambda A$ for some large $\lambda$ and then let $A$ be very small. With these choices, if we write (4.2) as $u = T(u)$, then $T$ maps the ball of radius $\beta$ in $e^{\kappa R}c_{\text{even}}^{2,\mu}$ to itself. A similar analysis shows that $T$ is a contraction on this ball.

This proves that there is a unique solution to $\mathcal{N}(u) = 0$, and that $\|u\|_{2,\mu,\kappa} \leq \beta$. Finally, since $\kappa < 0$, $\|u\| \leq \beta e^{\kappa R} \leq \beta$, and the derivatives of $u$ are similarly small, which implies that $\Sigma_{J}(u)$ is embedded.

Proposition 4.5. Let $\mathcal{F}_j$ be a sequence of geodesic networks as in Theorem 4.4, in particular the minimal neck separation $D(\mathcal{F}_j) \to \infty$ and $\Sigma_j$ the corresponding minimal surfaces. Suppose that the necksizes $(\eta_{\alpha,\beta})_j$ in the constituent horizontal catenoids all lie in a fixed interval $[c_1, c_2] \subset (0, \eta_0)$. Then for $j$ sufficiently large, $\Sigma_j$ is horizontally nondegenerate.

Proof. Suppose that this is not the case, so that there exists some subsequence $\Sigma_{J'}$, which we immediately relabel as $\Sigma_j$ and a function $\varphi_j \in L^2(\Sigma_j)$ which is even with respect to $R_\ell$ and which lies in the nullspace of the Jacobi operator $L_j$ on $\Sigma_j$. Renormalize $\varphi_j$ to have supremum equal to 1, and suppose that this supremum is attained at a point $p_j \in \Sigma_j$.

Because of the geometry of the $\Sigma_j$, there are only a few possibilities for the pointed Gromov-Hausdorff limit of the sequence $(\Sigma_j, p_j)$. If $p_j$ diverges from all of the neck regions, then the limit is a vertical plane; on the other hand, if $p_j$ remains within a bounded distance of some neck region, then $(\Sigma_j, p_j)$ converges to a horizontal catenoid. In either case, we obtain a bounded function $\varphi$ which lies in the nullspace of the corresponding Jacobi operator $L$. Now, using that $e^{\kappa r}$ is a supersolution of the equation sufficiently far out on any end when $-1 < \kappa < 1$, we easily deduce that a solution which is bounded by $e^{(1-\epsilon)R}$ for any $\epsilon > 0$ is in fact bounded by $e^{-(1-\epsilon)R}$, and in particular lies in $L^2$. This is clearly impossible because of the nondegeneracy of the vertical plane and the horizontal nondegeneracy of the horizontal catenoid.

5 Gluing nondegenerate surfaces

A construction which is closely related to the one in the last section is as follows. Let $\Sigma_1$ and $\Sigma_2$ be two minimal surfaces in $\mathbb{H}^2 \times \mathbb{R}$ with a finite number of vertical ends, each one symmetric with respect to the reflection $R_\ell$, and each one horizontally nondegenerate. Fix a vertical planar end $E_\ell \subset \Sigma_\ell$, and choose a sequence of isometries $\phi_{\ell,j}$ (of the form $\varphi_{\ell,j} \times \text{id}$ where each $\varphi$ is an isometry of $\mathbb{H}^2$) such that $\phi_{\ell,j}(\Sigma_\ell)$
converges to a fixed vertical plane $P = \gamma \times \mathbb{R}$. Parametrizing $\gamma$ as $\gamma(s)$, then we suppose that a half-plane in the end $E_1$ in $\Sigma_{1,j}$ is a horizontal graph over $(-B_{1,j}, \infty) \times \mathbb{R}$ with $B_{1,j} \to \infty$ and with graph function $v_{1,j}$, while a half-plane $E_2$ in $\Sigma_{2,j}$ is a horizontal graph over $(-\infty, B_{2,j}) \times \mathbb{R}$ with $B_{2,j} \to \infty$ and with graph function $v_{2,j}$.

We assume finally that both $v_{\ell,j}$ converge to 0 as $j \to \infty$.

Now let $\Sigma_{1,j}$ be the surface which agrees with $\Sigma_{\ell,j}$ away from the half-plane $(-1, \infty) \times \mathbb{R}$, and where the graph function is modified to be $\chi_1(s) v_{1,j}$, where $\chi_1(s)$ is a smooth monotone decreasing function which equals 1 for $s \leq -1$ and which vanishes for $s \geq 0$. We let $\Sigma_{2,j}$ be a similarly modified version of $\Sigma_{2,j}$.

Finally, let

$$
\Sigma(j) = \left( \Sigma_{1,j} \setminus ((0, \infty) \times \mathbb{R}) \right) \cup \left( \Sigma_{2,j} \setminus ((-\infty, 0) \times \mathbb{R}) \right).
$$

It is clear that $\Sigma(j)$ is exactly minimal outside of the vertical strip $(-1, 1) \times \mathbb{R}$.

Furthermore, it is clear that if $\Sigma_1$ and $\Sigma_2$ carry radial functions $R_1$ and $R_2$ as in the previous section, then we can form a radial function $R(j)$ on $\Sigma(j)$, and define weighted Hölder spaces $e^{cR(j)} C^{k,\mu}(\Sigma(j))$. In terms of these, the mean curvature $H(j)$ of $\Sigma(j)$ tends to zero.

A straightforward modification of the arguments in the preceding section yield a proof of the

**Theorem 5.1.** Let $\Sigma(j)$ be a sequence of nearly minimal surfaces, constructed as above. Assume (as stated earlier) that both $\Sigma_1$ and $\Sigma_2$ are horizontally nondegenerate. Then for $j$ sufficiently large, there exists a function $u \in e^{cR(j)} C^{2,\mu}(\Sigma(j))$ such that the surface $\Sigma(j, u)$, which is the normal graph over $\Sigma(j)$ with graph function $u$, is an embedded, horizontally nondegenerate minimal surface.

One must check first that $\Sigma(j)$ itself is nondegenerate for $j$ large, and then that the norm of the inverse of its Jacobi operator on these weighted Hölder spaces remains uniformly bounded as $j \to \infty$. These facts are both proved by contradiction, and the details of the proofs are very similar to what we have done above. The final step, using a contraction mapping to produce the function $u$ whose graph is minimal, is again done as before.

Notice that if the genera of $\Sigma_1$ and $\Sigma_2$ are $g_1$ and $g_2$, respectively, then $\Sigma(j)$ and hence the minimal surface $\Sigma(j, u)$ has genus $g_1 + g_2$.

We conclude this section with a brief remark about the reason why the fluxes of horizontal catenoids, or of the more general pieces considered in this section, play no role in this gluing. The reason is simply that we are gluing along vertical lines orthogonal to the axis of the catenoid and positioned very far from it. Although these lines are not closed, we may consider them as the limit of a sequence of closed curves which are rectangles lying over regions of the form $\{S_1 \leq s \leq S_2; |t| \leq T\}$ where we let $S_2, T \to \infty$. These curves are homologically trivial, so the flux over them vanishes. Hence there is no need to balance the fluxes of the summands in this construction against one another.
6 Deformation theory

We conclude this paper with a brief analysis of the moduli space of even, properly embedded complete minimal surfaces with finite total curvature in $\mathbb{H}^2 \times \mathbb{R}$. Let $\mathcal{M}_k$ denote the space of all such surfaces with $k$ ends, each asymptotic to a vertical plane, and which are symmetric with respect to the reflection $R_0$.

**Theorem 6.1.** The space $\mathcal{M}_k$ is a real analytic set with formal dimension equal to $2k$. There is a stratum of $\mathcal{M}_k$ consisting of horizontally nondegenerate elements which has dimension exactly equal to $2k$.

**Remark 6.2.** This dimension count agrees with our construction: indeed, $2k$ is precisely the dimension of the space of admissible geodesic networks with $k$ geodesic lines, regardless of the number of ‘cross-piece’ geodesic segments, since in a given network $\mathcal{F}$, each geodesic line $\gamma_\alpha$ has a two-dimensional deformation space, and any small perturbation of the geodesics uniquely determines the corresponding deformations of the geodesic segments $\gamma_{\alpha \beta}$. Note, however, that we are not demanding here that the minimal surfaces be ones that we have constructed. For example, it is conceivable that there exist surfaces whose necks are not centered on the plane of symmetry. This analysis of the deformation space is insensitive to this.

We do not factor out by the 3 dimensional space of ‘horizontal’ isometries of $\mathbb{H}^2 \times \mathbb{R}$. But if we do this, then the dimension count $2k - 3$ agrees with the dimension of the family of minimal surfaces in [18].

**Proof.** The proof is very similar to the ones in [12] and [17] (and in several places since then), so we shall be brief. A different approach to the moduli space theory – for minimal surfaces with finite total curvature and parallel ends – appears in [21], but that relies on a Weierstrass representation which is not available here.

Fix $\Sigma \in \mathcal{M}_k$ and enumerate its vertical planar ends as $\{P_\alpha\}_{\alpha \in A}$, so each $P_\alpha = \gamma_\alpha \times \mathbb{R}$. For any sufficiently small $\epsilon_{\alpha,j} \in \mathbb{R}$, $j = 1, 2$, we can deform $\gamma_\alpha$, and hence $P_\alpha$, by displacing the two endpoints of $\gamma_\alpha$ by these amounts, respectively (relative to a fixed metric on $S^1$). Thus small deformations of the entire ensemble of vertical planes are in correspondence with $2k$-tuples $\epsilon = (\epsilon_{\alpha,1}, \epsilon_{\alpha,2})_{\alpha \in A}$ with $|\epsilon| \ll 1$.

For each such $\epsilon$, let $\Sigma(\epsilon)$ denote a small deformation $\Sigma(\epsilon)$ of the surface $\Sigma = \Sigma(0)$, constructed as follows. For each $\alpha$, write the end $E_\alpha$ of $\Sigma$ as a normal graph over some exterior region $P_\alpha \setminus O_\alpha$ with graph function $v_\alpha$ defined in polar coordinates for $r \geq R_0$. Rotate $P_\alpha$ by the parameters $\epsilon_\alpha$ to obtain a new vertical plane $P_\alpha(\epsilon)$. Using the same graph function $v_\alpha$, now defined on an exterior region in $P_\alpha(\epsilon)$, we obtain the deformed end $E_\alpha(\epsilon)$; this is quite close to the original end $E_\alpha$ over the annulus $\{R_0 + 1 \leq r \leq R_0 + 2\}$, so we can write $E_\alpha(\epsilon)$ as the graph of a function $v_{\alpha,\epsilon}$ defined on this annulus in the original plane $P_\alpha$. Finally, use a fixed cutoff function $\chi_\alpha$ to define $\overline{v}_{\alpha,\epsilon} = \chi_\alpha v_\alpha + (1 - \chi_\alpha) v_{\alpha,\epsilon}$ so that the graph of this new function agrees with the original surface $\Sigma$ for $r \leq R_0 + 1$ and matches up smoothly with $E_\alpha(\epsilon)$ outside this annulus. This defines $\Sigma(\epsilon)$. Denoting its mean curvature function by $H(\epsilon)$, then clearly $H(\epsilon)$ vanishes outside the union of these annuli, hence $H(\epsilon) \to 0$ in $e^{\kappa R}C^2(\Sigma(\epsilon))$ as $|\epsilon| \to 0$.
The remainder of the proof follows the corresponding arguments in [12] and [7] essentially verbatim. When \( \Sigma \) is horizontally nondegenerate, the implicit function theorem produces an analytic function \( \epsilon \mapsto u_\epsilon \) such that the normal graph of \( u_\epsilon \) over \( \Sigma(\epsilon) \) is minimal. This is a real analytic coordinate chart in \( \mathcal{M}_k \) around \( \Sigma \). If \( \Sigma \) is horizontally degenerate, then we can apply a Lyapunov-Schmidt reduction argument to show that there exists a neighbourhood \( \mathcal{U} \) of \( \Sigma \) in some fixed finite dimensional real analytic submanifold \( Y \) in the space of all surfaces (with a fixed weighted Hölder regularity) and a real analytic function \( F : \mathcal{U} \to \mathbb{R} \) such that \( \mathcal{M}_k \cap \mathcal{U} = F^{-1}(0) \cap \mathcal{U} \).
