Density-matrix based determination of low-energy model Hamiltonians from \textit{ab initio} wavefunctions

Hitesh J. Changlani,\textsuperscript{1} Huihuo Zheng,\textsuperscript{1} and Lucas K. Wagner\textsuperscript{1}

\textit{Department of Physics, University of Illinois at Urbana-Champaign, 1110 West Green St, Urbana IL 61801, USA}

\textit{(Dated: April 16, 2015)}

We propose a way of obtaining effective low energy Hubbard-like model Hamiltonians from \textit{ab initio} Quantum Monte Carlo calculations for molecular and extended systems. The Hamiltonian parameters are fit to best match the \textit{ab initio} two-body density matrices and energies of the ground and excited states, and thus we refer to the method as \textit{ab initio} density matrix based downfolding (AIDMD). For benzene (a finite system), we find good agreement with experimentally available energy gaps without using any experimental inputs. For graphene, a two dimensional solid (extended system) with periodic boundary conditions, we find the effective on-site Hubbard $U^*/t$ to be $1.3 \pm 0.2$, comparable to a recent estimate based on the constrained-RPA approximation. For molecules, such parameterizations enable calculation of excited states that are usually not accessible within ground state approaches. For solids, the effective Hamiltonian enables large scale calculations using techniques designed for lattice models.

I. INTRODUCTION

The reliable simulation of systems for which the large-scale physics is not well-approximated by a non-interacting model, is a major challenge in physics, chemistry, and materials science. These systems appear to require a multi-scale approach in which the effective interactions between electrons at a small distance scale are determined, which then leads to a coarse-grained description of emergent correlated physics. This reduction of the Hilbert space is often known as "downfolding". In strongly-correlated systems, the correct effective Hamiltonian is strongly dependent on material-specific properties, motivating the need for a generic accurate method to determine it.

One can loosely categorize downfolding techniques into two strategies. The first strategy is based on performing \textit{ab initio} calculations and then matching them state by state to the effective model. Alternately, some approaches employ a model for the screening of Coulomb interactions, for which the \textit{ab initio} single particle wavefunctions provide the relevant inputs. For the purposes of this manuscript, the umbrella term we use for these strategies is "fitting". Techniques that fall into this class include the constrained density functional theory,\textsuperscript{12} the constrained random phase approximation,\textsuperscript{3} fitting spin models to energies,\textsuperscript{4,5} and efforts by one of us\textsuperscript{6} using reduced density matrices of quantum Monte Carlo calculations. The second class is based on Löwdin downfolding\textsuperscript{7,9} and canonical transformation theory\textsuperscript{10-14}, which involves a sequence of unitary transformations on the bare Hamiltonian, chosen in a way that minimize the size of the matrix elements connecting the relevant low energy (valence) space to the high energy one.

Downfolding by fitting has the advantage that it is conceptually straightforward to perform, although it demands an \textit{a priori} parameterization of the effective Hamiltonian. The methods have been applied to complex bulk systems\textsuperscript{15-20}, but it is only recently that their accuracy is being rigorously checked\textsuperscript{21}. On the other hand, canonical transformations do not need such parameterizations and can discover the relevant terms in an automated way. However, their application to complex materials remains to be carried out and tested.

Here we propose a scheme which aims to capture the "best of both worlds". On the one hand, we retain the simplicity of fitting and on the other we use information from accurate many-body wavefunctions to determine which terms are important. The deviations between \textit{ab initio} and the model properties allows us to assess the quality of the resultant model and to discover relevant physics from the calculation. Simultaneously, the method cannot depend too much on the quality of the \textit{ab initio} solution because of the inherent limitations of accuracy, especially for very big system sizes.

Once an effective model Hamiltonian in the reduced Hilbert space is obtained, it can be used to perform a calculation on a larger system using techniques designed for lattice models\textsuperscript{22-35}. This multi-step modeling procedure is needed since the \textit{ab initio} calculations for a given system size are, in general, computationally more expensive than the equivalent lattice calculations. Large sizes are crucial to study finite size effects, and in turn theoretically establish the presence of a phase. In addition, excited states and dynamical correlation functions have traditionally been difficult in \textit{ab initio} approaches, but have seen progress for lattice model methods\textsuperscript{36-38}.

---

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{downfold.png}
\caption{Schematic for downfolding. The full Hamiltonian $H$ is defined in the space of active (partially occupied), core (mostly occupied) and virtual (mostly unoccupied) orbitals. The objective is to map the physics of the original system to that of the effective one $\tilde{H}$ defined only in the active space.}
\end{figure}
In this paper, we demonstrate a downfolding method that uses data from \textit{ab initio} quantum Monte Carlo techniques to derive an effective coarse-grained Hamiltonian. This method, which we call non-eigenstate \textit{ab initio} density matrix downfolding (N-AIDMD), uses many-body simulations of non-eigenstates to fit an effective low-energy Hamiltonian. We demonstrate that the method can use wave functions of medium quality to derive highly accurate effective Hamiltonians. Along with a few simple examples, we downfold benzene from a 30-electron problem to a 6-electron one and show that the resulting Hamiltonian reproduces the experimental spectrum well. We also show that the method works for extended systems, by applying it to graphene.

II. METHODS

In the present section we discuss the methods we used to generate our \textit{ab initio} data. While most of our discussion is specific to QMC, the quantities used can also be calculated in almost any other wavefunction-based quantum chemistry method.

A. Variational and Fixed Node Diffusion Quantum Monte Carlo

\textit{Ab initio} Quantum Monte Carlo comprises of a suite of methods that efficiently sample the phase space of \( N \) electrons each moving in 3-dimensional real space. When the wavefunction as a function of \( 3N \) coordinates is known, the phase space can be sampled with variational Monte Carlo (VMC) using Metropolis algorithms. For ground state calculations, the Diffusion Monte Carlo (DMC) method, based on imaginary time evolution of the Schrödinger equation, is formally exact but in practice limited by the numerical sign problem. This problem ceases to exist if one knew the exact location of the nodes (zeroes) of the many-body wavefunction. Thus, the optimal strategy for very accurate calculations is to generate a good trial wavefunction, and optimize its parameters to minimize its variational energy. Then, we use this wavefunction to "fix the nodes" (which may only approximately correspond to the exact nodes) and perform a DMC calculation under this constraint. This last variant is called the fixed node DMC (FN-DMC) method and is known to be very accurate for a large variety of systems. While some more details are discussed here, we refer the interested reader to Ref.\cite{46} for an exhaustive review of concepts and applications. All the \textit{ab initio} QMC calculations were carried out with the QWalk package\cite{40}.

A typical QMC calculation was carried out as follows. First, we perform DFT calculations with the B3LYP\cite{41} or PBE functionals\cite{42} using GAMESS\cite{43} for molecules or CRYSTAL\cite{44} for solids. The lowest energy DFT orbitals provide the Slater determinant part of the trial wavefunction. For molecules, a multi-determinantal wavefunction is generated by performing a configuration interaction with singles and doubles excitations (CISD) from the reference Slater determinant. Once this is done, a Jastrow factor is introduced, resulting in the ansatz,

\[
\psi_T(r_1, r_2, ..., r_N) = \mathcal{J} \sum_i d_i D_i \tag{1}
\]

When we desire eigenstates, the full wavefunction (i.e. parameters in the Jastrow \( \mathcal{J} \) and the coefficients \( d_i \) of the determinants \( D_i \) are optimized to get the best possible variational energy within the ansatz chosen) using a technique introduced by Umrigar and coworkers\cite{45} with an efficient implementation by Clark et al.\cite{46}.

The variational energy is calculated via Metropolis sampling of \( |\psi_T|^2 \),

\[
E_{VMC} = \frac{\langle \psi_T | H | \psi_T \rangle}{\langle \psi_T | \psi_T \rangle} = \frac{\int |\psi_T(R)|^2 H\psi_T(R) \psi_T(R) \ dR}{\int |\psi_T(R)|^2 \ dR} \tag{2}
\]

where \( R \) is a compact notation for the \( 3N \) coordinates \((r_1, r_2, ..., r_N)\) and \( H\psi_T(R)/\psi_T(R) \) is the "local energy". With this trial wavefunction we perform FN-DMC to calculate the energy using the mixed (or projected) estimator,

\[
E_{DMC} = \frac{\langle \psi_T | H | \psi \rangle}{\langle \psi | \psi_T \rangle} = \frac{\int \psi_T(R) \psi(R) H\psi_T(R) \psi_T(R) \ dR}{\int \psi_T(R) \psi(R) \ dR} \tag{3}
\]

where \( \psi \equiv \exp(-\beta H)\psi_T \) is obtained by a stochastic projection of \( \psi_T \) under the constraint that \( \psi \) and \( \psi_T \) have the same sign everywhere.

We now discuss measurements in the QMC methods. For a generic operator \( \hat{O} \) the pure (VMC) and mixed estimators are computed as,

\[
\langle \hat{O} \rangle_{VMC} = \frac{\langle \psi_T | \hat{O} | \psi_T \rangle}{\langle \psi_T | \psi_T \rangle} \quad \langle \hat{O} \rangle_{mix} = \frac{\langle \psi_T | \hat{O} | \psi \rangle}{\langle \psi | \psi \rangle} \tag{4}
\]

The mixed estimator of an operator is equal to the pure estimator only in two limits; (1) when \( \psi_T \) is the exact wavefunction or (2) when the operator commutes with the Hamiltonian. In more general situations, higher accuracy can be obtained with the extrapolated estimator\cite{47} for eigenstates,

\[
\langle \hat{O} \rangle_{extrap} = 2\langle \hat{O} \rangle_{mix} - \langle \hat{O} \rangle_{VMC} \tag{5}
\]

For near-eigenstates, all these estimators must approach the same value; in practice, this may not be the case when very high accuracy is needed.

We will construct effective Hamiltonians using the two-body reduced density matrix (2-RDM) elements:
\[
\rho_{ijkl} \equiv \langle c_{i}^{\dagger} c_{j}^{\dagger} c_{k} c_{l} \rangle = \sum_{a \neq b} \int \phi_{a}^{\ast}(r'_{a})\phi_{b}^{\ast}(r'_{b})\phi_{i}(r_{a})\phi_{j}(r_{b})\Psi^{\ast}(R_{ab}^{\prime\prime})\psi(R)dr_{a}^{\prime}\psi_{b}^{\prime}\,dR,
\]

where \(R_{nb}^{\prime\prime} = (r_{1}, r_{2}, r'_{a}, \ldots, r'_{b}, \ldots, r_{N})\) is the set of coordinates with the many-body wavefunction and \(\phi_{i}(r)\) are pre-decided one-particle wavefunctions (orbitals) indexed by compact label \(i(j, k, l)\) which accounts for space and spin. The mixed estimator equivalent of Eq. (6) is obtained like that for the energy. More details of this computation have been previously discussed elsewhere by one of us. The chosen set of orbitals is often localized on the atoms; this property makes it convenient to derive Hubbard-like models. We explain their construction next.

\section{Localized orbitals}

Localized orbitals often provide an intuitive way of understanding an electronic system in terms of electron hops and on-site or inter-site repulsions. Thus, many works have been devoted to this subject; ranging from the Linearized Muffin-Tin Orbital (LMTO) method to the maximally localized Wannier function construction. Orbital localization has also been widely discussed in the quantum chemistry literature.

\begin{figure}[h]
\centering
\includegraphics[width=0.8\textwidth]{localized_orbitals.png}
\caption{(Left) One of the six symmetry equivalent \(\pi\) orbitals in the benzene molecule obtained by localizing three bonding and three anti-bonding orbitals. The 1-RDM computed within QMC confirms that the \(1s\)-like and the \(2p\) \(-\sigma\) orbitals (not shown) are close to fully occupied. Hence only the half filled \(\pi\) orbitals are used to fit a Hubbard-like Hamiltonian. (Right) Representative localized orbitals for the \(4 \times 4\) unit cell of graphene.}
\end{figure}

C. \textbf{Lattice model calculations}

The lattice model calculations for Hubbard models of benzene and graphene at half-filling were carried out with a combination of our own codes and the freely available QUEST determinantal Quantum Monte Carlo package. For the honeycomb lattice half-filled Hubbard model, the determinantal QMC method is sign problem free and the results are exact up to statistical errors. A time step of 0.1 was chosen and \(\beta\) (the imaginary time) was set to 20 for every calculation. Measurements were performed for 5000 sweeps, with an additional 2000 sweeps being used for equilibration.

\section{III. CRITERIA FOR A LOW ENERGY EFFECTIVE HAMILTONIAN}

Our aim is to obtain a low energy effective Hamiltonian defined in the active space of electrons. In this basis, the criteria any effective low energy model Hamiltonian must satisfy are:

(a) The reduced density matrices (RDM) of the ground and excited states obtained from the \textit{ab initio} calculation must match with that of the model calculation.

(b) The energy spectra of the \textit{ab initio} and model systems must match in the energy window of interest.

(c) The model must be detailed enough to capture the essential physics and yet simple enough to avoid overparameterization and overfitting.

The concept of matching RDMs [criterion (a)] has previously appeared in related contexts and in work by one of us. Most physical properties, such as the charge and spin structure factors, are functions of the 2-RDM. Since it is computationally expensive to calculate high-order RDMs, we use the matching condition only on the 2-RDM, \(\rho_{ijkl} = \langle c_{i}^{\dagger} c_{j}^{\dagger} c_{k} c_{l} \rangle\) where \(i, j, k, l\) are orbital indices (including space and spin). This criterion automatically ensures that the combined number of electrons occupying the orbitals is equal to those in the model Hamiltonian. If any input state does not have the expected electron number in the active space, it can not be described by the effective Hamiltonian.

The importance of excited state energies used in the fitting [criterion (b)] is highlighted by the fact that the wavefunctions, and their corresponding two-body density matrices, are invariant to many kinds of terms that enter the Hamiltonian.
For example, the transformation,

$$H' = H + \alpha S^2 + \beta n + \gamma S^2 n$$  \hfill (8)

is, by construction, consistent with all the 2-RDM data for any $\alpha, \beta, \gamma$ for systems which have definite spin symmetry and particle number. Imposing certain physical constraints on the form of the interactions can reduce the need for this criterion. To give a concrete example, consider wavefunction data generated from the ground state of an unfrustrated Heisenberg Hamiltonian in a bipartite lattice,

$$H = J \sum_{\langle i,j \rangle} S_i \cdot S_j,$$

where $\langle i,j \rangle$ refer to nearest neighbor pairs. Then adding $\alpha S^2$ gives the same reduced density matrices for the ground state, as long as $\alpha$ is small enough to not cause energy crossings i.e. not make an original excited state the new ground state. This additional term has the effect of introducing long-range Heisenberg couplings. Moreover, the effective Hamiltonian is not unique: the Lieb-Mattis model\(^{55}\) $H = S_A \cdot S_B$ (where $A(B)$ and $S_{A(B)}$ refer to the sublattice and corresponding spin), is also known to reproduce the low-energy limit of the Heisenberg model. Thus, imposing the requirement that the Hamiltonian has the nearest-neighbor form constrains $\alpha$ to zero and picks one particular model. Similar arguments should apply to extended Hubbard models in homogenous systems where a physical constraint is that the density-density interaction must decrease monotonically with distance between orbitals.

IV. AB INITIO DENSITY MATRIX BASED DOWNFOLDING (AIDMD) PROCEDURES

We now discuss two procedures that use density matrices and energies to calculate parameters entering the effective Hamiltonian, both have been schematically depicted in Fig. 3.

A. Eigenstate AIDMD method

In the first method, schematically depicted in Fig. 3(a), eigenstates from an $ab\ initio$ calculation are used to match density matrices and energies of the corresponding model. The QMC extrapolated estimator is taken to be an accurate representation of the true one. Then the parameters of the model Hamiltonian are obtained by minimizing a cost function that is a linear combination of the energy and density matrix errors,

$$\mathcal{N} \equiv \sum_s (E^a_s - E^m_s)^2 + f \sum_{i,j,k,l} \left( \langle c^+_i c^+_j c_i c_k \rangle^a_s - \langle c^+_i c^+_j c_i c_k \rangle^m_s \right)^2$$  \hfill (9)

where the subscript $s$ is an eigenstate index, $i,j,k,l$ are orbital indices and the superscripts $a$ and $m$ refer to $ab\ initio$ and model calculations respectively. There is no definite prescription for choosing the number $f$; a good heuristic is to choose a value that gives roughly the same size of errors for the two terms that enter the cost function. The cost minimization is performed with the Nelder Mead simplex algorithm.

In practice we found that since the number of available eigenstates and the accuracy of true estimators is limited, a second method discussed next is more suited for downfolding.

B. Non-eigenstate AIDMD method

Consider a set of $ab\ initio$ energy averages $\tilde{E}_s$, i.e. expectation values of the Hamiltonian, and corresponding 1 and 2 body RDMs $\langle c^+_i c_j \rangle_s$, $\langle c^+_i c^+_j c_i c_k \rangle_s$ for arbitrary low-energy states characterized by index $s$. Assume a 2-body Hamiltonian with effective parameters $t_{ij}$ (1-body part) and $V_{ijkl}$ (2-body part) along with a constant term $C$; the total number of parameters being $N_p$. Then for each state $s$, we have the equation,

$$\tilde{E}_s = \langle H \rangle_s = C + \sum_{ij} t_{ij} \langle c^+_i c_j \rangle + \sum_{ijkl} V_{ijkl} \langle c^+_i c^+_j c_i c_k \rangle$$  \hfill (10)

where we have made the assumption that the chosen set of operators corresponding to single particle wavefunctions or orbitals, explain all energy differences seen in the $ab\ initio$ data. The constant $C$ is from energetic contributions of all other orbitals which are not part of the chosen set.

We then perform calculations for $M$ low-energy states which are not necessarily eigenstates. However, these states must have similar descriptions of the core and virtual spaces. The objective of choosing a sufficiently big set is to explore parts of the low-energy Hilbert space which show variations in the 2-RDM elements. Since the same parameters describe all $M$ states, they must satisfy the linear set of equations,

$$(\tilde{E}_1 \cdots \tilde{E}_M) = \begin{pmatrix} 1 & \langle c^+_1 c_2 \rangle & \cdots & \langle c^+_1 c^+_1 c_{N_p} \rangle & \cdots \\ 1 & \langle c^+_1 c_2 \rangle & \cdots & \langle c^+_1 c^+_1 c_{N_p} \rangle & \cdots \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 1 & \langle c^+_1 c_{N_p+1} \rangle & \cdots & \langle c^+_1 c^+_1 c_{N_p} \rangle & \cdots \\ 1 & \langle c^+_1 c_{N_p+1} \rangle & \cdots & \langle c^+_1 c^+_1 c_{N_p} \rangle & \cdots \end{pmatrix} \begin{pmatrix} C \\ t_{ij} \\ \vdots \\ V_{ijkl} \end{pmatrix}$$  \hfill (11)

which is compactly written as,

$$\mathbf{E} = \mathbf{A} \mathbf{x}$$  \hfill (12)

where $\mathbf{E} = (\tilde{E}_1, \tilde{E}_2, \cdots \tilde{E}_M)^T$ is the $M$ dimensional vector of energies, $\mathbf{A}$ is the $M \times N_p$ matrix composed of density matrix elements and $\mathbf{x} = (C, t_{ij}, V_{ijkl}, \cdots)^T$ is a $N_p$ dimensional vector of parameters. This problem is overdetermined for $M > N_p$, which is the regime we expect to work in.

In the case of any imperfection in the model, which is the most common case, the equality will not hold exactly and one must then instead minimize the norm of the error, $\mathcal{N}$:

$$\mathcal{N} \equiv ||\mathbf{A} \mathbf{x} - \mathbf{E}||^2$$  \hfill (13)

This cost function can be minimized in a single step by using the method of least squares, employing the singular value decomposition of matrix $A$. This matrix also encodes exact (or
near-exact) linear dependences. Thus, the quality of the fit is directly judged by assessing (1) the singular values of the $A$ matrix and (2) the value of the cost function itself i.e. the deviations of the input and fitted energies. We will refer to this as the non eigenstate (N)-AIDMD method throughout the rest of the paper. This idea is schematically depicted in Fig. 3(b).

The matrix $A$ gives a very natural basis for understanding renormalization effects. For example, consider a set of wavefunctions that show that the correlator $(n_in_j)$ does not change significantly. This would lead to the corresponding column of matrix $A$ being identical (up to a scale factor) to the first column of 1’s. Physically, this would correspond to the coupling constant $V_{ijji}$ being irrelevant for the low-energy physics; it can take any value including zero and can be absorbed into the constant shift term. This could also alternatively mean that the input data is correlated and does not provide enough information about $V_{ijji}$, so care must be taken in constructing the set of wave functions.

In summary, the N-AIDMD method performs the following operation. The 2-RDMs and energy expectation values of many non-eigenstate correlated states are calculated. Then, given an effective Hamiltonian parameterization, the linear equation in Eqn 12 is constructed and solved. Standard model fitting principles apply, and we can evaluate the goodness of fit to determine whether a given effective Hamiltonian can sufficiently describe the data.

**C. Quantum Monte Carlo specific adaptation**

The formalism introduced above applies to any method that calculates energies and density matrices. In this paper, all the expectation values entering the $A$ matrix are calculated for the chosen low-energy wavefunctions by Monte Carlo sampling. We perform two independent calculations to estimate the parameters, one using variational and the other using mixed estimators. In the latter case, we modify the linear equations (12) by using $E_s = \langle \psi_T^s | H | \psi_s \rangle$ and the projected estimates of the density matrix elements i.e. $\langle \psi_T^s | c_i^\dagger c_j | \psi_s \rangle$ and $\langle \psi_T^s | c_i^\dagger c_j c_k | \psi_s \rangle$ in the construction of the $A$ matrix. The implicit normalization of these mixed estimates by $\langle \psi_T^s | \psi_s \rangle$ is assumed. This projector formulation is also amenable to coupled-cluster calculations which work with projected energies and density matrices.

The bias arising out of fixing the nodes of the projected wavefunction does not affect our formulation. This is because the method regards $\psi_0 \psi_T$ as some arbitrary positive sampling function associated with a low energy state, and it is this same distribution that is used for the evaluation of the density matrix elements. Each such distribution provides a linear equation encoding the relationship between the FN-DMC energy and the projected density matrix elements and the unknown parameters. Up to errors from statistical uncertainties and from the assumption of the form of the Hamiltonian, this relationship is exact.

The VMC and FN-DMC parameters are found to be different from each other. For example, for the benzene molecule presented in section VI, the parameter values agree with each other up to 10%. The largest discrepancy is from different constant terms. This discrepancy is expected, because VMC does not provide an accurate description of the core and virtual spaces.

Ideally, only the FN-DMC calculations should be used to estimate the parameters. However, the mixed estimator in FN-DMC is biased because of the inaccuracy of the trial wavefunction. Thus, we propose a better estimator for the parameters,

$$p = 2p_D - p_V$$

where $p$ is the true parameter, and $p_D$ and $p_V$ are the corresponding parameters obtained from FN-DMC and VMC calculations. The details of this result are explained in Appendix A.

**V. SIMPLE APPLICATION: HUBBARD TO HEISENBERG MODEL**

To demonstrate our formalism for a simple example, we consider the two site Hubbard model and fit information from the lowest two states to a Heisenberg model.

We analytically solve for all four eigenstates of the Hamiltonian,

$$H = -t \sum_{i,j} c_{i,\sigma}^\dagger c_{j,\sigma} + \text{h.c.} + U \sum_i n_{i,\uparrow} n_{i,\downarrow}$$

for two opposite spin electrons on two sites, where $t$ is the hopping, $U$ is the Hubbard onsite interaction. The Hilbert space on a single site (orbital) is spanned by four states $|0\rangle$ (unoccupied), $|\uparrow\rangle$ (single up occupied), $|\downarrow\rangle$ (single down occupied), $|\uparrow\downarrow\rangle$ (doubly occupied). For completeness, we discuss some features of the solution method below.

First notice that the triplet state $|\psi_t\rangle \equiv \frac{1}{\sqrt{2}} (|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle)$ with energy $E_t = 0$ and the state $|\psi_d\rangle \equiv \frac{1}{\sqrt{2}} (|\uparrow\rangle \downarrow\rangle - |\downarrow\rangle \uparrow\rangle)$ with energy $E_d = U$. are exact eigenstates of the problem independent of the values of $t$ and $U$. 

---

**Figure 3. Schematic of ab initio density matrix downfolding (AIDMD) methods employed for determining the effective Hamiltonian parameters.**

(a) In the eigenstate (E)-AIDMD, the reduced density matrices (RDM) are calculated for the ab initio counterparts. (b) The non-eigenstate (N)-AIDMD method uses RDMs and energies of arbitrary states to construct a matrix of relevant density matrices and performs a least square fitting method to determine the optimal parameters.
To get the other two states, write the Hamiltonian in the basis of \(|\psi_s\rangle = \frac{1}{\sqrt{2}} (|\uparrow \downarrow\rangle + |\downarrow \uparrow\rangle)\) and \(|\psi'_s\rangle = \frac{1}{\sqrt{2}} (|\uparrow \downarrow\rangle - |\downarrow \uparrow\rangle)\),

\[
H = \begin{pmatrix}
0 & -2t \\
-2t & U
\end{pmatrix}
\]

Then diagonalizing it, we get the energies to be,

\[
E_{\pm} = \frac{U \pm \sqrt{U^2 + 16t^2}}{2}
\]

The lowest energy corresponds to the singlet, \(E_-\) and the corresponding eigenvector is

\[
|\psi_-\rangle = \frac{2t}{\sqrt{4t^2 + E_-^2}}|\psi_s\rangle - \frac{E_-}{\sqrt{4t^2 + E_-^2}}|\psi'_s\rangle
\]

with the next excited state being the triplet \(|\psi_t\rangle\).

We choose the Heisenberg form to fit to

\[
\tilde{H} = C + JS_1 \cdot S_2
\]

To determine the parameters \(C\) and \(J\), form the \(2 \times 2\) \(A\) matrix with the lowest two energy states,

\[
\begin{pmatrix}
\begin{pmatrix}
E_- \\
n E_-
\end{pmatrix}
\end{pmatrix}
= \begin{pmatrix}
1 & 1 \\
-3/4 & -4/3
\end{pmatrix}
\begin{pmatrix}
C \\
J
\end{pmatrix}
\]

Using derived values of \(E_s\) and \(E_t\) = 0, we get,

\[
J = \frac{E_s(4 + (E_-/t)^2)}{4 + 3(E_-/t)^2}
\]

which to lowest order in \(t/U\) is \(J = -4t^2/U\).

Observe that the correlator for \(|S_i \cdot S_j\rangle\) is not exactly \(1/4\) but only approximately so. This is expected since the fluctuations from the high-energy states are not exactly zero, if it were, it would be equivalent to exactly block-diagonalizing the Hamiltonian. This exact block diagonalization is not possible in general, unless it is also accompanied with a change in the low energy degrees of freedom entering the model.

If we now rotate the two low energy eigenstates and define the orthogonal linear combinations,

\[
|\psi'_1\rangle = p|\psi_-\rangle + q|\psi_t\rangle
\]

\[
|\psi'_2\rangle = q|\psi_-\rangle - p|\psi_t\rangle
\]

and calculate their energies and construct the corresponding \(A\) matrix, we get \(J\) to be independent of \(p\) and \(q\). This property is desirable as the method does not hinge on the requirement of eigenstates as inputs.

In terms of canonical transformations (here equivalent to second order perturbation theory), the matrix element of the effective Hamiltonian between the singly occupied states is,

\[
\langle \uparrow \downarrow | \tilde{H} | \downarrow \uparrow \rangle = \sum_n \frac{\langle \uparrow \downarrow | H | n \rangle \langle n | H | \downarrow \uparrow \rangle}{0 - E_n}
\]

\[
= \frac{-2t^2}{U}
\]

Since this matrix element must equal \(J/2\) in the Heisenberg model we arrive at the same result, namely \(J = -4t^2/U^{56}\).

VI. APPLICATION TO A MOLECULE: BENZENE

We show the workings of the described AIDMD methods for the benzene molecule. Our choice of system is motivated by the simplicity of the system (one band model and presence of many symmetries) and the availability of experimental energies to compare to.

DFT calculations were first performed in the TZVP basis with Burkatzki-Filippi-Dolg pseudopotentials\(^{57}\), using the molecular geometry that corresponds to a B3LYP optimized calculation. These serve as a starting point for the QMC calculations, discussed in the Methods section. In the charge neutral sector, there are a total of 30 electrons (15 \(\uparrow\) and 15 \(\downarrow\) for the spin-singlet state) and our objective is to downfold this system to an effective one with 6 electrons (3\(\uparrow\), 3 \(\downarrow\)).

The model Hamiltonian is defined in the space of six \(\pi\) orbitals; a representative localized orbital has been shown in Fig. 2. These orbitals were obtained by localizing the highest three occupied B3LYP orbitals from the \(S = 0\) ground state DFT calculation and the lowest three unoccupied orbitals with \(\pi\) orbital symmetry, a well established procedure in the literature\(^{58}\). The overall phase of these orbitals is adjusted to enable use of parameter symmetries directly when fitting.

Appendix A discusses the QMC data used for fitting and the initial pre-processing to determine the eligibility of states that can be described by a six-\(\pi\) orbital Hamiltonian.

A. On-site Hubbard model

We consider the Hubbard model for six orbitals of benzene, given by Eq. (15), where the notation \(t\) is the nearest-neighbor hopping and \(U^*\) will be used for the effective on-site Coulomb repulsion. We will discuss multiple ways of using reduced density matrix elements to estimate these parameters.

1. Hubbard \(U^*/t\) from the E-AIDMD method

An estimate of \(U^*/t\) is obtained by directly matching the half-filled ground state (\(S = 0\)) 2-RDM element corresponding to the “double occupancy” correlator \(\langle n_\uparrow n_\downarrow \rangle\) of the \(ab\) \textit{initio} and lattice-model calculations. This element equals \(0.25\) for the non interacting case \((U^* = 0)\) and its value reduces for \(U^* > 0\).

Fig. 4 shows the dependence of \(\langle n_\uparrow n_\downarrow \rangle\), computed in the ground state at half filling, on \(U^*/t\) in the Hubbard model. The plot also indicates the value of this correlator computed from various wavefunctions and estimators. The trends are consistent with our expectations; the Slater-Jastrow wavefunction at the VMC level underestimates the strength of the effective interactions, which is partly remedied by the extrapolated estimator from FN-DMC. However, the bias (systematic error) is expected to be large because of the considerable difference in the two estimates. This bias is reduced by the multideterminantal-Jastrow wavefunction we employed; the difference between the variational and extrapolated estimator is about 5%.
of the optimal parameters, $t = 2.6 \text{ eV}$ agrees with the value of $t = 2.54 \text{ eV}$ reported by Bursill et al.\textsuperscript{58}. The extrapolated value of $U^*/t \approx 1.0$ is broadly consistent with a recently reported estimate\textsuperscript{59} to within 10-20%.

3. Assessing the quality of the $U^*/t$ model

Fig. 5 shows comparison of the extrapolated QMC estimates of the one-body density matrix, density-density and spin-spin correlators and those for the Hubbard model for various values of $U^*/t$. The value of $U^*/t = 1.4$ gives the smallest errors for most observables, except for the nearest-neighbor density-density correlator which prefers values of $U^*/t \sim 0$. In the limit that the model is perfect, all estimates must yield the same value; the differences reflect an inadequacy of the on-site Hubbard model in describing all the data. This is evidence for the need for long-range interactions.

B. Extended Hubbard model

Having established the need for long-range interactions in benzene, we consider the extended-Hubbard or Parisier-Pople-Parr model,

$$H = -\sum_{ij} t_{ij} c_{i \sigma}^\dagger c_{j \sigma} + \text{h.c.} + U \sum_i n_{i \uparrow} n_{i \downarrow} + \sum_{ij} V_{ij} n_{i \sigma} n_{j \sigma}$$

(25)

where $U$ is the on-site Hubbard interaction and $t_{ij}$ and $V_{ij}$ are inter-orbital hopping and density-density interactions. We will compare our results with Bursill et al\textsuperscript{58}, who considered only a nearest neighbor hopping and took $V_{ij}$ to be of the Ohno form\textsuperscript{60}

$$V_{ij} = \frac{U}{\sqrt{1 + (\alpha r_{ij})^2}}$$

(26)

where $\alpha$ is a fit parameter and $r_{ij}$ is the spatial separation between nuclei. This parameterization has been widely used in the modelling of various organic polymers. Here we will not make any assumptions about the form of the interactions and instead use the N-AIDMD method to determine these parameter values.

We repeat similar analyses as those for the Hubbard model, in addition to carefully looking at the variations in the 1- and 2-RDM matrix elements. This data has been discussed as part of Appendix B and has been shown in Fig. 11. For a parameter to be reliably estimated there should be a large variation in the corresponding density matrix element for different wavefunctions in the low energy space. By this metric, we find that the next nearest neighbor hopping $t_{02}$ is irrelevant in the charge-neutral sector. We thus attempt to fit to a model only with the nearest neighbor $t \equiv t_{01}$ along with $U$, $V_{01}$ and $V_{02}$; $V_{03}$ is not needed as it simply sets the chemical potential.

Fig 6 shows energy fits to the on-site and extended-Hubbard models both with VMC and DMC calculations. The inadequacies of the on-site Hubbard model are rectified by the extended

![Figure 4. Double occupancy of the π orbital of benzene as a function of $U^*/t$, computed in the half filled ground state. Comparisons are made with the values from the variational (pure) and extrapolated estimators obtained from the \textit{ab initio} QMC calculation with Slater-Jastrow and CISD-Jastrow wavefunctions.](image)

2. Hubbard $U^*/t$ from the N-AIDMD method

As mentioned previously, the idea of matching density matrix elements is useful only for comparing exact eigenstates. However, it is difficult to construct eigenstates with very high accuracy in the \textit{ab initio} calculations and at times also for the equivalent model for large system sizes. This is why we appeal to the N-AIDMD method, introduced and explained in Sec. IV B, which is relatively insensitive to the nature of the states input to the method. For charge-neutral benzene, we construct the $A$ matrix by taking various states in a 10 eV energy window above the ground state using VMC and DMC methods.

Fig. 6 shows the comparison of the fitted energy and the input VMC or DMC energy. The former is obtained by taking the linear combination of the \textit{ab initio} VMC or DMC density matrices weighted by the optimized parameters. A perfect agreement between the fitted and input data would correspond to all energies falling exactly on the $y = x$ line. By this measure, the Hubbard model for benzene is reasonable, though not accurate, as is seen in Fig. 6(a) amd (d). The presence of significant deviations of the order of 1–2 eV from the $y = x$ line indicates the need for a more refined model, which we discuss in the next section.

The VMC data yields optimal parameters of $t = 3.0 \text{ eV}$ and $U^* = 5.2 \ (U^*/t = 1.7)$ and the FN-DMC gives $t = 2.8 \text{ eV}$ and $U^* = 3.9 \ (U^*/t = 1.4)$. The extrapolated estimate
Figure 5. Comparison of \textit{ab initio} Quantum Monte Carlo and Hubbard model correlation functions for the half filled singlet ground state for various values of $U^*/t$. The main panels show the (a) one body density matrix (b) density-density correlators (c) spin-spin correlators as a function of distance with respect to a reference site (d)-(f) show the errors of the corresponding model correlation functions with respect to the \textit{ab initio} data. Most correlators are captured adequately, except for the nearest neighbor density-density correlator.

Figure 6. Comparison of input and fitted energies using the N-AIDMD procedure. The top panels (a)-(c) show the VMC results and the bottom ones (d)-(f) show the DMC ones. (a)-(d) correspond to the on-site Hubbard model, (b)-(e) the long range Hubbard model and (c)-(f) with additional third-nearest neighbor hopping.
Table I. Model Hamiltonian parameters (in eV) from various downfolding methods, using data from states in the charge neutral sector of benzene. $V_{03}$ sets the constant shift or chemical potential for the interaction terms; its value has been set to exactly match previous semi-empirical fits.

| Parameter | PPP [Ref. 58] | PPP-VMC | PPP-DMC | PPP-Extrap | $U^*$ [Ref. 59] | $U^*$-VMC | $U^*$-DMC |
|-----------|----------------|----------|----------|------------|----------------|-----------|-----------|
| $t$       | 2.54           | 2.87(1)  | 2.70(1)  | 2.65(2)    | 2.54           | 3.04(4)   | 2.80(1)   |
| $U$       | 10.06          | 11.95(4) | 10.92(4) | 9.89(6)    | 5.04           | 5.2(2)    | 3.9(1)    |
| $V_{01}$  | 7.18           | 7.41(5)  | 7.13(3)  | 6.78(8)    | -              | -         | -         |
| $V_{02}$  | 5.11           | 5.40(3)  | 5.41(2)  | 5.40(4)    | -              | -         | -         |
| $V_{03}$  | 4.57           | 4.57     | 4.57     | 4.57       | -              | -         | -         |
| $U/t$     | 3.96           | 4.16(2)  | 3.96(2)  | 3.73(3)    | 1.20           | 1.7(1)    | 1.39(5)   |

Our parameters are summarized in Table I. The fitted PPP Hamiltonian is generally consistent with the Ohno parameterization, but there are some deviations of the order of $0.3-0.5$ eV, that improve the quality of the fitted energies. We emphasize that we have not provided any experimental inputs; rather we have used only the QMC data (energies and density matrices) from multiple states to obtain the Hamiltonian parameters.

In order to check the robustness of the fit, we estimated errors in our parameters from a Jacknife analysis. In this scheme the input states to the N-AIDMD method were randomly discarded and the fit performed with the retained half. Many such randomly generated ensembles of input data were taken and the resultant parameters were averaged over all of these. The difference of the parameters of this reduced data set and the full data set provides an estimate of the systematic error.
which we report in Table I. The other source of errors is from statistical noise, which in the present case was found to be much smaller than the systematic error.

VII. APPLICATION TO A SOLID: GRAPHENE

As an application of the AIDMD methods to solid materials, we consider graphene, a 2D solid of carbon atoms arranged on a honeycomb lattice. Graphene has great potential technological applications, which has spurred much work devoted to understanding it thoroughly. In addition, there have been several proposals for engineering exotic phases in graphene. That said, it is only recently that systematic studies to estimate the role of electron-electron interactions in graphene have been carried out. While some of its long-distance properties appear to be adequately described by a tight-binding model, the short range features, crucial for phenomena such as magnetism, require more refined modeling.

![GrapheneDoubleOccupancy](image)

Figure 8. (Left) Double occupancy of the π orbitals of 4 × 4 graphene for QMC. Non Interacting (U*/t = 0.0) and RPA (U*/t = 1.6). This data is best explained by a Hubbard model with U*/t = 0.6. (Right) Double occupancy vs U*/t for L × L graphene unit cells with periodic boundary conditions for L = 2, 4, 6, 8. Very small finite size effects exist for L ≥ 4.

Early studies modelled graphene as a honeycomb lattice Hubbard model with a U/t estimated to be ≈ 3.8. This would put graphene on the verge of a metal-insulator transition. However, recent results by Wehling et al. realized the importance of long-range interactions, which renormalize the on-site interaction to an effectively lower value. Schuler et al. reported this effective U*/t = 1.6 ± 0.2. This means graphene lies well in the semimetal phase of the Hubbard model.

Setting aside the question of determining all the long range interactions in graphene, we ask what U*/t best describes our ground state Quantum Monte Carlo data. To do so, we first generated the π-like Wannier functions within QWalk, a representative of which has been shown in Fig. 2.

Just as in the case of benzene, we used the fact that the effective strength of the Coulomb interaction U*/t is most sensitive to the 2-RDM element \( \langle n_{i \uparrow} n_{i \downarrow} \rangle \). For the 4 × 4 unit cell with periodic boundary conditions, and using optimized Slater Jastrow wavefunctions, the extrapolated value is found to be 0.221(5) corresponding to a U*/t ≈ 1.1(1). This estimate of U*/t is obtained from comparisons to lattice determinant QMC calculations, which were carried out for sizes ranging from 2 × 2 to 8 × 8 to check for finite-size effects. As Fig. 8 shows, the 2 × 2 unit cell is distinctly different from the larger unit cells, however, the finite-size errors in the double occupation correlator are negligible beyond sizes L ≥ 4. The finite size effects for other short range correlation functions (not shown) are also negligible beyond L ≥ 4.

We also calculated many non-eigenstates for 3 × 3 graphene in an energy window 3 eV above the ground state. Fig. 9 shows the VMC and FN-DMC energy fits to tight-binding and Hubbard models. The hopping t for the tight-binding model is found to be in the range of 2.2 to 2.8 eV. A precise estimate of this parameter is not particularly meaningful because the model is inadequate at capturing many states, particularly spinful excitations, in this energy window. We note that a value of t = 2.80 eV has been previously calculated with DFT methods. The Hubbard model reduces the errors of the tight-binding model, and the value of U*/t is in the range of 1.9 (VMC) to 1.3 (FN-DMC). We expect the FN-DMC value to be closer to the true value of U*/t in a small energy window associated with the ground state. We also note that this value is within 2σ of the value derived from the constrained RPA parameters.

However the Hubbard model too has outliers of about 0.4 eV, which are large for an accurate model of a solid material. This inadequacy is confirmed by assessing various correlators in the half filled ground state. Fig. 10 shows the up density-up density and up density-down density correlators as a function of distance between carbon atoms. On the scale of Fig. 10(a) (and well within the accuracy of our calculations) the like spin correlations were captured well for all values of U*/t in the range from 0 to 2. However, as Fig. 10(b) shows, the Hubbard model for large U*/t tends to exaggerate the effective interaction between the two electron spin flavors at small separations. In particular, the nearest neighbor unlike spin density-density correlator is found to be in better agreement with U*/t ≈ 0 than any finite value. This, just like the case of benzene, suggests the need for longer range interactions in the model. There are also small deviations between the ab initio QMC and the Hubbard model results at longer distances. These correlations do not depend significantly on U*/t and these data in isolation do not rule out any model.

VIII. CONCLUSION

We have demonstrated ab initio density matrix downfolding (AIDMD) methods where ab initio Quantum Monte Carlo (QMC) data is used to fit simple effective Hamiltonians. We have elaborated on the fitting procedures and the intricacies of the QMC method needed to perform calculations. The limitations of the model were judged by assessing the quality of the fitted energies and 2-body density matrices. This feature is
Figure 9. Comparison of model and QMC energies of the $3 \times 3$ periodic unit cell of graphene. The fitting procedure involves the use of reduced density matrix elements and energies as inputs and is described in the text. The top panels (a)-(b) show the VMC results and the bottom (c)-(d) show the DMC ones. (a) and (c) correspond to the tight binding model on a honeycomb lattice, and (b) and (d) correspond to the on-site Hubbard model.

Useful for constructing refined models needed for the accurate simulation of real materials.

For the benzene molecule, while the on-site Hubbard model with $U^*/t \approx 1.2$ was able to capture most features of the QMC ground state data, the deviations of the density matrices revealed the need for longer range interactions. Including these improved the quality of agreement with the QMC results and experiments. This Hamiltonian parameterization could be used to calculate low-frequency response functions and to check semi-empirical methods.

Since QMC calculations use size-consistent wavefunctions for extended systems and scale favorably, we believe the type of calculations presented here will be a promising alternative to DFT-based downfolding approaches for solid materials. Our demonstration for the single band model of graphene yielded an effective $U^*/t = 1.3 \pm 0.2$, in the same range as a recently reported estimate based on the constrained-RPA method. In more complicated materials, where the form of the Hamiltonian is unclear, we suggest that the dominant terms can be obtained from canonical transformation theory followed with an accurate fit to the QMC data. It will also be useful to compare the predictions of the proposed AIDMD
scheme with other complementary proposals for downfolding.\textsuperscript{14,68,69}

Finally, we remark that previously unsolved model Hamiltonians are now being accurately treated with tensor network methods.\textsuperscript{70,71} With parallel advances in the \textit{ab initio} QMC simulation of high-temperature superconductors,\textsuperscript{72,73} a clear future direction is to deduce more refined models for these compounds, using the ideas discussed in the paper.

\section{Appendix A: Estimation of True Effective Hamiltonian Parameters from VMC and FN-DMC Calculations}

In section IV C, we discussed the discrepancy between parameters obtained from VMC and FN-DMC. This is attributed to the inability of the trial wavefunctions used in VMC to provide an accurate description of the core and virtual spaces.

As mentioned in the text, ideally, only the FN-DMC calculations should be used to estimate the parameters. However, the mixed estimator in FN-DMC is biased because of the inaccuracy of the trial wavefunction. To minimize this bias, we propose estimators which combine FN-DMC and VMC parameters.

Consider a trial VMC wavefunction $\psi_T$ which deviates from the DMC wavefunction $\psi$ by a small amount $\delta\psi_h$ orthogonal to $\psi_T$ i.e.,

$$\langle \psi \rangle = |\psi_T\rangle + \langle \delta\psi_h \rangle$$

To obtain the parameter $p$ coupled to an operator $\rho_p$ in the effective Hamiltonian i.e.

$$H = \sum_p p \rho_p$$

we take partial derivatives with respect to the change of a density matrix element i.e.

$$p = \frac{\partial\langle \psi | H | \psi \rangle}{\partial\langle \psi | \rho_p | \psi \rangle}$$

Since the pure estimators for projected (DMC) wavefunctions are not easily evaluated in QMC, we use other estimators using which we indirectly obtain $p$.

The parameter obtained from the mixed estimators within FN-DMC, is formally defined as,

$$p_D = \frac{\partial\langle \psi | H | \psi_T \rangle}{\partial\langle \psi | \rho_p | \psi \rangle}$$

On substituting the relation between $\psi$ and $\psi_T$ wavefunctions, we get,

$$p_D = \left( \frac{\partial\langle \psi | H | \psi \rangle}{\partial\langle \psi | \rho_p | \psi \rangle} \right) \left( 1 - \delta \frac{\partial\langle \psi | H | \psi_h \rangle}{\partial\langle \psi | H | \psi \rangle} \right) \left( 1 - \delta \frac{\partial\langle \psi | \rho_p | \psi_h \rangle}{\partial\langle \psi | \rho_p | \psi \rangle} \right)^{-1}$$

which to linear order in $\delta$ is,

$$p_D \approx p \left( 1 + \delta \left( \frac{\partial\langle \psi | \rho_p | \psi_h \rangle}{\partial\langle \psi | \rho_p | \psi \rangle} - \frac{\partial\langle \psi | H | \psi_h \rangle}{\partial\langle \psi | H | \psi \rangle} \right) \right)$$

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure10}
\caption{Comparison of ab initio Quantum Monte Carlo and Hubbard model correlation functions for the $i^{th}$ neighbor of a reference site for the half filled singlet ground state of $4 \times 4$ graphene for various values of $U^*/t$. (a) shows the up density - up density correlator and (b) shows the up density - down density correlator. The optimal Hubbard model overestimates the attraction between electrons of opposite spins at short distances.}
\end{figure}
A similar expression for parameters obtained from VMC calculations,

\[ p_V = \frac{\partial \langle \psi_T | H | \psi_T \rangle}{\partial \langle \psi_T | \rho_p | \psi_T \rangle} \]  

(33)

is derived and leads to the result,

\[ p_V \approx p \left( 1 + 2\delta \left( \frac{\partial \langle \psi | \rho_p | \psi_h \rangle}{\partial \langle \psi | \rho_p | \psi \rangle} - \frac{\partial \langle \psi | H | \psi_h \rangle}{\partial \langle \psi | H | \psi \rangle} \right) \right) \]  

(34)

where we have used the hermiticity of the Hamiltonian and the operator \( \rho_p \).

On combining equations (32) and (34), to leading order in \( \delta \) we get,

\[ p = 2p_D - p_V + O(\delta^2) \]  

(35)

As expected, all estimates are consistent with each other in the limit of exact wavefunctions.

XI. APPENDIX B: QMC DATA FOR THE BENZENE MOLECULE

Table II shows the QMC data for several eigenstates of benzene. Most of these states along with many other non-eigenstates constitute our data set for fitting a model. The calculations confirm the general expectation that significant energy gains are obtained by improving wavefunctions going from the single-Slater-Jastrow form to the multi-determinantal-Jastrow form (the determinants being selected from a CISD calculation). Moreover, the DMC calculations improve total energies significantly; typically, the DMC values are 2–3 eV lower than the corresponding VMC value.

The total electron count from the one-body density matrix is assessed to verify the validity of fitting to a six-\( \pi \) orbital Hamiltonian. Table II shows that for charge-neutral benzene, the singlet state (\( S = 0 \)) has up and down electron counts of 2.96 each, which are close to the expected values of 3.3. For the \( S = 2 \) state, roughly 9 eV above the ground state, the deviations were slightly larger; the summed occupation numbers were 4.92 and 1.0 in comparison to the expected values of 5 and 1. Since there is a slight deviation of these numbers from integers, we rescale the one and two body density matrices by factors (all slightly greater than 1) that correctly accounts for sum rules for each individual state used in the AIDMD methods.

However, for the \( S = 3 \) state, the electron occupation numbers deviate significantly from the corresponding value in the model; almost by one integer. This indicates that the \( S = 3 \) state is inadequately described by the proposed Hamiltonian and hence can not be used in the fitting procedure. This deviation is not completely unexpected since this state is \( \sim 17 \) eV above the ground state and a potential high-energy state. Said differently, the active space at this energy scale is considerably different from that assumed for the ground state and its low-energy excitations. Thus, this QMC data suggests that it is only reasonable for the effective Hamiltonian concept to hold only in an energy window of the order of 10 eV above the ground state.

We now assess some aspects of our non-eigenstate data. For the N-AIDMD method, we desire large variations in the density matrix elements for different wavefunctions in the low-energy space, in order to accurately estimate the Hamiltonian parameters. Fig. 11 shows these variations for all relevant density-matrix elements (within FN-DMC) that were needed for estimating the parameters of the extended Hubbard model. \( t_{\alpha\beta} \) was found to be irrelevant, as the summed density matrix elements coupling to it were found to not vary significantly (not shown in the plot).

Figure 11. Variation of density matrix elements for various states used in the AIDMD method. The summation sign \(\sum\) indicates a sum over all RDM elements that couple to the same parameter in the lattice model. The panels show (a) the sum over all the nearest neighbor one body density matrix elements summed over both spin types and (b) the sum over on-site double occupancies. (c) and (d) show sums over nearest and next-nearest neighbor density-density correlators respectively. As is discussed in the text, variations in the density matrix elements are needed for the corresponding parameters to be estimated, else they can be taken to be effectively zero.

A bipartite lattice is one with two sublattices $A$ and $B$ with only $A \rightarrow B$ connections but no $A \rightarrow A$ or $B \rightarrow B$ ones.

To map a fermion model to a spin model, a Jordan-Wigner phase is introduced which remains fixed, as there are no charge fluctuations. In this notation the relative signs between basis states entering in the singlet and triplet states is reversed and $J = +4t^2/U$.
