Most of the existing acoustic metamaterials rely on architected structures with fixed configurations, and thus, their properties cannot be modulated once the structures are fabricated. Emerging active acoustic metamaterials highlight a promising opportunity to on-demand switch property states; however, they typically require tethered loads, such as mechanical compression or pneumatic actuation. Using untethered physical stimuli to actively switch property states of acoustic metamaterials remains largely unexplored. Here, inspired by the sharkskin denticles, we present a class of active acoustic metamaterials whose configurations can be on-demand switched via untethered magnetic fields, thus enabling active switching of acoustic transmission, wave guiding, logic operation, and reciprocity. The key mechanism relies on magnetically deformable Mie resonator pillar (MRP) arrays that can be tuned between vertical and bent states corresponding to the acoustic forbidding and conducting, respectively. The MRPs are made of a magnetoactive elastomer and feature wavy air channels to enable an artificial Mie resonance within a designed frequency regime. The Mie resonance induces an acoustic bandgap, which is closed when pillars are selectively bent by a sufficiently large magnetic field. These magnetoactive MRPs are further harnessed to design stimuli-controlled reconfigurable acoustic switches, logic gates, and diodes. Capable of creating the first generation of untethered-stimuli-induced active acoustic metadevices, the present paradigm may find broad engineering applications, ranging from noise control and audio modulation to sonic camouflage.

1. Introduction

Acoustic metamaterials with tailored architectures exhibit unconventional capability in controlling acoustic waves [1–5] and have enabled a wide range of previously unachievable applications, such as superlensing [6–12], cloaking [13–15], logic operation [16–20], nonreciprocal propagation [21–25], topological insulation [20, 26–29], and wave guiding [30, 31]. Despite the diverse applications, most of the existing paradigms rely on architected structures with fixed configurations, and thus, their properties cannot be modulated once the structures are fabricated [1–5]. Emerging active acoustic metamaterials highlight a special opportunity to enable on-demand switch property states of the fabricated acoustic metamaterials [32, 33]. However, the existing active metamaterials typically require tethered loads, such as mechanical compression or pneumatic actuation [20, 30, 31, 34]. Compared to tethered loads, untethered physical stimuli (such as electromagnetic field, light, and temperature) are more appealing owing to their special advantages including noncontact with the structures, nonlocal modulation, and rapid switching [35, 36]. However, using untethered physical stimuli to on-demand switch property states of acoustic metamaterials remains largely unexplored [35, 36]. Although there are recent reports on using the electromagnetic fields to modulate the effective constitutive parameters of acoustic metamaterials [35, 36], using untethered stimuli to enable reconfigurable acoustic devices such as waveguide, logic gates, or nonreciprocal diodes remains elusive.

Here, we report a class of active acoustic metamaterials whose configurations can be on-demand switched via untethered magnetic fields, thus enabling active switching of acoustic transmission, wave guiding, logic operation, and reciprocity. The key mechanism relies on magnetically deformable Mie resonator pillar (MRP) arrays that can be tuned between vertical and bent states corresponding to the acoustic forbidding
and conducting, respectively. The MRPs are made of an iron-filled magnetoactive elastomer and feature wavy air channels to enable an artificial Mie resonance within a designed frequency regime [37–39]. The Mie resonance induces an acoustic bandgap, which is closed when pillars are selectively bent by a sufficiently large magnetic field (e.g., 0.13 T). These magnetoactive MRPs are further harnessed to design stimuli-controlled reconfigurable acoustic switches (i.e., shifting between different propagation pathways), reconfigurable acoustic logic gates (i.e., switching among NOT, AND, and OR gates), and reconfigurable acoustic diodes (i.e., switching between the nonreciprocal diode and reciprocal conductor). Integrating stimuli-responsive smart materials and Mie resonances, the present paradigm highlights a unique and promising avenue for acoustic metamaterials that can reversibly, repeatedly, and on-demand switch acoustic propagation, logic operation, and reciprocity via untethered physical stimuli.

2. Sharkskin-Inspired Design Principle

The design principle of magnetoactive reconfigurable acoustic metamaterials is inspired by the sharkskin [40–42]. Fast-swimming sharks feature skin denticles that are shaped like “V” trenches and aligned in the direction of fluid flow (Figure 1(a)). It has been proven that the aligned skin denticles can significantly reduce the flow drag because the V-shaped trenches can guide a turbulent flow to become a laminar flow [43]. It has been further discovered that tilting the skin denticles by a small angle can drastically increase the flow drag [44]. Sharks can smartly switch the skin flow drag by reversibly tilting the skin denticles (Figure 1(a)) [41, 45].

Inspired by this natural paradigm in tuning the flow drag, we here propose a class of magnetoactive MRP arrays that can smartly switch the acoustic transmission by reversibly bending MRPs via a remotely controlled magnetic field (Figure 1(b)–(g)). Each MRP (diameter $D = 1.5$ cm and height $H = 4.25$ cm) has six-section wavy air channels that enable an artificial Mie resonance within a designed frequency regime [37–39]. When the pillar spacing $L$ is relatively small (e.g., $L/D = 1.5$), the Mie resonances around adjacent MRPs are coupled to form an acoustic barrier to enable a low acoustic transmission within 9040–9140 Hz (<0.2, Figure 1(b), (c), and (h))). Besides, the pillars are made of a magnetoactive elastomer reinforced by ferromagnetic iron nanoparticles (see Materials and Methods and Fig. S1), and thus, they can be selectively bent via a sufficiently large magnetic field (e.g., 0.13 T) to open a large pillar-to-pillar spacing for the remaining vertical pillars, leading to a high acoustic transmission within 9040–9140 Hz (>0.8, Figure 1(d), (e), and (h))). When the remotely controlled magnetic field is reduced or turned off, the bent MRPs return to the vertical state, and thus, the acoustic transmission turns back to the low level within 9040–9140 Hz (<0.05) behind the MRP (Figure 1(i), Movie S1 with cycle period 5 s, and Movie S2 with cycle period 1 s).

3. Mechanism of the MRP Array

Next, we analyze the mechanism of the MRP array. An MRP features six-section wavy air channels with the relative width as $d/D = 0.07$ (Figure 2(a)). The propagation length of the acoustic wave within the air channel is longer than that in the solid medium. Effectively, the acoustic energy within a certain frequency regime is trapped within the air channels [37]. This point can be verified by a numerical simulation which shows that the acoustic energy is concentrated within the MRP center region around 9100 Hz (Figure 2(b) and S2a). This phenomenon can be explained as an artificial Mie resonance within the MRP structure [37–39, 46, 47]. From the perspective of an effective medium, this Mie resonance is corresponding to negative effective bulk modulus and positive effective density within frequency 9050–9120 Hz (Figure 2(c) and S2a). This frequency regime (9050–9120 Hz) is considered as the Mie resonance frequency. This frequency regime is consistent with the numerically simulated bandgap (Fig. S3). To verify this Mie resonance frequency, we further carry out analytical modeling of the MRP using an equivalent multiphase composite model (Supplementary Information, Fig. S4) [37, 48, 49]. The analytical model shows that the Mie resonance frequency of the MRP with diameter 1.5 cm and 64% solid volume fraction is ~8.9 kHz (Figure S4), which is relatively close to the numerical simulations (Figure 2(c)).

The MRPs can be harnessed to shield the acoustic wave if multiple MRPs are arranged in an array (Figure 2(d) and (e)). When the pillar spacing $L$ is relatively small (e.g., $L/D = 1.5$), the Mie resonances in adjacent pillars are coupled to construct an acoustic shielding layer to block the acoustic transmission around the Mie resonance frequency regime (Figure 2(d) and (e)). This acoustic forbidding behavior at 9100 Hz is visualized by a numerical simulation shown in Figure 2(f) (Fig. S2b): the acoustic pressure amplitude drastically decreases to a very small value (<0.05) behind the MRP array. This behavior is validated by the experimentally measured acoustic transmission through the MRP array (Figure 2(g)): the acoustic transmission becomes lower than 0.15 within 9050–9120 Hz. The experimentally measured acoustic transmissions roughly agree with the numerical simulations over 8800–9400 Hz (Figure 2(g)). When the pillar spacing is relatively large (e.g., $L/D = 2.5$), the acoustic wave can escape between MRPs to enable a relatively high acoustic transmission (>0.8, Figure 2(h)–(k) and S2b). To verify this phenomenon, we study a control pillar array with solid pillars without air channels ($D = 1.5$ cm and $L/D = 1.5$) (Fig. S5). Both experiments and simulations show the acoustic transmissions over 8800–9400 Hz are above 0.8 (Fig. S5), implying that the air channels within the MRPs really play an important role to enable the low acoustic transmission around 9100 Hz. To further verify the phenomenon, we gradually vary the pillar spacing and numerically simulate the acoustic transmission through the MRP.
Figure 1: Sharkskin-inspired design principle of the magnetoactive reconfigurable acoustic metamaterials. (a) Schematics to show the sharkskin denticles for switchable flow drag via reversibly tilting the denticles. (b, c) Schematic and sample of the vertical Mie resonator pillar array. Inset in (b) shows the cross-section of the pillar. (d, e) Schematic and sample of the pillar array with two pillars bent via a magnetic field. The red arrows indicate the direction of the magnetic field. The selective actuation of the central two pillars is because of their higher iron volume fraction (18.48% by weight, Fig. S8a). (f, g) Schematic and sample of the pillar array when the magnetic field is turned off. (h) The acoustic transmissions of samples corresponding to (c), (e), and (g) in functions of the frequency. (i) The applied magnetic field intensity and the corresponding acoustic pressure at 9100 Hz within two switching cycles. The scale bars in (c), (e), and (g) represent 1 cm. The shaded area indicates a regime with negative modulus and positive density. (d, e) Schematic and sample for an MRP array with a small spacing \((L/D = 1.5)\). (f) Numerically simulated pressure of an acoustic wave moving through the MRP array with a small spacing \((L/D = 1.5)\). (g) The experimentally measured and numerically simulated acoustic transmission of the MRP array with a small space in functions of the frequency. The shadowed area indicates the Mie resonance frequency regime. (h, i) Schematic and sample for an MRP array with a large spacing \((L/D = 2.5)\). (j) Numerically simulated pressure of an acoustic wave moving through the MRP array with a large spacing \((L/D = 2.5)\). (k) The experimentally measured and numerically simulated acoustic transmission of the MRP array with a large spacing in functions of the frequency. (l) Image sequence to show the magnetically induced bending of an MRP with increasing magnetic fields. The inset shows a schematic for the application of the magnetic field to the MRP. (m) Bending angles of MRPs with various volume fractions of the iron particle in functions of the magnetic field. The shaded area indicates the critical magnetic field \(B_c\). (n) The experimentally measured critical magnetic fields for various volume fractions of the iron particle in a function of \(\sqrt{E/\Delta \chi}\), where \(E\) is Young’s modulus of the elastomer and \(\Delta \chi\) is the effective magnetic susceptibility difference. The error bars indicate the variation of the magnetic field within the shaded area in (m). Scale bars in (e) and (i) denote 1 cm.
array. We find the acoustic transmission increases with increasing pillar spacing within 9050–9150 Hz (Fig. S2c). In this work, the enlargement of the pillar spacing is enabled by the bending of selected pillars in the pillar array (Figure 1(d) and (e)). Once selected pillars are bent, the remaining vertical pillars construct a pillar array with a larger spacing (i.e., $L/D = 4.6$) that leads to high acoustic transmission.

4. Magnetically Induced Bending of MRPs

To achieve precise control of the magnetically induced bending of MRPs, we need to understand the underlying mechanics. We first carry out experiments on the magnetically induced bending of a bottom-fixed MRP under a magnetic field $B$ with a tilted angle $\alpha$ (Figures 2(l) and S6). With increasing magnetic field $B$, the pillar bends by an angle $\theta$ (Figure 2(l)). When the angle $\theta$ reaches 15–18°, further increasing $B$ will suddenly bend and pinch the pillar onto the substrate. This can be understood as a critical condition for the magnetically induced buckling of the MRP. To quantify this phenomenon, we plot the bending angle $\theta$ in a function of the applied magnetic field (Figure 2(m)): after the critical magnetic field $B_c$, the bending angle $\theta$ abruptly reaches 90°.

We then develop an analytical model to understand the magnetically induced buckling of the MRP. Using a similar analysis in the previously reported study on magnetically induced bulking of tilted beams (Supplementary Information, Fig. S7) [35], we express the critical magnetic field of the buckling as

$$B_c = \beta \left( \frac{H}{D} \right) \sqrt{\frac{\mu_0 E}{\Delta \chi}} \left( \frac{I}{AH^2} \right),$$

(1)

where $\beta$ is a dimensionless parameter dependent on the magnetic field angle $\alpha$ and the aspect ratio of the MRP $H/D$. $\mu_0$ is the magnetic permeability of the vacuum, $E$ is Young’s modulus of the elastomer, $I$ is the second moment of area, $A$ is the cross-section area of the solid part, and $H$ is the pillar length. $\Delta \chi$ is the effective magnetic susceptibility difference between the axial and orthogonal directions and can be estimated as $\Delta \chi \equiv \chi \prime - \chi \prime \prime (1 + \chi / 2)$, where $\chi$ is the magnetic susceptibility of the elastomer. To validate Equation (1), we maintain the geometry of the pillar and vary the volume fraction of the ferromagnetic iron particle within the magnetoactive elastomer. We find that the critical magnetic field for the magnetically induced buckling decreases as the volume fraction of the iron particle increases from 3.14% to 18.48% (Figure 2(m)). According to Equation (1), when the geometry parameters and the magnetic field angle maintain constant, the critical magnetic field $B_c$ should scale with $\sqrt{E/\Delta \chi}$. As shown in Figure 2(n), this scaling law agrees with the experimental results for MRPs with various volume fractions of the iron particle (parameters are listed in Table S2).

Note that to enable the magnetic buckling of selected pillars shown in Figure 1(d) and (e), we use pillars with higher iron volume fraction at selected locations. For example, the central two MRPs have an iron volume fraction of 18.48% but the other two have an iron volume fraction of 3.14% in Figure 1(e). When a sufficiently large magnetic field (0.13 T) is applied, only the central two MRPs buckle. It should also be noted that the inhomogeneity of the iron volume fraction among four MRPs does not change the key physics of the Mie resonance shown in Figure 2(a)–(k). The numerical simulations of MRP array with inhomogeneous iron volume fractions display a low acoustic transmission within 9050–9150 Hz (Fig. S8), similar to that of the MRP array with homogeneous iron volume fraction (Figure 2(g)). The numerical results of the MRP array with inhomogeneous iron volume fractions also agree with the corresponding experimental results in Figure 1(h) (Fig. S8).

5. Magnetoactive Acoustic Double-Throw Switch

Next, we harness MRPs to design a magnetoactive acoustic double-throw switch (Figure 3). We first use MRPs to design a three-branch channel with two outputs (A and B) and one input (C) (Figure 3(a) and (b)). The channel wall is composed of MRP arrays with a low iron volume fraction (3.14%) and a small pillar spacing ($L/D = 1.5$) to prevent the acoustic leaking within a designed frequency regime. Two sets of MRPs with a high iron volume fraction (18.48%) and a small pillar spacing ($L/D = 1.5$) are located on the pathways of C-to-A and C-to-B. At the as-fabricated state, the acoustic transmissions of C-to-A and C-to-B are expected to be blocked by the MRPs around the Mie resonance frequency. This point can be first validated by numerical simulations that show the drastically reduced acoustic pressure at channels A and B (Figures 3(c) and S9a). Experiments show that the acoustic transmissions of C-to-A and C-to-B are both below 0.25 within 8800–8950 Hz (Figure 3(d)). We denote the as-fabricated state as “A off B off” state (Figure 3(a)–(d)). Note that this Mie resonance frequency region (8800–8950 Hz) is slightly different from that shown in Figure 1 and 2 (9050–9120 Hz). This difference can be explained by the geometrical inconsistency among different fabricated MRPs: numerical simulations show that the Mie resonance frequency varies from 8620 Hz to 9300 Hz by varying the pillar diameter by 7% (Fig. S10). This effect of pillar diameter variation can also be verified by the analytical modeling of an MRP which shows that the Mie resonance frequency changes from 9480 Hz to 8300 Hz by varying the pillar diameter from 1.4 to 1.6 cm (Fig. S4, Supplementary Information).

To switch the “A off B off” state to “A on B off” state, we use a magnetic field (0.13 T) to bend the MRPs on the pathway of C-to-A (Figure 3(e) and (f)). Numerical simulations show that the acoustic pressure at channel A increases drastically after bending the MRPs (Figure 3(g) and S9b). Experiments show that the transmission of C-to-A increases to ~0.8 within 8800–8950 Hz, while the transmission of C-to-B remains below 0.25 (Figure 3(h)). Similarly, when the MRPs on the pathway of C-to-B are bent by a magnetic field, the switch transforms to “A off B on” state (Figure 3(i)–(l) and S9c). When the MRPs on the pathway
of C-to-A and C-to-B are all bent by respective magnetic fields, the switch transforms to the state of “Ao nBo n” (Figure 3(m)–(p) and S9d). The above four states of the double-throw switch can be on-demand and reversibly modulated via the remotely controlled magnetic fields.

6. Magnetoactive Reconfigurable Acoustic Logic Gate

Next, we harness MRPs to design magnetoactive reconfigurable acoustic logic gates (Figure 4). Existing acoustic logic gates primarily rely on designed acoustic metastructures with fixed geometries [16–19], and very few of them can switch logic operators with tethered interventions [20]. Reconfigurable acoustic logic gates that can on-demand switch operators by untethered stimuli have not been explored. Here, we demonstrate a magnetoactive reconfigurable acoustic logic gate with a three-branch channel slightly modified from the acoustic switch shown in Figure 3: we use branches A and B as two inputs and branch C as the output (Figure 4). To design a NOT gate (Figure 4(a)), we place 6 MRPs (a high iron volume fraction 18.48% and a small pillar spacing L/D = 1.5) at the central location of the channel. Effectively, 2 rows of MRP arrays are located on the pathway of A-to-C and 2 rows of MRP arrays on the pathway of B-to-C (Figure 4(b)). According to the results shown in Figure 3(d), (h), and (l), the acoustic transmission through one row of MRP array is ~0.35 at 8760 Hz. When input A and input B are both strong signals (normalized acoustic pressure amplitude 1), the output C behind two rows of MRP arrays is expected to feature a normalized pressure of (0.35 + 0.35) × 0.35 = 0.25 at 8760 Hz (less than 0.5) (Figure 4(c)). We here denote that the normalized pressure equal to or larger than 0.5 as the digital “1” (strong) and otherwise as the digital “0” (weak). Numerical simulations show that the acoustic pressure amplitude at the output channel C is much smaller than the input channels A and B at 8760 Hz (Figure 4(d) and S11a). Experiments show that the normalized pressures in output C are all less than 0.5 whenever the inputs A and/or B are strong with a normalized pressure “1” or weak with a normalized pressure “0.2” at 8760 Hz (Figures 4(e) and S12a).

To switch the NOT gate to an AND gate (Figure 4(f)), one row of MRP array is bent by a magnetic field
Figure 4: Magnetoactive reconfigurable acoustic logic gates. Operation schemes (a, f, and k), samples (b, g, and l), simplified operation schemes with normalized acoustic pressure (c, h, and m), numerical simulations for the case of “A1B1” at 8760 Hz (d, i, and n), and measured normalized pressures of output C (e, j, and o) of NOT gate (a–e), AND gate (f–j), and OR gate (k–o), respectively. "A#B#" in (d), (h), and (l) indicates the normalized pressures in inputs A and B, respectively. The normalized pressure values shown in (c), (e), (h), (j), (m), and (o) are calculated by normalizing the pressure amplitude values by the acoustic pressure generated by the speaker with the power input of 1 V at 8760 Hz. Note that the selective actuation of the central six pillars is because of their higher iron volume fraction (18.48% by weight). The bent pillars are removed in the simulations of (l) and (n).
Numerical simulations show that the acoustic pressure
tral MRPs and the outside curved MRP arrays (Figure 5(c)).

Research
by a circular pathway (spacing \( L \geq D \))
and thus, only one row of MRP array exists on the
pathway of both A-to-C and B-to-C (Figure 4(g)). Since the
acoustic transmission (normalized pressure) through one
row of MRP array is \(-0.35 \) at 8760 Hz, the normalized pres-
sure in output C is expected to couple the signals from inputs
A and B, leading to a normalized pressure of \( 0.35 + 0.35 = 0.7 \)
(Figure 4(h)). This point can be validated by numerical simu-
lations which show that the normalized pressure amplitude at
output C is around 0.6-0.75 at 8760 Hz (Figure 4(i) and S11b).
Experiments show that the normalized pressure at output C is \(-0.6 \) (above 0.5 and marked as “1”) when the inputs A
and B are both strong (normalized pressure “1”) at 8760 Hz
(Figures 4(j) and S12b). To further switch the AND gate to an
OR gate (Figure 4(k)), we use three magnets to bend 6
MRPs in the center of the channel (Figure 4(l) and S13).
Numerical simulations show that acoustic wave propagation
to the output channel C does not have evident resistance at
8760 Hz (Figure 4(n) and S11c). Experiments show that the
normalized pressure at output C is above 0.5 when either the
input A or the input B is strong (normalized pressure “1”) at
8760 Hz (Figure 4(o) and S12c). Note that the above three
acoustic logic operators can be on-demand and reversibly
switched by controlling the untethered magnetic fields. Addi-
tional analyses and numerical studies show that the magne-
toactive reconfigurable logic gates should work not only at
8760 Hz but also through 8700-8830 Hz and 8930-9070 Hz
(Figs. S14-S15, more discussion in Supplementary Informa-
tion). This point is further confirmed by experiments at
8700 and 9050 Hz which are located at two frequency
branches, respectively (Fig. S16).

7. Magnetoactive Reconfigurable
Acoustic Diode

Finally, we harness the MRPs to design a magnetoactive
reconfigurable acoustic diode to smartly switch the recipro-
city. Existing acoustic diodes or rectifiers that exhibit nonrecip-
rocal acoustic wave propagation typically rely on acoustic
metastructures with time-varying elements or nonlinearity
[21–25, 50, 51]. An acoustic diode that can be switched by
untethered stimuli has not been reported. Here, we harness
untethered magnetic fields to demonstrate on-demand
switching between the nonreciprocal acoustic diode and the
reciprocal acoustic conductor.

The idea for the acoustic diode is based on a cloak-like
waveguide (Figure 5(a)–(d)). When an engineering object is
placed on the pathway of an acoustic wave, the acoustic pres-
sure amplitude behind the object is significantly reduced due
to the refection or absorption of the object (Figure 5(a), (b),
S17a and b). Experimental results show that the acoustic
transmission within 8500-8800 Hz is reduced by more than a
factor of 2 when the object is placed (Figure 5(b)). When
the object is surrounded by 6 MRPs with spacing \( L/D = 1.5 \),
the direct interaction between the incoming wave and the
object is shielded by the MRPs within a certain Mie reso-
nance frequency (e.g., 8500-8760 Hz), and the wave is guided
by a circular pathway (spacing \( L/D \geq 2.5 \)) between the 6 cen-
tral MRPs and the outside curved MRP arrays (Figure 5(c)).
Numerical simulations show that the acoustic pressure
amplitude behind the object increases drastically after the
6-MRP envelope is installed (8650 Hz, Figures 5(c) and
S17c). Experiments show that the acoustic transmission of
the wave is around 80-90% of that of the reference state
without the object over frequency range of 8500-8760 Hz
(Figure 5(e)). Note that the waveguide at the cloak-like state
is not a perfect acoustic cloak because the incident acoustic
mode is disrupted by the structure [52]. Interestingly,
when the front two MRPs are bent by a magnetic field
(i.e., 0.13 T), the cloak-like state is destroyed because the
incoming acoustic wave can have direct interaction with the
object, thus leading to a significantly low acoustic transmis-
ion within 8500-9000 Hz (Figure 5(d), (e), and S17d).

The numerical simulations show that the acoustic amplitude
behind the object drastically reduces after bending the front
MRPs (Figure 5(d)), with the acoustic pressure field similar
to that of the object state shown in Figure 5(b). Figure 5(e)
shows the acoustic transmission of four interesting states
within 8500-8760 Hz: the cloak-like and the reference states
exhibit high acoustic transmission, and the blocked and
object states exhibit low acoustic transmission. The experi-
mentally measured acoustic transmissions of the four states
within 8500-9000 Hz roughly agree with the respective
numerical simulations (Fig. S18). Besides, it should be noted
that the cloak-like state (Figure 5(c)) and the blocked state
(Figure 5(d)) can be reversibly and cyclically switched by
controlling the magnetic field (Figure 5(f), Movie S3).

The acoustic diode (Figure 5(g)) is further designed based
on the waveguide shown in Figure 5(a)–(d). The acoustic
transmission of the MRP array with an applied magnetic field
(i.e., 0.13 T) is relatively low (\(<0.4\)) within 8500-9000 Hz in
the forward wave direction (Figure 5(h)). However, the
acoustic transmission increases drastically to 0.7-0.8 within
8580-9000 Hz in the backward wave direction (Figure 5(i)),
because the wave is guided by the MRPs to move around
the object. The nonreciprocal wave propagation is visualized
by the numerical simulations (Figure 5(h) and (i)) and
validated by the experimentally measured acoustic trans-
missions in two directions (Figure 5(j)). The experiment-
ally measured acoustic transmissions in two directions
within 8500-9000 Hz agree with the numerical simulations
(Fig. S19). Effectively, the acoustic diode demonstrated here
resembles the reported acoustic diodes that are composed of
a sonic crystal with its own band structure and a nonlinear
medium to destroy the system symmetry [22, 23, 25]. In this
system, the MRPs define the band structure and the interac-
tions between the incoming wave and the encapsulated object
serve as the nonlinear element. Note that the acoustic mode
has been changed during the transmission through the diode
structure. It is possible due to the structural complexity, sim-
ilar to the reported acoustic diode by Liang et al. [23, 25],
where the highly nonlinear microbubble medium may also
change the acoustic mode.

When the magnetic field is reduced or turned off, the
bent MRPs become vertical and the structure turns back to
a state of the relatively high acoustic transmission (\(<0.7\)) in
both directions within 8580-8860 Hz because the waves
are guided in both directions (Figure 5(k)–(n)). Therefore,
on-demand tuning the applied magnetic field can enable
Figure 5: Magnetoactive reconfigurable acoustic diode. (a–d) Schematics, samples, and numerical simulations at 8650 Hz of four states: reference state (a), object state (b), cloak-like state (c), and blocked state (d). The object used is a cotton-covered plastic block. The selective actuation of two pillars in (d) is because of their higher iron volume fraction (18.48% by weight). reversible switching between a nonreciprocal acoustic diode (Figure 5(g)–(j)) and a reciprocal acoustic conductor (Figure 5(k)–(n)) within 8580-8860 Hz.

8. Discussion

In summary, we report a class of active acoustic metamaterials whose configurations can be on-demand switched via untethered magnetic fields, thus enabling active switching of acoustic transmission, wave guiding, logic operation, and reciprocity. The mechanism primarily relies on synergistic integration of MRP arrays and their large deformation actuated by magnetic fields. The MRP arrays allow a large freedom for constructing various acoustic metadevices (e.g., waveguide, logic gate, and diode) via the judicious design of the MRP layout. The magnetically induced large deformation of MRPs allows the configuration modulation and thus leads to function switching of the acoustic metadevices without fabricating new structures. This study highlights a unique paradigm for applying stimuli-responsive smart materials to acoustic metamaterials and metadevices to enable active control of their acoustic properties [32, 33]. This paradigm may promote the integration between various smart or soft materials and acoustic metamaterials to achieve unprecedented functionalities [53, 54]. The unique paradigm may also promote the study of active acoustic metadevices in switching of acoustic properties via other untethered stimuli, such as electric field, light, and temperature. Besides, as the first generation of untethered-stimuli-induced active acoustic metadevices (including waveguide, logic gate, and diode), these active acoustic metadevices may be used in broad engineering settings, ranging from on-demand noise control in smart infrastructures, automobile, and aircraft [55] and audio modulation for the next generation sound devices [56] to sonic camouflage [13–15]. Furthermore, the concept of the active acoustic metamaterials enabled by magnetoactive structures may be extended to design various switchable acoustic metadevices. For example, the magnetoactive elastomers can be used to design twisted helicoids to design optical angular momentum metastructures [57] which can be tuned on and off via magnetically modulating the axial lengths. As another example, magnetoactive acoustic tunneling may be realized by assembling magnetoactive Mie resonator arrays into the tunnel, thus enabling actively switching between the tunneling with supercoupling and regular wave guiding [58]. Likewise, the paradigm may be extended to other active acoustic metadevices, such as superlenses [6–12] and topological insulators [20, 26–29, 59, 60].

9. Materials and Methods

9.1. Sample Preparation. Mie resonator pillars (MRPs) were fabricated with a molding process using additive manufacturing technique (Fig. S1). Molds were made with a fused deposition modeling (FDM) method with either ABS or dissolvable filament. The elastomer compound used for MRP is a mixture of 19.6 ml of liquid silicon rubber with various grams (5-35 g, Mold Max, Smooth-on) of iron nanoparticles (Sigma) (Table S2). After mixing the liquid rubber evenly with the iron nanoparticles for 3-5 minutes, the mixture was slowly filled in the molds. Once the elastomer mixture was cured for 4 to 5 hours, the molds were either dissolved with solvent, d-limonene, or manually dissembled. When the solvent was used, the elastomer structure was dried on the hot plate (60°C) overnight. Then, a thin elastomer strap (1-2 mm) was added around the top of the elastomer pillar to prevent the spreading or opening of MRPs due to their own weight. In each experiment, we attach the MRPs on the testing platform with a superglue (Gorilla).

9.2. Magnetic Actuation. We put a magnet under the testing platform, yet 20-30 mm ahead of the MRP. This applies a diagonal magnetic field to the MRP. The magnetic field intensity was changed by moving the magnet upward. When the distance between the magnet and the MRPs becomes small enough, the MRPs pinched on to the substrate. Once the magnet was moved downward or removed, the bent MRPs returned to the upright position.

9.3. Measurement of Acoustic Transmission. Acoustic experiments were conducted in testing chambers with acoustic insulators (cotton pads) on the chamber walls. Two loudspeakers (OT19NC00-04, Typhmony) controlled by a function generator (PI-8127, PASCO, USA) were placed in the chambers to provide the acoustic signals. The acoustic signals were collected by microphones (378B02 with 426E01, PCB Piezotronics, USA) and processed by a signal conditioner (482C05, PCB Piezotronics) and displayed by an oscilloscope (TBS1052B, Tektronix, USA). The noise was further removed with Savitzky–Golay filter in MATLAB to calculate the acoustic amplitude. The acoustic transmission was measured as $P_w/P_{wo}$, where $P_w$ and $P_{wo}$ are acoustic amplitudes with and without the metadestructures, respectively. The transmission measurement averaged over 2-4 measuring spots along a line normal to the wave propagation direction.

9.4. Acoustic Simulation. Numerical simulations were implemented with the acoustic module in COMSOL Multiphysics v5.2—a commercial finite element software. The set-ups for the numerical simulations are illustrated in Figs. S2, S9, S11, and S17. In a typical simulation, three material phases were involved in the numerical models: elastomer with high iron volume fraction (18.48%), elastomer with low iron volume fraction (3.14%), and air. The densities and sound speeds of the elastomers are shown in Table S2. Perfectly matching layers were employed to ensure the open boundary along the acoustic transport direction. The simulation was validated by benchmark calculations, and the mesh accuracy was ascertained through a mesh refinement study. The acoustic transmission was calculated by dividing the averaged acoustic pressure amplitude by the averaged background pressure amplitude over a line normal to the wave propagation direction.

Conflicts of Interest

The authors declare that there is no conflict of interest regarding the publication of this article.
Authors’ Contributions

K.H.L. and Q.W. conceived the idea and designed the research. K.H.L. carried out experiments with the technical support of K.Y., A.X., and Z.F. K.H.L., H.A., and Q.W. developed the analytical models and carried out the numerical simulations. K.H.L. and Q.W. wrote the first manuscript. All authors contributed to interpreting the results and revising the manuscript.

Acknowledgments

Q.W. acknowledges the funding support from the Air Force Office of Scientific Research Young Investigator Program (FA9550-18-1-0192, program manager: Dr. Ming-Jen Pan) and the National Science Foundation (CMMI-1762567). We thank Dr. Guoliang Huang at the University of Missouri and Dr. Chu Ma from the Universit of Wisconsin-Madison for fruitful discussions.

1. Analogy between sharkskin denticles and Mie resonator pillars

We use the metaphor of sharkskin because of the analogy in following 3 aspects:

1) Pillar-like structures: The sharkskin features pillar-like denticle arrays on its surface1-3. In this paper we employ Mie resonator pillar arrays.

2) Function in actively switching flow transmission: The sharkskin can smartly switch the surface fluid flow transmission4. This paper is to actively switch the acoustic flow transmission.

3) Actuation via tilting pillars: The modulation of flow drag of the sharkskin is through tilting the pillar-like denticles2, 5, 6. The modulation of acoustic transmission in this paper is through magnetically-induced pillar bending/tilting.
2. Modeling of the Mie resonator pillar (MRP)

**Analytical modeling.** Here, we estimate the resonance of the MRP based on a homogenization procedure presented in Reference\(^7\). For the MRP in **Fig. S4a**, the medium can be simplified into six channels (**Fig. S4b**), which are shorter than a wavelength\(^8\). Such a model can then be homogenized and equivalently represented as three two-dimensional regions with different effective properties as seen in **Fig. S4c**. The pressure fields in the different regions, denoted here as \(I\), \(II\) and \(III\), are expressed mathematically by a combination of Bessel function \(J_m\) and Hankel function \(H_m\) as\(^7,\(^9\):

\[
P^{I}(r) = \sum_m C_m J_m(k_0 r) e^{im\theta}, \quad r < r_2
\]

\[
P^{II}(r) = \sum_m [F_m J_m(k_1 r) + F_m H_m(k_1 r)] e^{im\theta}, \quad r_2 < r < r_1
\]

\[
P^{III}(r) = \sum_m [c_m J_m(k_0 r) + D_m H_m(k_0 r)] e^{im\theta}, \quad r > R
\]

where \(R = D/2\) is the total radius of the individual resonator, \(r_2\) is the inner radius of the resonator housing the air core, and \(r_1 = r_2 + (R - r_2)\eta\) is the outer radius of a uniform equivalent layer with \(\eta\) being the filling ratio of the air channels. In our case, the filling ratio \(\eta\) is approximately equal to 0.36. Note here that all the radii are measured from the center of the resonator, i.e. \(r = 0\). To satisfy the continuity at the interfaces \(r = r_2\) and \(r = r_1\), the pressure field and \(\frac{1}{\rho} \partial_r P(r)\) are matched at the boundaries\(^10\), which gives two sets of conditions:

\[
P^{I}(r_2) = P^{II}(r_2)
\]

\[
\frac{1}{\rho_0} \partial_r P^{I}(r_2) = \frac{1}{\rho_1} \partial_r P^{II}(r_2)
\]

\[
P^{II}(r_2) = P^{III}(R)
\]
\[
\frac{1}{\rho_1} \partial_r P^{II}(r_2) = \frac{1}{\rho_0} \partial_r P^{III}(R) \quad (S7)
\]

where \(\rho_{0,1}\) denote the density of regions I, III and II, respectively. Consequently, one can get the following equations, for the \(m\)th term of the summation:

\[
G_m J_m(k_0 r_2) - E_m J_m(k_1 r_2) - F_m H_m(k_1 r_2) = 0 \quad (S8)
\]

\[
\frac{k_0}{\rho_0} G_m \partial_r J_m(k_0 r_2) - \frac{k_1}{\rho_1} [E_m \partial_r J_m(k_1 r_2) + F_m \partial_r H_m(k_1 r_2)] = 0 \quad (S9)
\]

\[
c_m J_m(k_0 R) + D_m H_m(k_0 R) - E_m J_m(k_1 r_1) - F_m H_m(k_1 r_1) = 0 \quad (S10)
\]

\[
\frac{k_0}{\rho_0} c_m \partial_r J_m(k_0 R) + \frac{k_0}{\rho_0} D_m \partial_r H_m(k_0 R) - \frac{k_1}{\rho_1} [E_m \partial_r J_m(k_1 r_1) + F_m \partial_r H_m(k_1 r_1)] = 0 \quad (S11)
\]

which can be cast into a compact matrix form:

\[
\begin{bmatrix}
J_m(k_0 r_2) & -J_m(k_1 r_2) & -H_m(k_1 r_2) & 0 \\
\frac{k_0}{\rho_0} \partial_r J_m(k_0 r_2) & -\frac{k_1}{\rho_1} \partial_r J_m(k_1 r_2) & -\frac{k_1}{\rho_1} \partial_r H_m(k_1 r_2) & 0 \\
0 & -J_m(k_1 r_1) & -H_m(k_1 r_1) & H_m(k_0 R) \\
0 & -\frac{k_1}{\rho_1} \partial_r J_m(k_1 r_1) & -\frac{k_1}{\rho_1} \partial_r H_m(k_1 r_1) & \frac{k_0}{\rho_0} \partial_r H_m(k_0 R)
\end{bmatrix}
\begin{bmatrix}
G_m \\
E_m \\
F_m \\
D_m
\end{bmatrix} =
\begin{bmatrix}
0 \\
0 \\
-J_m(k_0 R) \\
-\frac{k_0}{\rho_0} \partial_r J_m(k_0 R)
\end{bmatrix}
\quad (S12)
\]

where the coefficients \(G_m\) through \(D_m\) are now normalized by the coefficient \(c_m\). We assume that the effective uniform medium density has the same bulk modulus as the background medium, but different density defined as \(\rho_1 = \rho_0 / \eta^2\). Of interest here is the determination of scattering coefficient \(D_m\). Using the scheme presented in reference for calculating \(D_m\) via a physically revealing model, the scattering coefficient is found by:
\[ D_m = - \frac{u_m}{u_m + iv_m} \]  

where \( i \) is the imaginary unit and \( U_m \) and \( V_m \) are defined as the following determinants:

\[
U_m = \begin{vmatrix}
J_m(k_0 r_2) & J_m(k_1 r_2) & Y_m(k_1 r_2) & 0 \\
\frac{k_0}{\rho_0} \partial_r J_m(k_0 r_2) & \frac{k_1}{\rho_1} \partial_r J_m(k_1 r_2) & \frac{k_1}{\rho_1} \partial_r Y_m(k_1 r_2) & 0 \\
0 & J_m(k_1 r_1) & Y_m(k_1 r_1) & J_m(k_0 R) \\
0 & \frac{k_1}{\rho_1} \partial_r J_m(k_1 r_1) & \frac{k_1}{\rho_1} \partial_r Y_m(k_1 r_1) & \frac{k_0}{\rho_0} \partial_r J_m(k_0 R)
\end{vmatrix} \quad (S14)
\]

\[
V_m = \begin{vmatrix}
J_m(k_0 r_2) & J_m(k_1 r_2) & Y_m(k_1 r_2) & 0 \\
\frac{k_0}{\rho_0} \partial_r J_m(k_0 r_2) & \frac{k_1}{\rho_1} \partial_r J_m(k_1 r_2) & \frac{k_1}{\rho_1} \partial_r Y_m(k_1 r_2) & 0 \\
0 & J_m(k_1 r_1) & Y_m(k_1 r_1) & Y_m(k_0 R) \\
0 & \frac{k_1}{\rho_1} \partial_r J_m(k_1 r_1) & \frac{k_1}{\rho_1} \partial_r Y_m(k_1 r_1) & \frac{k_0}{\rho_0} \partial_r Y_m(k_0 R)
\end{vmatrix} \quad (S15)
\]

where \( Y_m \) is the Bessel function of the second kind. Following the assumptions \( k_0 R \ll 1 \) and \( k_0 r_2 \ll 1 \), the first monopole frequency is found by setting \( m = 0 \) \(^7\). If the diameter of the MRP is 1.5 cm, the Mie resonance is estimated as \( f_R \approx 8.9 \) kHz, which is found from the frequency response of \( |D_0| \) where it approaches 1, signaling the occurrence of a scattering resonance (Fig. S4d) \(^7\). The magnitude \( |D_0| \) and angle of \( D_0 \) are depicted in Figs. S4d, e. This result is close to the experimentally observed and numerically simulated 9.1 kHz (Fig. 2).

**Effect of geometrical inconsistency.** If the fabrication of the MRP cannot accurately follow the geometrical design, the diameter of the MRP may have geometrical inconsistency. If the diameter of the MRP varies from 1.4 cm to 1.6 cm (7\% of variation around 1.5 cm), the Mie resonance frequency changes from 9.48 kHz to 8.3 kHz (Figs. S4d, e). This variation of the Mie resonance frequency can fully cover the interesting frequency range in the experiments: 8600-9200 Hz. This theoretically predicted effect of the geometrical inconsistency also agrees well with the numerical simulations shown in Fig. S2c.
3. Theoretical analysis of magnetically-induced buckling

Following the previously reported work on magnetically-induced buckling of tilted beam\textsuperscript{11}, we here develop an analytical model for the magnetically-induced bending of the pillar. The magnetically-induced bending can be modeled as a tilted pillar under a magnetic field with an angle $\alpha$ to the pillar (Fig. S7). We construct two coordinate systems: global Cartesian coordinate $(x,y)$ and local curvilinear coordinate $(s, \theta)$ shown in Fig. S7. The free energy of the magnetic-field deformed pillar can be written as$^{11-16}$

$$\Pi = \int_0^H \frac{E_1}{2} \left(\frac{d\theta}{ds}\right)^2 ds - \int_0^H A \left[\int_0^B M \cdot dB\right] ds$$ (S16)

where $s$ is the curvilinear coordinate along the beam, $\theta$ is the angle between the tangent line and the horizontal axis, $E$ is Young’s modulus of the magnetoactive elastomer, $H$ is the pillar length, $I$ is the second moment of the cross-section area, $A$ is the cross-section area, $B$ is the applied magnetic field vector, and $M$ is the magnetization vector.

We first assume that the pillar aspect ratio $(H/D)$ is relatively large, and the pillar can be considered as a slender structure. The variation of Eq. S16 leads to a governing equation of the magnetically-induced bending written as$^{11-16}$

$$\lambda^2 \left(\frac{d^2\theta}{ds^2}\right) + \sin(2\theta + 2\alpha) = 0$$ (S17)

where $\lambda = \sqrt{2E_\mu I/(AB^2\Delta\chi)}$ is a characteristic length, $\mu_0 = 4\pi \times 10^{-7} N \cdot A^{-1}$ is the magnetic permittivity of the vacuum, and $\alpha$ is the initial tilted angle of the beam. $\Delta\chi$ is the effective magnetic susceptibility difference between the axial and orthogonal direction and can be estimated as $\Delta\chi \approx \chi - \chi/(1 + \chi/2)$, where $\chi$ is the magnetic susceptibility of the elastomer.

At the critical point of the buckling, the characteristic length $\lambda$ should scale with the beam length $H$. Therefore, the critical magnetic field of the buckling should follow a scaling law as
Once the applied magnetic field is larger than the critical magnetic field for the pillar buckling, the pillar will be bent and pinched on the substrate.

According to Eq. S18, the critical magnetic field is affected by the Young’s modulus, magnetic susceptibility, cross-section geometry, and the length of the pillar. Besides, we notice that the critical magnetic field should also be affected by the tilting angle $\alpha$ of the magnetic field. The effect of the tilting angle should be reflected by the pre-factor of the scaling law, $\beta$. In addition, Eq. S18 is derived based on a slender assumption. If the slender condition is relaxed to extended to relatively small pillar aspect ratio (e.g., $H/D=2.83$ in this work), the contribution of the geometrical factor $H/D$ should be also reflected by the pre-factor $\beta$. Therefore, the critical magnetic field of the buckling can be written as

$$B_c \propto \sqrt{\frac{\mu_0 E}{\Delta x} \left( \frac{I}{AH^2} \right)}$$

(S18)

where the pre-factor is a function of tilting angle $\alpha$ and pillar aspect ratio $H/D$.

To validate the theoretical model in Eq. S19, we employ Mie resonator pillars (MRPs) with varied concentration of the ferromagnetic iron particle within the magnetoactive elastomer but maintain the geometry of the pillar and tilting angle $\alpha = \pi/4$. The variation of the iron concentration changes the Young’s modulus and magnetic susceptibility of the magnetoactive elastomer. We measure the material and geometrical parameters of the MRPs and show them in Table S2. Experiments verify that the critical magnetic field indeed follows a linear relationship with $\sqrt{\frac{\mu_0 E}{\Delta x} \left( \frac{I}{AH^2} \right)}$ (Fig. 2n).
4. Design principle of the reconfigurable acoustic logic gates

The design of the switchable logic gate is based on two mechanisms:

(1) The transmission ratios of the MRP arrays decreases with the row number of the array. For example, the acoustic transmission through one row of MRP array is around 0.35 at 8760 Hz; thus, the acoustic transmission through two rows of MRP array is around $0.35^2=0.12$ at 8760 Hz (Figs. 4c, h, m, and S14). If two inputs are applied, the output transmission of one-row MRP array is $0.35+0.35=0.7$ (above 0.5), but the output transmission of two-row MRP array is only $0.12+0.12=0.24$ (below 0.5). We here denote that the normalized pressure equal to or larger than 0.5 as “1” and otherwise as “0”. Then, these two types of MRP array show different output states: the former outputs “1” but the latter outputs “0”.

(2) The magnetic field can be used to bend a row of MRP array to leave only one-row MRP array. On-off switching the magnetic field can one-demand switch between one-row array and two-row array.

According to the design principle, to enable switching among NOT, AND, and OR operators, the acoustic transmission of one-row MRP array can be around 0.25-0.5. The corresponding frequency range is slightly below or above the Mie resonance frequency range, for example, 8700-8830 Hz and 8930-9070 Hz (according to data shown in Fig. S14a). To verify this working frequency range for the switching of three logic operators, we carry out numerical simulations that show the frequencies through 8700-8830 Hz and 8930-9070 Hz work well for the switching of three logic operators (Figs. S14 and S15). This point is also confirmed by experiments at 8700 and 9050 Hz which are located at two frequency branches, respectively (Fig. S16).
5. Supplementary tables

Table S1. Experimentally-measured materials and geometrical parameters of Mie resonator pillars. The sound speed within the filled elastomer is estimated by assuming the Poisson’s ratio as 0.48.

| Iron weight per 22 g elastomer | Iron volume fraction (%) | Young’s modulus of filled elastomer (MPa) | Density of filled elastomer (kg/m³) | Sound speed within filled elastomer (m/s) | Effective magnetic susceptibility difference $\Delta \chi$ | Height H (cm) | Cross-section area of solid part (cm²) | The second moment of area (cm⁴) |
