(Dated: May 12, 2011)

The distribution of Cr atoms in Fe$_{100-x}$Cr$_x$ alloys with $x \leq 25$ within the first two coordination shells, 1NN − 2NN, around probe $^{57}$Fe atoms was studied using Mössbauer Spectroscopy. Clear evidence was found that the distribution is not random but instead characteristic of a given atomic configuration, $(m, n)$ (m being the number of Cr atoms in 1NN, and n that in 2NN). The behavior was described quantitatively in terms of average SRO parameters, $<\alpha_1>$ (for 1NN), $<\alpha_2>$ (for 2NN) and $<\alpha_{12}>$ (for 1NN − 2NN) as well as in terms of a local short-range order (SRO) parameter, $\alpha(m,n)$, for each pair $(m,n)$. A change of sign (inversion) was found both in $<\alpha_1>$ and in $<\alpha_{12}>$, though going with $x$ in opposite directions. No inversion was observed in $<\alpha_{12}>$, which was either positive or negative depending on the metallurgical state of the samples. These findings prompt a revision of current interpretation of experimental and theoretical results relevant to the issue.

PACS numbers: 75.40.-s, 76.80.+y, 81.30.Hd,

Among various binary alloys of iron, Fe-Cr alloys occupy a special role for both scientific and technological reasons. They can be treated as good systems for testing models and theories, especially those relevant to magnetism where different phases are exhibited depending on alloy composition.$^1$ Their crystallographic structure, which for many years was regarded as homogenous bcc over the whole concentration range, turned out to be much more complex when a tetragonal $\sigma$-phase and a miscibility gap were discovered. The latter two phenomena are on one hand of interest per se and have been the subject of intensive studies,$^2$ and on the other hand, are also of a great importance technologically, namely in the production of important grades of stainless steels$^3$ for which the Fe-Cr alloys are the basic ingredient. Consequently, their useful properties such as a good resistance to high-temperature corrosion and good mechanical properties (toughness, ductility and welding ability) may be severely degraded if the $\sigma$-phase precipitates or phase separation into Fe-rich and Cr-rich phases occurs.

Recently there has been increased interest in Fe-Cr alloys. This is driven both by the discovery of giant magnetoresistance in Fe/Cr layers$^4$ and also by the potential for Fe-Cr-based steels to be used in the construction of a new generation of power plants – advance fusion and fission reactors or high power accelerator spallation targets.$^5$ In the latter application, the materials undergo irradiation damage which can seriously degrade their mechanical properties. On the lattice scale, the radiation causes lattice defects, and, consequently, a redistribution of Fe/Cr atoms that can result in a short- range order (SRO) or phase decomposition into Fe-rich and Cr-rich phases.

According to previous neutron diffraction (ND) studies$^6,7$ the Cowley SRO-parameter, $<\alpha_{12}>$, was found to change its sign at $x \approx 10 - 11$. This finding was qualitatively confirmed by a Mössbauer spectroscopic (MS) study,$^8$ yet the value of the critical concentration was not determined. Additionally, theoretical calculations predicted the existence of such an inversion, but for different values of $x$.$^9,10$ The aim of the present investigation was to study the issue in more detail using MS, since this method applied to the Fe-Cr alloys can provide precise and relevant information on SRO for each statistically meaningful atomic configuration, $(m,n)$, where $m$ is the number of Cr atoms in the first-nearest neighbor shell, 1NN, and $n$ is the number in the second-nearest neighbor shell, 2NN.$^{11,12}$ Such information would be much more detailed than the one recently found with ND,$^5$ where the inversion of the SRO parameter was found as the average over the 1NN − 2NN volume.

There are 63 different atomic configurations possible for the bcc structure within such volume. Although for a random distribution the probability of most of them, $P(m,n)$, is very small, all those with $P(m,n) > \sim 0.01$ are measurable using MS. This improvement over the information available by ND means that MS can be used as a more adequate basis for quantitative verification of different theoretical models pertinent to the issue.$^9,10,13,14$

$^{57}$Fe Mössbauer spectra were recorded at 295 K in transmission mode on four series of Fe$_{100-x}$Cr$_x$ alloys, I, II, IIIa and IIIb, with different histories and compositions using a standard spectrometer with a sinusoidal drive and a $^{57}$Co/Rh source of 14.4 keV gamma rays.

Samples of series I, with $0 \leq x \leq 15$, were 40 years old. They were prepared as follows: Armco iron and 4N purity chromium were melted in a vacuum induction furnace. After melting, they were kept in a liquid state for about 10 minutes and cooled down to an ambient temperature. The ingots were next forged into flat bars (8 mm thick), which were subsequently cold-rolled into 2 mm thick tapes. The tapes were annealed in a vacuum at 840°C for 1h, and then cooled in a furnace. The 2 mm thick tapes were next rolled down to a thickness of 0.1 mm from which 20-30 $\mu$m thick foils were obtained.
again by cold rolling. Samples of series II, three years old and with \(15 \geq x \leq 25\), were prepared in a similar way. Examples of the spectra recorded on these samples are shown in Fig. 1.

The series IIIa and IIIb samples were EFDA/EURATOM model Fe-Cr alloys that had been prepared in 2007. They were delivered in the form of bars 10.9 mm in diameter, in a recrystallized state after cold reduction of 70\% and then heat treated for 1h under pure Ar flow at the following temperatures: 750\(^\circ\)C for Fe\(_{94.4}\)Cr\(_{5.6}\), 800\(^\circ\)C for Fe\(_{86.75}\)Cr\(_{10.25}\) and 850\(^\circ\)C for Fe\(_{85}\)Cr\(_{15}\) followed by air cooling. For the MS measurements, a slice ~1 mm thick was cut off from each bar using a diamond saw, and was subsequently cold-rolled down to a final thickness of 20-30 \(\mu\)m. Samples obtained in this way constituted the series IIIa. Some of the latter in the form of 20mm-diameter circular foils were annealed at 800 \(^\circ\)C for 4h under Ar flow followed by a liquid nitrogen quenching. The samples that underwent this heat treatment constituted the series III. All the spectra were analyzed in the same way i.e. with the two-shell model. It was assumed that only Cr atoms situated within the 1NN and 2NN neighbor-shells cause measurable changes in spectral parameters i.e. the hyperfine field, \(B\), and the isomer shift, \(IS\). It was also assumed that the changes both in \(B\) and in \(IS\) were additive i.e. \(X(m,n;x) = X(0,0;x) - m\Delta X_1 - n\Delta X_2\), where \(X = B\) or \(IS\) and \(\Delta X_{12}\) stands for the change in \(X\) due to one Cr atom in 1NN (index 1) or in 2NN (index 2).

This procedure proved to be successful in the analysis of the spectra of various Fe-rich Fe-X alloys (e.g. Ref.15). Each spectrum was treated as composed of a number of subspectra, \(N\), corresponding to a particular atomic configuration, \((m,n)\). Its relative spectral area was equal to the probability of the atomic configuration associated with the spectrum, \(P(m,n)\). The latter is the relevant quantity for a quantitative description of a real atoms distribution over lattice sites in a given sample. Theoretically, the probabilities for the random case, \(P_r(m,n;x)\), can be calculated from the formula:

\[
P_r(m,n;x) = \binom{8}{m} \binom{6}{n} x^{m+n} (1-x)^{14-m-n}\quad (1)
\]

Most of the possible 63 configurations have vanishingly small probabilities, and can therefore be neglected. In practice, one usually takes into account only the most probable ones in order to fulfill the condition: \(\sum P(m,n;x) > 0.99\). This condition significantly reduces \(N\) from 63 to e. g. \(N = 4\) (\(x = 1\)), \(N = 10\) (\(x = 10\)), \(N = 14\) (\(x = 15\)). Using the above described procedure, we have successfully fitted all the measured spectra with the following values of the spectral parameters: \(\Delta B_1 = 31.0 \pm 0.5\) kOe, \(\Delta B_2 = 21.3 \pm 0.6\) kOe, \(\Delta IS_1 = -0.022 \pm 0.001\) mm/s and \(\Delta IS_2 = -0.009 \pm 0.001\) mm/s which agree well with those previously reported\[11,12\]. The values of \(P(m,n)\) determined from the analysis for the most significant 6 configurations are presented in Fig. 2 together with the corresponding ones calculated from formula (1). It is clear that the actual distribution is, in general, not random, and the degree and direction of deviation from randomness is characteristic of a given atomic configuration. In particular, the \(P(0,0)\) values are close to the \(P_r(m,n)\) ones for all \(x\) values, though those determined for the series IIIb show a systematic deviation. The distribution of atoms is partly random for \((0,1)\), \((1,0)\) and \((2,0)\) configurations, and non-random for \((1,1)\) and \((0,2)\) configurations. In order to quantitatively describe the actual departure from the randomness for \((m,n)\), we introduce the following measure for the short-range order:

\[
\alpha(m,n) = \frac{P(m,n)}{P_r(m,n)} - 1\quad (2)
\]

This SRO parameter can be regarded as an adequate

![FIG. 1: Examples of \(^{57}\)Fe Mössbauer spectra recorded at 295 K on Fe-Cr alloys with various Cr content in at\% (3=3.25, 5=4.85, 10=10.25, 15=14.9, 21=21.0, 25=25.0). The solid lines are equations of best fit.](image)
FIG. 2: (Color online) Probabilities of various atomic configurations, $P(m, n)$, around the probe $^{57}$Fe atoms as calculated for a random distribution (solid lines) and as derived from the spectra (open triangles series I and II, open circles series IIIa, full circles series IIIb).

FIG. 3: (Color online) SRO parameters, $\alpha(m, n)$, for various atomic configurations versus Cr content, $x$, as calculated using formula (2). Open triangles stand for series I and II, open circles for series IIIa, and full circles for series IIIb.

measure for the departure of the actual distribution of atoms from the random distribution, and its value can be easily determined based on the spectral parameters. $\alpha(m, n) > 0$ when the actual probability of finding an $(m, n)$ atomic configuration around the probe Fe atom is higher than the one for the random distribution (atomic short-range ordering), and $\alpha(m, n) < 0$ otherwise (clustering). In our opinion this definition is simple and justified, at least from the viewpoint of MS, as it ascribes a positive value of $\alpha$ to a larger number of Cr atoms within $1NN - 2NN$ shell, as seen by the probe Fe atoms, than the one expected for the random case, and a negative value otherwise.

Values of $\alpha(m, n)$ obtained from formula (2) for all 4 series are presented in Fig. 3. Here it is clearly evident that the $\alpha(m, n)$’s are characteristic of a given $(m, n)$ and that they also depend on the samples’ histories. It is evident then that the actual distribution of atoms in the Fe-Cr system is much more complex than the one obtained from the ND experiments. The inversion of the SRO parameter at $x \approx 10$, can locally (i.e. in terms of $(m, n)$) only be seen for the following configurations: $(1,0)$ series I and IIIa, $(2,0)$ series IIIa and IIIb, and perhaps $(0,0)$ series IIIa. The opposite inversion takes place at $x \approx 3$ in $\alpha(0, 2)$. On the other hand, $\alpha(1, 1) < 0$ over the whole concentration range showing a saturation behavior. It is also worth noticing that $\alpha(0, 0) \approx 0$ for $x < \approx 10$, but only for the cold-rolled samples.

An important issue is the effect of heat treatment on the distribution. To get some insight one can compare the $\alpha(m, n)$’s calculated for series IIIa and IIIb. Interestingly, for some configurations viz. $(0,0)$ and $(1,0)$ they are significantly different, while for other viz. $(0,1), (2,0)$ and $(1,1)$ they are similar. In these circumstances, it seems reasonable to also introduce average values of $\alpha$ to the description of the actual distribution of Cr atoms in the studied samples. Thus, the average $\alpha$ for the $1NN$ shell, $<\alpha_1>$, that for the $2NN$ shell, $<\alpha_2>$, and also the average for the $1NN - 2NN$ shells, $<\alpha_{12}>$, can be defined as follows:

$$<\alpha_i> = \frac{<k>}{<k_r>} - 1$$  \hspace{1cm} (3)
of series IIIa and IIIb. However, the inversions go in op-
tions of the average

represents consensus about the definition of SRO parameters. It should be remembered that both defini-

FIG. 4: (Color online) The average SRO parameters for the

quantities but calculated for the random distribution. A
graphical illustration of \( \alpha_1 \), \( \alpha_2 \) and \( \alpha_{12} \) is displayed in Fig. 4 on the left-hand side of the panel. Al-
ternatively, following Wittle and Campbell, and staying
with the 1NN − 2NN model and bcc structure, one can define \( \alpha_1 \), \( \alpha_2 \) and \( \alpha_{12} \) as follows:

\[
\alpha_i = \frac{k}{l(1-x)} - 1 \tag{4}
\]

where \( k = m, n, m + n \) and \( l = 8, 6, 14 \) for \( i = 1, 2, 12 \), respectively. It should be remembered that both defini-
tions of the average \( \alpha \) differ in sign in comparison to that
introduced by Cowley.

The average SRO parameters obtained using formula (4) are presented on the right-hand side panel of Fig. 4. Quantitative agreement between the corresponding average SRO parameters obtained with the two approaches can be readily seen. Concerning the crucial question of the inversion, one can definitely observe its existence both in \( \alpha_1 \) and \( \alpha_2 \), especially in the samples of series IIIa and IIIb. However, the inversions go in op-

To summarize, the distribution of Cr atoms in the 1NN − 2NN shells was studied quantitatively using Mössbauer spectroscopy on the level of atomic configurations in 4 series of Fe-Cr with having different metallurgical states. Clear evidence was found that the actual distribution is much more complex than the one accepted to date from ND. In particular, it was shown here that the change of the SRO-parameter sign observed with ND at 10-11 at% Cr and regarded as an experimental confirmation of various theoretical calculations including SRO itself, is exclusively a feature of the 1NN shell. The average SRO parameter for the 2NN shell was also found to exhibit inversion but in the opposite direction, i.e. from clustering to ordering. Consequently, the SRO parameter averaged over the two shells, \( \alpha_{12} \), does not show any inversion and its actual value depends on the metal-
lurgical state of the samples: for the cold-rolled ones it is positive, hence indicative of the atomic short-range or-
dering, whereas for the quenched samples it is negative, indicating the existence of clustering. In other words, the actual distribution of atoms in the Fe-Cr alloys is very sensitive to their metallurgical state. This, in turn, reflects the fact that the initial state of these alloys is metastable. Upon heating the alloys decompose into Fe-
rich and Cr-rich phases. The degree of the decomposi-
tion, hence the actual distribution of atoms (and values of the SRO-parameters) depends on samples’ metallurgical histories as experimentally revealed in this study, and theoretically demonstrated by performing Monte Carlo atomistic simulations.
