ABSTRACT

We carried out an optical polarimetric study in the direction of the RCW 95 star forming region in order to probe the sky-projected magnetic field structure by using the distribution of linear polarization segments which seem to be well aligned with the more extended cloud component. A mean polarization angle of $\theta = 49^\circ 8 \pm 7^\circ 7$ was derived. Through the spectral dependence analysis of polarization it was possible to obtain the total-to-selective extinction ratio ($R_V$) by fitting the Serkowski function, resulting in a mean value of $R_V = 2.93 \pm 0.47$. The foreground polarization component was estimated and is in agreement with previous studies in this direction of the Galaxy. Further, near-infrared images from Vista Variables in the Via Láctea (VVV) survey were collected to improve the study of the stellar population associated with the H\textsc{ii} region. The Automated Stellar Cluster Analysis (ASteCA) algorithm was employed to derive structural parameters for two clusters in the region, and a set of PAdova and TRieste Stellar Evolution Code (PARSEC) isochrones was superimposed on the decontaminated colour-magnitude diagrams (CMDs) to estimate an age of about 3 Myr for both clusters. Finally, from the near-infrared photometry study combined with spectra obtained with the Ohio State Infrared Imager and Spectrometer (OSIRIS) mounted at the Southern Astrophysics Research Telescope (SOAR) we derived the spectral classification of the main ionizing sources in the clusters associated with IRAS 15408$-$5356 and IRAS 15412$-$5359, both objects classified as O4 V stars.

Key words: ISM: individual objects (RCW 95) – ISM: magnetic field – H\textsc{ii} regions – infrared: stars – open clusters and associations: general

1 INTRODUCTION

Massive star forming regions generally are hosted by highly obscured clouds that in galaxies like the Milky Way, are mainly found associated with the spiral arms \citep{2010ARA&A..48..431L, 2003ApJ...593..888L}. Also, the H\textsc{ii} regions generated by the massive stars formed there can be identified from the diffuse extended emission produced by the hydrogen recombination lines associated with the H\textsc{r} transition in the optical, with the Pa\textsc{b} and Br\textsc{y} ones in the near-infrared (NIR), as well as by recombination line surveys like the radio one made by \cite{1987A&AS...70..485C}.

The RCW 95 Galactic star forming region is located at $l = 326^\circ.7$ and $b = +0^\circ.8$ \citep{1960ApJ...132..386R} and presents two bright infrared nebulosa that can be seen in Fig. \cite{1970ApJ...161..984G} that performed a Galactic 5 GHz radio survey in which they found a strong continuum source with angular diameter of 3$^\prime$.3, while \cite{1983ApJ...275...85S} and \cite{1987ApJ...320..405C} from radio recombination line measurements of the H109\textsc{r} and H110\textsc{r} transitions, found that the main radial velocity component of the associated hydrogen recombination line has a mean value of $-44$ km s$^{-1}$, which for a standard Galactic rotation curve corresponds to a heliocentric distance of 2.4 kpc \citep{2002ApJ...565.1102G}. A near-infrared study of the stellar content of Galactic H\textsc{ii} regions performed by \cite{2011A&A...536A..45M} gives a range of distances for the RCW95 region from kinematic and non-kinematic (trigonometric and K-band spectrophotometric parallaxes) methodologies. A kinematic distance of 2.8$\pm$0.3 kpc is given and spectrophotometric distances of 1.63$\pm$0.63 kpc and 2.02$\pm$0.78 kpc result by adopting two extreme interstellar extinction laws from \cite{1990ApJ...355..184M} and

ratio (\(\tau\)) data, we were able to compute the total-to-selective extinction and composed of a cal elements placed before the detector along the stellar beam path, during two observing runs in February and April 2010. The polarimetric module consisted of an arrangement of opti- elements placed before the detector along the stellar beam path, during two observing runs in February and April 2010. The polarimetric module consisted of an arrangement of optical elements placed before the detector along the stellar beam path, and composed of a retarder, an analyzer and a filter wheel (Magalhaes et al. 1996). The retarder is a half-wave plate positioned with an orientation relative to the North Celestial Pole (NCP), which causes a rotation of the polarization plane of the incident light beam. It can be rotated in steps of 22°, with each 90° rotation corresponding to a polarization modulation cycle. Finally, a Savart plate splits the beam into two orthogonally polarized components (the ordinary and extraordinary beams), with each beam passing through spectral filters before finally reaching the CCD detector.

Image reduction and photometry were done using IRAF\(^1\) tasks. Point-like sources were identified and selected with the DAOFIND task for stars with counts 5σ above the local background. Magnitude measurements were performed using aperture photometry with the PHOT task, for 10 different sized rings around each star.

The polarimetric parameters for all selected sources were computed using a set of specific IRAF tasks that includes FORTRAN routines designed for this kind of data (PCCDPACK pack-

In this work, one of our goals was to study the interstellar linear polarization component in the direction of the RCW 95 Galactic H\(\alpha\) Region. The behavior of the magnetic field lines that permeate this star forming region was determined, and by applying the empirical Serkowski relation (Serkowski et al. 1975) to the polarimetric data, we were able to compute the total-to-selective extinction ratio (\(\tau\)) mean value in this direction of the Galaxy. Also, another objective was to improve the study of the region’s stellar population, which was done with point spread function (PSF) photometry on near-infrared VVV images, combined with J-, H- and K-band spectroscopic data taken with OSIRIS at SOAR telescope.

### 2 Observations and Data Reduction

#### 2.1 Optical Polarimetry

Optical VRI polarimetric data were collected with the 0.9-m telescope of the Cerro Tololo Interamerican Observatory (CTIO, Chile, operated by the National Optical Astronomy Observatory—NOAO) during two observing runs in February and April 2010.

The polarimetric module consisted of an arrangement of optical elements placed before the detector along the stellar beam path, and composed of a retarder, an analyzer and a filter wheel (Magalhaes et al. 1996). The retarder is a half-wave plate positioned with an orientation relative to the North Celestial Pole (NCP), which causes a rotation of the polarization plane of the incident light beam. It can be rotated in steps of 22°, with each 90° rotation corresponding to a polarization modulation cycle. Finally, a Savart plate splits the beam into two orthogonally polarized components (the ordinary and extraordinary beams), with each beam passing through spectral filters before finally reaching the CCD detector.

Image reduction and photometry were done using IRAF\(^1\) tasks. Point-like sources were identified and selected with the DAOFIND task for stars with counts 5σ above the local background. Magnitude measurements were performed using aperture photometry with the PHOT task, for 10 different sized rings around each star.

The polarimetric parameters for all selected sources were computed using a set of specific IRAF tasks that includes FORTRAN routines designed for this kind of data (PCCDPACK pack-

#### 2.2 Near-infrared Photometry

The near-infrared photometric image data in the J (1.25\(\mu\)m), H (1.65\(\mu\)m) and Ks (2.15\(\mu\)m) bands were retrieved from the ESO Public Survey VVV designed to scan the inner Milky Way (Minniti et al. 2010) with the VISTA InfraRed CAmera (VIRCAM) at the 4.1-m Telescope at Cerro Paranal Observatory, in Chile (Sutherland et al. 2015). VIRCAM provides observations with a field of view

Turnshek et al. (1990), *Gil-Hutton & Benavidez (2003), **Possati et al. (2007). These routines compute the normalized linear polarization (\(Q\) and \(U\) Stokes’s parameters) with a least-squares fit solution of the modulation curves (relation of the relative intensities between the ordinary and extraordinary beams for each position angle of the half-wave plate), resulting in the determination of the degree and angle of linear polarization (\(P\) and \(\theta\), respectively), with the latter measured from the NCP to the east (Eq. 1). In addition, since Eq. 1 usually generates an overestimation of the positive quantity \(P\), a correction for this bias was applied as given by Eq. 2 (Wardle & Kronberg 1974). The \(\sigma_P\) values adopted were the larger ones between the error from the fitting process and the theoretical error from photon noise (Magalhaes et al. 1984).

\[
P = \sqrt{Q^2 + U^2} \quad \text{and} \quad \theta = \frac{1}{2} \arctan(U/Q) \quad (1)
\]

\[
P \rightarrow \sqrt{P^2 - \sigma_P^2} \quad (2)
\]

Final calibrations of polarization zero-point angle and degree were made in order to determine possible intrinsic instrumental contribution using polarimetric standard stars observed each night and shown in Table 1. For the polarization degree the intrinsic instrumental polarization contribution is below the typical errors of ~ 0.05%. The polarization angle corrections from the standard stars correspond to the difference between the polarization angle value from the catalog and those from our instrumental measurement (\(\Delta \theta = \theta_{\text{cat}} - \theta_{\text{inst}}\)). The errors for the polarization angle were computed from \(\sigma_\theta = 28.65 (\sigma_P/P)\) for \(P \gg \sigma_P\) (Serkowski 1974).

The polarization survey areas are shown in Fig. 4 in different colour boxes related to each spectral band. The V optical band covers an area of 9′0 × 8′6 (red box), the R optical band covers an area of 9′6 × 10′0 (green box) and the I optical band covers an area of 10′0 × 10′0 (yellow box). A sample of the polarimetric survey is shown in Table 2.

---

1 IRAF is distributed by the National Optical Astronomy Observatory, which is operated by the Association of Universities for Research in Astronomy, Inc., under cooperative agreement with the National Science Foundation.
of 1.48 \times 1.11 \text{ deg}^2 and a spatial resolution of 0\textquoteleft 034 per pixel. In this study we have selected the Tile d098 in the J, H and Ks bands of the VVV survey covering the field of RCW 95 H\alpha region around $\alpha_{2000} = 15^h44^m5.16^s$ and $\delta_{2000} = -53^\circ30\arcmin4.05\arcsec$, which comprises the area of the polarimetric survey in this work.

Because of crowding within the RCW 95 H\alpha region, PSF photometry was performed using IRAF tasks from the DAophot package (Stetson 1987) for stars peaked 10$\sigma$ above the local background. The best fitting for the PSF was obtained from ‘penny2’ function. The PSF radius and PSF fitting radii used for each filter are indicated in Table 2. The PSF fitting and stellar subtraction process were run several times in order to reveal and obtain the magnitudes for the very close faint companions in the most crowded areas. The completeness limits values for J, H and Ks bands are 18.5, 18.2 and 16.7 mag, respectively, and were estimated from the distribution of cumulative star counts as a function of magnitude, as shown in Fig. 2, where a linear relation was fit to determine the point at which the number of detected sources decreases in the distribution. The above completeness limits represent an improvement of about 1.1, 2.0 and 3.1 magnitudes in the J, H and Ks bands, respectively, when compared to the earlier survey (aperture photometry) by Roman-Lopes & Abraham (2004). The completeness resulting from this procedure are similar to artificial star tests for uncrowded fields as shown by Maia et al. (2016). In order to recover photometric information from saturated stars in the VVV images they were replaced with 2MASS magnitudes transformed to the VVV photometric system according to Soto et al. (2013). A sample of the photometric results is shown in Table 4.

### 2.3 Near-infrared Spectroscopy

NIR spectroscopic observations for the two brightest sources selected from our photometric study were performed with the OSIRIS at the SOAR telescope. The J-, H- and K-band spectroscopic data were acquired on April 4th 2015, with the night presenting good seeing conditions. We also used the NIR spectra of HD 303308 as template and the spectroscopic data for this object was acquired by Alexandre Roman-Lopes on March 4th 2007. Table 5 summarizes the NIR observations.

The spectroscopic dataset was reduced following standard NIR reduction procedures that are detailed in Roman-Lopes (2009), and shortly explained here. The dispersed images were subtracted for each pair of images taken at the two positions along the slit. Because of crowding within the RCW 95 H\alpha region, PSF photometry was performed using IRAF tasks from the DAophot package (Stetson 1987) for stars peaked 10$\sigma$ above the local background. The best fitting for the PSF was obtained from ‘penny2’ function. The PSF radius and PSF fitting radii used for each filter are indicated in Table 2. The PSF fitting and stellar subtraction process were run several times in order to reveal and obtain the magnitudes for the very close faint companions in the most crowded areas. The completeness limits values for J, H and Ks bands are 18.5, 18.2 and 16.7 mag, respectively, and were estimated from the distribution of cumulative star counts as a function of magnitude, as shown in Fig. 2, where a linear relation was fit to determine the point at which the number of detected sources decreases in the distribution. The above completeness limits represent an improvement of about 1.1, 2.0 and 3.1 magnitudes in the J, H and Ks bands, respectively, when compared to the earlier survey (aperture photometry) by Roman-Lopes & Abraham (2004). The completeness resulting from this procedure are similar to artificial star tests for uncrowded fields as shown by Maia et al. (2016). In order to recover photometric information from saturated stars in the VVV images they were replaced with 2MASS magnitudes transformed to the VVV photometric system according to Soto et al. (2013). A sample of the photometric results is shown in Table 4.

2.3 Near-infrared Spectroscopy

NIR spectroscopic observations for the two brightest sources selected from our photometric study were performed with the OSIRIS at the SOAR telescope. The J-, H- and K-band spectroscopic data were acquired on April 4th 2015, with the night presenting good seeing conditions. We also used the NIR spectra of HD 303308 as template and the spectroscopic data for this object was acquired by Alexandre Roman-Lopes on March 4th 2007. Table 5 summarizes the NIR observations.

The spectroscopic dataset was reduced following standard NIR reduction procedures that are detailed in Roman-Lopes (2009), and shortly explained here. The dispersed images were subtracted for each pair of images taken at the two positions along the slit. Next the resultant images were divided by a master normalized flat, and for each processed frame, the J-, H- and K-band spectra were extracted using the IRAF task APALL, with subsequent wavelength calibration being performed using the IRAF tasks IDENTITY/DISPCCOR applied to a set of OH sky line spectra (each with about 30-35 sky lines in the range 12400 - 23000 Å). The typical error (1$\sigma$) for this calibration process is estimated as $\pm 12$ Å which corresponds to half of the mean FWHM of the OH lines in the mentioned spectral range. Telluric atmospheric corrections were done using J-, H- and K-band spectra of A type stars obtained before and after the target observations. The photospheric absorption lines present in the high signal-to-noise telluric spectra, were subtracted from a careful fitting (through the use of Voigt and Lorentz profiles) to the hydrogen absorption lines and respective adjacent

continuum. Finally, the individual J-, H- and K-band spectra were combined by averaging (using the IRAF task SCOMBINE) with the mean signal-to-noise ratio of the resulting spectra being well over 100.

3 RESULTS AND ANALYSIS

3.1 Optical Polarimetry

3.1.1 Map of the distribution of Polarization Segments

From the optical polarimetric survey it was possible to derive the spatial distribution of the linear polarization segments in the direction of RCW 95. The resulting R-band map can be seen in Fig. 4. There they are represented by green segments of line that are plotted on a RGB composite image (centred on the main cluster) made from the J (blue), H (green) and Ks (red) bands of VVV images, with each segment representing the degree of polarization and polarization angle ($P$ and $\theta$), respectively, of each star with good photometric measurements in the observed field. The size of each segment is proportional to the polarization degree (the scale reference for a 5% polarization degree is indicated at the top-right corner of the map), and the orientation representing the polarization angle measured from NCP (equatorial reference). As a complement and in order to identify a possible correlation between the magnetic field component projected onto the plane of the sky, and the more extended dust component of the molecular cloud, we also constructed a contour map that was derived from a Spitzer-MIPS 70µm image taken from the NASA/IPAC Infrared Science Archive (IRSA).

The polarization angle maps appear similar in all spectral bands, with the mean values being compatible considering the uncertainties ($\langle \theta_J \rangle = 51° \pm 7°$, $\langle \theta_H \rangle = 49° \pm 7°$ and $\langle \theta_Ks \rangle = 49° \pm 8°$). As can be seen from the polarization map distribution obtained for the R band data, Fig. 4 our sample contains a high number of sources with polarization values obeying the condition $P/\sigma_P > 3$ (82%, 88% and 78% for the V, R and I bands, respectively). In the analysis of the results, we choose to be conservative by excluding all sources presenting $P/\sigma_P$ values not satisfying the mentioned condition. Indeed, from an inspection of the results obtained for the associated objects, it was concluded that most of them correspond to bad quality data measurements mainly resulting from the presence of bad pixels, cosmic rays on the detector and/or sources close to the borders of the images, where the photometric sensitivity drops considerably. However, in order to enrich the discussion sometimes the low quality polarimetric data corresponding to sources with $P/\sigma_P < 3$ were also used in order to complement the associated analysis.

As can be seen from the background NIR composite image (Fig. 4), the interstellar extinction in this direction of the Galaxy is high and highly variable, with the two star clusters clearly seen to the center and to the north-east, apparently associated with the most optically obscured parts of the region. Also, the spatial distribution of the two clusters seems well correlated with the 70µm contours with the extended cloud surrounding them in a somewhat elongated geometrical configuration. This is important because it could indicate that in this case the expansion of the Hβ regions tends to follow the magnetic field (B) lines perhaps suggesting a correlation between the mean B orientation and the Galactic plane. In this sense, we can see that the overall polarization segments distribution seems to be well aligned with the more extended cloud component, with a mean polarization angle of 49°8 as inferred from the histograms of polarization angles in Fig. 4. In this figure we highlight the three distributions related to the $P/\sigma_P$ quality data criteria stated above. There the blue one corresponds to sources with $P/\sigma_P > 3$ ("good quality data"). A Gaussian fit was applied to each distribution resulting in a mean polarization angle for the R band of $\theta_R = 49° \pm 7°$. There is a correlation in the mean value for all quality data but with higher dispersion toward lower values of $P/\sigma_P$ up to $\sigma_0 = 10°2$ for the red distribution. In addition, in

2 http://irsa.ipac.caltech.edu/Missions/spitzer.html
**Figure 3.** Spatial distribution map of the R band polarization segments in the direction of the RCW 95 H
cii region (area ∼ 10′ × 10′) with north to the top and
east to the left. The sizes of each segment are proportional to the polarization degree (an equivalent to a 5% polarization degree segment is indicated in the right
corner of the image). Each segment’s orientation is measured from the NCP. Just $P/\sigma_P > 3$ data are shown. The countour lines correspond to the Spitzer-MIPS
70µm over a RGB composition from VVV data in the J, H and Ks bands.

**Figure 4.** R band polarization angle histograms. Each colour represent the quality data where grey correspond to all data with $P/\sigma_P > 1$, blue for data with $P/\sigma_P > 3$ and red for data with $1 < P/\sigma_P < 3$. The mean polarization angle from a Gaussian fit to each distribution results in 49°87, 49°78 and 47°99 for the
grey, blue and red distributions, respectively. There is an increase in the dispersion with lower values of $P/\sigma_P$ (from $\sigma_\theta = 7.70$ for the blue distribution up to
$\sigma_\theta = 10.22$ for the red one).

In order to evaluate some correlation between the mean B orientation and the Galactic plane it is possible to convert the polarization
angles from equatorial to Galactic coordinates according to [Stephens et al. 2011]. The Galactic polarization angle for the R band is then
$\theta_G = 87°0$ which means that the mean B orientation shows a good
correlation with the Galactic plane (the position angle of Galactic
plane is 90°).

The histograms for the observed values of the polarization degree are shown in Fig. [5]. There we also can see those corresponding to the three distributions described earlier as shown in Fig. [4].
polarization degree values for the best quality data ranges between \( P = 0 - 10\% \) with the higher frequencies occurring for values between \( P = 3 - 6\% \) (with \( \sim 60\% \) of the blue distribution sources lying within this range). The red distribution does not show any apparent preferential range of polarization degree values, however they correspond to the 11\% of the R band entire sample.

### 3.1.2 Wavelength dependence of polarization degree and the observed total-to-selective extinction ratio

The V, R and I band polarimetric survey in principle allow us to study the wavelength dependence of the polarization degree, which in turn can be related to specific properties of the interstellar reddening law in the direction of RCW 95 H\( \alpha \) region. This wavelength dependence can be described by the Serkowski empirical relation (Serkowski et al. 1975):

\[
P(\%\) = \( P_{\text{max}} \exp\left[ -K \ln^2\left( \frac{\lambda_{\text{max}}}{\lambda}\right) \right]\) \tag{3}
\]

where \( P(\%\) and \( P_{\text{max}} \) are the polarization degree at a wavelength \( \lambda \) and the maximum polarization level computed from the fitting, respectively, with \( \lambda_{\text{max}} \) corresponding to the wavelength where such maximum is reached. The \( K \) parameter determines the width of the peak in the Serkowski curve, and in general it is assumed as \( K = 1.15 \) for the optical spectral range (Serkowski et al. 1975).

Based on the polarimetric dataset derived from the V, R and I bands observations (197 sources with good measurements), we selected all sources presenting \( P/\sigma_P > 3 \) in all three bands (153 sources, \( \sim 78\% \)), and constructed the \( P(\%) \) vs. \( \lambda^{-1}(\mu\text{m}^{-1}) \) diagrams shown in the top panel of Fig. 6. The fitting process to each star was performed using the EMCEE code adapted for the Serkowski relation applied to the individual values of \( P_{\text{max}} \) and \( \lambda_{\text{max}} \) for each source in our sample (Foreman-Mackey et al. 2013; Serón Navarrete et al. 2016). The \( P(\%) \) vs. \( \lambda^{-1}(\mu\text{m}^{-1}) \) diagrams seen in the top panel of Fig. 5 show how the examples of the Serkowski relation (red lines) applied for two sources in our sample, and by using the mentioned parameters of Eq. (3), we computed the associated \( R_V \) values with the Eq. (4) (Serkowski et al. 1975; Whittet & van Breda 1978):

\[
R_V = (5.6 \pm 0.3) \lambda_{\text{max}} \tag{4}
\]

with the derived parameters being indicated in the top-left corner of each \( P(\%) \times \lambda^{-1}(\mu\text{m}^{-1}) \) diagram in the Fig. 6.

In order to calculate the mean value of \( R_V \) in the direction of RCW 95, we applied the fitting process only to the sources presenting \( \chi^2_{\text{red}} < 2 \) from the Serkowski relation fitting. From the entire sample, 106 sources meet the mentioned conditions resulting in a mean total-to-selective extinction ratio value (weighted average) \( R_V = 2.93 \pm 0.47 \) which, given its uncertainty, can be compared to the standard value of \( R_V = 3.09 \pm 0.03 \) for Galactic interstellar grains (Rieke & Lebofsky 1985).

In the bottom panel of Fig. 6 we present the Serkowski relation plotted over the 106 sources (blue dots with error bars in light-blue) used to compute the mean \( R_V \) value in the direction of RCW 95. The uncertainties on the derived polarimetric parameters increase to the right side of the plot just toward lower \( \lambda \) values, as expected because the heavy extinction in general contributes to decrease the signal-to-noise ratio values toward bluer colours, mainly for the stars in the direction of RCW 95.

3.1.3 Foreground R-band polarization component

For an assumed heliocentric distance of 2.4 kpc (Giveon et al. 2002), it is expected that at least part of the polarization levels measured for the stars in our sample are possibly affected by a line of sight foreground interstellar component. In this sense, we proceed to estimate this foreground contribution by using the NIR photometric colours of the probable foreground and background sources, taking into account the observed connection with the associated polarimetric parameters. The NIR photometric colours taken from the results presented in Sect. 4.2 were correlated with our polarimetric sample to identify the sources corresponding to the main-sequence and red-giant and/or super-giant Galactic disk population, as can be seen in Fig. 7. There the blue distribution corresponds to the low-reddened sources in the CMD, which in turn are associated with the main-sequence disk stars. On the other hand, the probable giant field sources (e.g. those mainly located behind the star forming region) correspond to the red dots. Both the blue and the red sample were manually selected from the mentioned locus in the CMD avoiding to select sources located in ambiguous position in the diagram. The observed polarization degree distributions of this two groups of objects are shown in Fig. 8 which is colour coded in the same way. We can see that the polarization degree levels for the foreground sources peaks around \( P_R = 2.0\% \), with no background sources showing polarization degree lower than this value in the red distribution, which we assume as the probable mean value of the foreground component of the interstellar polarization value in this direction of the Galaxy.

We also analyzed the polarization angle distribution for stars with \( P_R < 2.0\% \) and \( P_R > 2.0\% \), and by Gaussian fittings we estimated the mean polarization angle associated with each distribution. The results are shown in Fig. 9. The angles are \( \theta = 43^\circ \) for the foreground component and \( \theta = 50^\circ \) for the background component.
show that there is no significant difference between the polarization angle for the two source groups resulting in a mean polarization angle of $\theta = 46.5^\circ \pm 8.5^\circ$. From a search in the associated literature we found that Mathewson & Ford (1970) derived values $P \approx 2.19\%$ and $\theta = 51^\circ$ for HD 141318, a star in the vicinity of the RCW 95, both values well in line with our estimates for the mean polarization angle and foreground polarization component in this part of the Galaxy.

The Stokes parameters associated with the foreground component can be estimated using the Eq. (2) as follow:

$$Q_f = P \cos 2\theta$$
$$U_f = P \sin 2\theta$$

where $Q_f$ and $U_f$ are the Stokes parameters associated with the foreground component with $P$ and $\theta$ estimated above, resulting in values of $Q_f = 0.137$ and $U_f = 1.955$, respectively.

### 3.2 VVV near-infrared photometric study

In the following sections we describe the study of the stellar population in the direction of the RCW 95 H\relbar\relbar region. The stellar clusters studied are those associated with the infrared sources IRAS 15408–5356 and IRAS 15412–5359, hereafter identified as 15408 and 15412, respectively.

#### 3.2.1 Cluster parameter determinations

The initial reference coordinates for each cluster are those of the IRAS sources, which are $\alpha_{2000} = 15^h34^m42.8^s$ and $\delta_{2000} = -54^\circ05'56''$ for IRAS 15408–5356 and $\alpha_{2000} = 15^h45^m03.4^s$ and $\delta_{2000} = -54^\circ09'08''$ for IRAS 15412–5359. In order to determine the best values of the centre for each cluster, we made use of the Automated Stellar Cluster Analysis (ASCA) algorithm (Perren et al. 2015). The latter allowed us to compute the central coordinates of the cluster as the point with maximum spatial density value, by fitting a two-dimensional Gaussian kernel density estimator (KDE) to the density map of each cluster. In Fig. 10 we show the results of the 2D Gaussian KDE fitting for 15408 (middle) and 15412 (bottom). The area values used for each centre computation are indicated in the upper panel of the figure, with the red and green boxes corresponding to the clusters 15408 and 15412, respectively. As a complement, we also indicate by a yellow box, the area corresponding to the field shown in Fig. 1.

For the determination of structural parameters, we applied a radial density profile (RDP) analysis using a function that describes the variation of the stellar number density (stars/area), with the distance from the center of the cluster defined by Equation (6) (King 1962; Alves et al. 2012).

$$\sigma(r) = \sigma_0 \left[\frac{1}{\sqrt{1 + \left(\frac{r}{r_c}\right)^2}} - \frac{1}{\sqrt{1 + \left(\frac{r}{r_c}\right)^2}}\right]^2 + \sigma_f$$ (6)
where $r_c$ is the core radius, $r_t$ is the tidal radius, $\sigma_0$ is the central star density and $\sigma_f$ is the field star density. The latter correspond to a minimum density level of the combined background and foreground stars, indicating the contribution of contaminating field stars per unit area throughout the region in the direction of the cluster. Furthermore, $\sigma_f$ is crucial for estimating the cluster limiting radius (hereafter cluster radius, $r_{cl}$), defined as the distance from the cluster centre to the point where the RDP reach the $\sigma_f$ level. Specifically, the algorithm first count the number of RDP points that fall below a given maximum tolerance interval above $\sigma_f$. When the number of these points reaches a fixed value, the point closest to the $\sigma_f$ is stored as the most probable radius for this iteration, which is repeated increasing the tolerance around $\sigma_f$. Finally, the estimation for $r_{cl}$ is obtained from the average of the set of radius values stored after each iteration, where its associated error correspond to the standard deviation of this average.

The RDP determination for both clusters was then performed using the ASteCA algorithm, which computes the RDP by generating square rings of increasing sides via an underlying 2D histogram (grid) in the spatial diagram of the analyzed region, counting the stars within each square ring and dividing by its area. In Fig. 8 we show the RDP obtained for the clusters 15408 and 15412, where each dot represent the number of stars per unit area as described above, with the associated uncertainties represented by the error bars. The horizontal blue line indicates the $\sigma_f$ value, the red arrow indicates the determined $r_{cl}$ value and the gray region indicates the associated uncertainty. The 3-parameter King profile (King 1962) is indicated by the dashed green line and the core radius is represented by the vertical green line. The tidal radius of the cluster’s King profile is indicated by the green arrow. In Table 6 we list all parameter values obtained from the RDP analysis, where the different radii are shown in two rows, the upper one shows them in degrees and the lower one in parsecs. This result suggests that the two clusters found by Dutra et al. (2003), for which the estimation of centers and angular dimensions were based on visual inspection on the 2MASS Ks images, actually correspond to the single cluster 15408 in this work.
3.2.2 Luminosity and Mass Functions

The luminosity function (LF) of the RCW 95 region was evaluated by adding together the identified members from both 15408 and 15412 clusters. A $M_K$ LF was built by applying the distance modulus and reddening corrections to the stars magnitude and binning the sample using a 0.75 magnitude interval. A Monte-Carlo procedure was used to propagate both the photometric uncertainties and the adopted extinction uncertainty into a LF uncertainty, by assuming a normal error distribution. The resulting LF is shown in Fig. 12.

The mass function (MF) of RCW 95 was then evaluated by using the mass-$M_K$ relationship from the 3.2 Myr (log $t$ = 6.5) PARSEC isochrone, the adopted age of both clusters. Mathematically, each bin $i$ of the LF, $\phi(M_K,i)$, was converted into a mass function bin, $\xi(m_i)$, according to the following relation:

$$\xi(m_i) = \phi(M_K,i) \frac{dM_K}{dm} |_{m_K}$$  \hspace{1cm} (7)

where $dM_K/dm$ represents the $M_K$-mass relationship, evaluated at the $M_K$ magnitude. Similarly, the $M_H$ and $M_J$ LFs were also used to obtain additional constraints to the mass function shape. Derivation of the total observed stellar mass ($M$) is easily done through the following summation over all mass bins in a given band:

$$M = \sum_i \xi(m_i)m_i$$  \hspace{1cm} (8)

Fig. 13 shows the resulting MF for the RCW 95 region, along with the derived total mass of observed stars. Since we are taking advantage of measurements in three bands, the total mass was obtained through an average of the summation in each band. The mass spectrum shows a power-law behavior at masses higher than $2 M_\odot$, but flattens for lower masses in all filters. This result was also found in the mass function of each cluster individually, albeit at a lower confidence level, specially for cluster 15408.

A fit of the stellar initial mass function (IMF), modelled by a power-law of the form $\xi(m) = A m^{-\alpha}$ (hereafter K13 [Kroupa et al., 2013]), was performed on the higher mass bins ($m > 2 M_\odot$) yielding a slope of $\alpha = 2.29 \pm 0.12$, in accordance with the expected IMF slope at this mass range. The flattening at lower mass bins probably signals higher than average incompleteness towards the clusters rather than selective mass loss driven by evolutionary effects. Although the cutoff limit at $2 M_\odot$, corresponding to $K \sim 15.5$, is about 1 magnitude brighter than the derived completeness limit, crowding and higher extinction in young clusters is known to cause an increase in incompleteness towards its centre with relation to the mean incompleteness value derived from stellar counts [Maia et al., 2016].

Given the youth of the region, it is unlikely that stars as massive as a solar mass star have been depleted by dynamical effects such as stellar evaporation. Therefore, the MF normalisation (calculated at $2 M_\odot$) was used to extrapolate K13 IMF down to the hydrogen burning limit (0.08 $M_\odot$). Integration of this function to recover the unseen stellar content yielded a total stellar mass of $1220 \pm 213$ $M_\odot$ for the RCW95 region, with 39% held by the cluster 15408 and 61% held by the cluster 15412.

3.2.3 Near-infrared spectroscopic classification of the most massive members and cluster ages

Through the use of CMDs built from the JHKs VVV photometry, combined with NIR follow-up spectroscopic observations of the main sources in each cluster, we were able to obtain valuable information about the stellar population of each cluster. The CMD in the direction of each cluster contain sources of both, background and foreground Galactic disk population. As a consequence the observed CMDs are the result of a mix of young and old stellar sources that in principle are difficult to interpret. In order to relieve this effect, we applied the decontamination method described in [Maia et al., 2010], which is based on a statistical comparison between the observed CMD for each cluster and those in the direction of associated control regions. It enables the decontamination of the Galactic field population from the CMD of the cluster. The areas for the decontamination procedure were chosen accordingly with the results obtained in Table 6 which are summarized in Fig. 12. The same control region was used for the decontamination of both clusters, which is centered at $\alpha_{2000} = 15^h 44^m 38\fs6$ and $\delta_{2000} = -54^\circ 18' 53''$ (measuring about 2.8 x 2.8 square arcmin). It was selected from the visual inspection of the Spitzer 3.6 $\mu$m and 8.0 $\mu$m images of the region, looking for adjacent regions showing no extended emission at longer wavelengths, with the aim of avoiding as much as possible the areas immersed in the associated molecular complex. Finally, among all the possible control regions, we selected the nearest field with similar Galactic latitude $b$.

The resulting CMDs for each cluster are shown in Fig. 14 where the left panels correspond to the observed CMD in the direction of each cluster, the middle panel shows the CMD made from the sources found in the direction of the control region, while the decontaminated CMD for each cluster are represented by the right panels. We also indicate there the two sources for which we obtained NIR spectroscopic data that enabled us to refine the classification of the main ionizing source of the 15408 cluster, as well as to confirm the massive nature of the brightest source in the CMD of the 15412 cluster. From an inspection of the two decontaminated CMDs, we can see that the associated vertical main-sequences are both seen at (J-Ks)~2.0 with the probable turn-on regions occurring approximately at J~16 mag, indicating that the two clusters are under about the same amount of interstellar extinction, and probably have similar ages.

Fig. 15 shows the combined CMD containing point sources from the 15408 and 15412 clusters, which are represented by the

### Table 6. Structural parameters of both clusters 15408 and 15412.

| ID Cluster | Centre \((ra \pm \sigma_{ra}, dec \pm \sigma_{dec})_{J2000}\) | Cluster Radius \((r_c)\) | Core Radius \((r_c)\) | Tidal Radius \((r_t)\) |
|------------|--------------------------------|----------------|----------------|----------------|
| 15408      | (236.179 ± 0.002, −54.11 ± 0.001) | 0.049 ± 0.003 | 0.024 ± 0.003 | 0.1 ± 0.03 |
| 15412      | (236.247 ± 0.001, −54.143 ± 0.001) | 0.019 ± 0.002 | 0.006 ± 0.002 | 0.06 ± 0.06 |
red and green symbols, respectively. In this diagram we represent by the blue dashed line the non-reddened 3.2 Myr PARSEC (Bressan et al. 2012; Chen et al. 2015) isochrone (solar metallicity shifted to a heliocentric distance of 2.4 kpc), with each mass in the interval 5 to 80 $M_\odot$ indicated. There we also show a set of PARSEC isochrones computed for ages 2.0 Myr, 3.2 Myr and 5 Myr, reddened by $A_V = 11$ and 13.

From the position of sources IRS1 and IRS2 in the CMD of Fig. [15] and accordingly with the stellar models, we can see that both stars are probably very luminous objects with inferred masses of $40 - 50$ $M_\odot$, which according to Martins et al. (2005) should correspond to stars of O4V-O5V types. With our new SOAR-OSIRIS NIR spectra taken for the two brightest source in both clusters we confirmed this assumption. The associated J-, H- and K-band spectra of IRS1 and IRS2 stars are presented in Fig. [16]. We also show

![Figure 11](image11.png)

**Figure 11.** Radial density profile of the regions of clusters 15408 and 15412. The black dots correspond to the RDP point from the center of each cluster. The 3-parameter King profile is represented by the dashed green line, the vertical green line indicates the cluster core radius and the tidal radius is represented by the green arrow. The horizontal blue line indicates the $\sigma_r$ value and the cluster radius with its uncertainties are indicated by the red arrow and the grey region, respectively.

![Figure 12](image12.png)

**Figure 12.** $M_K$ luminosity function of the RCW95 region. Error bars were calculated using a Monte-Carlo procedure to propagate photometric and extinction uncertainties. The adopted distance modulus and extinction corrections are also shown.

the J-, H- and K-band template spectra of HD 303308, a known O4V Galactic star. From the comparison of the former with the template spectra we can see that besides the residual hydrogen emission line features present in the IRS1 spectra, which could not be completely removed during the reduction process, all other photospheric lines seen in the J-, H- and K-bands are pretty similar, indicating that the three stars are probably of the same spectral type. Indeed, the J-, H-, K-band spectral features of IRS1 and IRS2 are very similar (besides the residual hydrogen emission line features present in the IRS1 spectra, which could not be completely removed during the reduction process, all other photospheric lines seen in the J-, H- and K-bands are pretty similar, indicating that the three stars are probably of the same spectral type. Indeed, the J-, H-, K-band spectral features of IRS1 and IRS2 are very similar (besides the residual hydrogen emission line features present in the spectra of the former) to those of HD 303308 (O4V) and HD 46223 (O4V) (Hanson et al. 2005). The fact that the He $\lambda$17007 absorption lines are less intense than the He $\lambda$16930 lines, and the presence of He $\lambda$121890 absorption lines in the K-band, along with strong C iv and N iv $\lambda$20800-21160 emission lines of similar intensity in all K-band spectra, led us to the conclusion...
that both sources are indeed early O-type stars probably of the O4V type. This spectral classification of the source IRS1 represents a more accurate classification than that previously determined by Martins & Plez (2006), and from the observed connection with the associated polarimetric parameters we estimated the line of sight foreground interstellar component. In order to estimate this mean foreground component, we made use of the VVV NIR photometric colours of the probable foreground and background sources, and based on the observed connection with the associated polarimetric parameters we estimated the mean polarization degree in the direction of RCW95 as $P_E = 2.0\%$.

- Using the Automated Stellar Cluster Analysis (ASsCa) algorithm developed by Perren et al. (2015), and the statistical decontamination method of Maa et al. (2019), we derived estimates for the cluster limiting radius $r_{lim}$, core radius $r_{core}$ and tidal radius $r_t$ of the two clusters in the RCW95 region. From the photometry data coupled with a set of Padova and Trieste Stellar Evolution Code (PARSEC) isochrones (Bressan et al. 2012; Chen et al. 2015), we estimated an age of about 3 Myrs for both clusters.
- The LF of the RCW95 region was evaluated from the identified members of both 15408 and 15412 clusters and its MF determined from the mass-$M_{K}$ relationship of the 3.2 Myr ($\log t = 6.5$) PARSEC isochrone, the adopted age of both clusters. The $M_{J}$ and $M_{K}$ LFs were also considered to obtain additional constraints on the MF shape. The resulting mass spectrum shows a power-law behaviour at masses higher than $2 M_{\odot}$ but flattens for lower masses in all filters. The stellar IMF was evaluated for $m \gtrsim 2 M_{\odot}$, yielding a slope of $\alpha = 2.29 \pm 0.12$, in accordance with the expected IMF slope at this mass range. MF normalisation was used to extrapolate the K13 IMF down to the hydrogen burning limit ($0.08 M_{\odot}$) that finally yields a total stellar mass of $1220 \pm 213 M_{\odot}$ for the RCW95 region, shared by the clusters 15408 (39%) and 15412 (61%).

- These results, together with the compact nature of the clusters as derived from their structural parameters, are in agreement with star formation scenarios in which a number of small sub-clusters form first from a molecular cloud and then merge to produce fewer larger ones (Krumholz 2014).

- From our near-infrared photometric study of VVV images of the RCW95 region, combined with new SOAR-OSIRIS NIR spectra of the two brightest sources of the sample, we were able to refine the spectral classification of the main ionizing source of the 15408 cluster, as well as identifying the existence of another early-O star, unknown until the present and the dominant source of Lyman photons in the new cluster 15412 identified there. Both objects

4 CONCLUSIONS

In this work we performed a study of the interstellar linear polarization component in the direction of the RCW 95 Galactic Hii region, a massive, dense and rich star-forming region. The behaviour of the magnetic field lines that permeate this star-forming region was determined, and from the empirical Serkowski relation applied to the polarimetric data, we were able to compute the total-to-selective extinction ratio ($R_V$) mean value in this direction of the Galaxy. Also, another objective of this work was to improve the study of the clusters stellar population, which was done with PSF photometry applied to new near-infrared VVV images, combined with J-, H- and K-band spectroscopic data taken with OSIRIS at SOAR.

From the analysis of the spectroscopic data and related optical-NIR photometry, our main results are:

- The CTIO optical V-, R- and I-band polarimetric maps look similar in all three spectral bands, with the mean values ($\theta_V$) = $51.2 \pm 7.6$, ($\theta_R$) = $49.8 \pm 7.7$ and ($\theta_I$) = $49.4 \pm 8.9$ being compatible considering the associated uncertainties. The overall polarization segments distribution seems to be well aligned with the more extended cloud component, with a mean polarization angle of $49.8^\circ$.

- The polarization degree values for the best quality data ranges between $P = 0 - 10\%$ with the higher frequencies occurring for values between $P = 3 - 6\%$ (with ~ 60% of the source distribution lying within this range). For the assumed RCW 95 heliocentric distance of 2.4 kpc, it is expected that the polarization levels measured for the stars in our sample are affected by a line of sight foreground interstellar component. In order to estimate this mean foreground component, we made use of the VVV NIR photometric colours of the probable foreground and background sources, and based on the observed connection with the associated polarimetric parameters we estimated the line of sight foreground interstellar component of the polarization degree in the direction of RCW95 as $P_E = 2.0\%$.

- The polarization degree values for the best quality data ranges between $P = 0 - 10\%$ with the higher frequencies occurring for values between $P = 3 - 6\%$ (with ~ 60% of the source distribution lying within this range). For the assumed RCW 95 heliocentric distance of 2.4 kpc, it is expected that the polarization levels measured for the stars in our sample are affected by a line of sight foreground interstellar component. In order to estimate this mean foreground component, we made use of the VVV NIR photometric colours of the probable foreground and background sources, and based on the observed connection with the associated polarimetric parameters we estimated the line of sight foreground interstellar component of the polarization degree in the direction of RCW95 as $P_E = 2.0\%$.

- The polarization degree values for the best quality data ranges between $P = 0 - 10\%$ with the higher frequencies occurring for values between $P = 3 - 6\%$ (with ~ 60% of the source distribution lying within this range). For the assumed RCW 95 heliocentric distance of 2.4 kpc, it is expected that the polarization levels measured for the stars in our sample are affected by a line of sight foreground interstellar component. In order to estimate this mean foreground component, we made use of the VVV NIR photometric colours of the probable foreground and background sources, and based on the observed connection with the associated polarimetric parameters we estimated the line of sight foreground interstellar component of the polarization degree in the direction of RCW95 as $P_E = 2.0\%$.

Figure 14. Colour-magnitude diagrams $J \times(J − Ks)$ of the clusters 15408 and 15412. (left) CMD in the direction of each cluster. (middle) CMD in the direction of the control region. (right) Decontaminated CMD of each cluster. There were labeled those sources with near-infrared spectra (IRS1 and IRS2).

Table 7. Summary of extinction values of sources labeled in Fig. 15

| ID    | $\alpha_{2000}$ (h:m:s) | $\delta_{2000}$ (°:′″) | $(J − H)_0$ | $E(J − H)$ | $E(B − V)$ | $A_V$ ($R_V = 2.93 ± 0.47$) | $A_K$ | Spectral Type   |
|-------|--------------------------|------------------------|--------------|------------|------------|-----------------------------|-------|-----------------|
| IRS1  | 15:44:43.39              | -54:05:53.5            | -0.11        | 1.342 ± 0.051 | 4.067 ± 0.470 | 11.920 ± 2.438 | 1.335 ± 2.438 | O4 V   |
| IRS2  | 15:44:59.55              | -54:08:47.6            | -0.11        | 1.356 ± 0.037 | 4.109 ± 0.510 | 12.039 ± 2.442 | 1.348 ± 2.442 | O4 V   |
| IRS3  | 15:44:39.74              | -54:06:32.0            | -0.11        | 1.206 ± 0.051 | 3.655 ± 0.469 | 10.709 ± 2.199 | 1.199 ± 2.199 |       |
| IRS4  | 15:44:57.91              | -54:08:21.5            | -0.11        | 1.473 ± 0.037 | 4.464 ± 0.553 | 13.080 ± 2.649 | 1.465 ± 2.649 |       |
| IRS5  | 15:44:55.80              | -54:08:10.7            | -0.11        | 1.408 ± 0.031 | 4.267 ± 0.526 | 12.502 ± 2.528 | 1.400 ± 2.528 |       |
| IRS6  | 15:45:03.96              | -54:08:08.2            | -0.11        | 1.376 ± 0.048 | 4.170 ± 0.526 | 12.218 ± 2.493 | 1.368 ± 2.493 |       |

are found to be O4V stars, which are the main ionizing sources of the H${\alpha}$ region.

ACKNOWLEDGMENTS

This work is based [in part] on observations made with the Spitzer Space Telescope, which is operated by the Jet Propulsion Laboratory, California Institute of Technology under a contract with NASA. This research made use of data obtained at the Southern Astrophysical Research (SOAR) telescope, which is a joint project of the Ministério da Ciência, Tecnologia, e Inovação (MCTI) da República Federativa do Brasil, the U.S. National Optical Astronomy Observatory (NOAO), the University of North Carolina at Chapel Hill (UNC), and Michigan State University (MSU). We acknowledge the use of data from the ESO Public Survey program ID 179.B-2002 taken with the VISTA 4.1 m telescope. JV-G acknowledges the financial support of the Dirección de Investigación of the Universidad de La Serena (DIULS), through a “Concurso de Apoyo a Tesis 2013”, under contract No PT13147. G.A.P.F. acknowledges the partial support from CNPq and FAPEMIG (Brazil).

Figure 15. CMDs $J \times (J-K_s)$ of the decontaminated clusters 15408 (red) and 15412 (green). The yellow, blue and black solid lines correspond to a 2 Myr, 3.2 Myr and 5 Myr isochrones at $A_V = 11 - 13$ with $Z = 0.016$ for a distance of 2.4 kpc. The dashed blue line correspond to the unreddened 3.2 Myr isochrone where the respective stellar masses for MS stars are indicated. The dashed black line indicates the reddening vector for a O4 V star (Martins et al. 2005) indicating the location of $A_V = 0, 10, 20$ and 30 mag according to interstellar extinction law from Rieke & Lebofsky (1985) using the $R_V = 2.93 \pm 0.47$ from the polarimetric study. Stars marked with IRS1-6 labels are those in Table 7.
