Fluctuations and correlations in hexagonal optical patterns

Damià Gomila and Pere Colet

Institut Mediterrani d’Estudis Avançats, IMEDEA (CSIC-UIB), Campus Universitat Illes Balears, E-07071 Palma de Mallorca, Spain.

We analyze the influence of noise in transverse hexagonal patterns in nonlinear Kerr cavities. The near field fluctuations are determined by the neutrally stable Goldstone modes associated to translational invariance and by the weakly damped soft modes. However these modes do not contribute to the far field intensity fluctuations which are dominated by damped perturbations with the same wave vectors than the pattern. We find strong correlations between the intensity fluctuations of any arbitrary pair of wave vectors of the pattern. Correlation between pairs forming 120° is larger than between pairs forming 180°, contrary to what a naive interpretation of emission in terms of twin photons would suggest.

I. INTRODUCTION

The properties of the fluctuations and correlations in spatially extended patterns out of thermodynamical equilibrium were studied long ago in the context of hydrodynamic systems [12]. More recently there has been a new surge of interest in the field of nonlinear and quantum optics since Lugiato and Castelli pointed out the existence of a purely quantum phenomenon in a spatial stationary dissipative structure [3], the reduction of fluctuations below quantum limits in the difference between the intensities of the two Fourier modes of a stripe pattern. Since then, the properties of the fluctuations and correlations of stripe patterns in different nonlinear optical models have been widely studied [1,2]. Stripe patterns in these systems appear as supercritical transitions, and close to the threshold for pattern formation the harmonics of the fundamental wave vectors can be neglected. Therefore considering the homogeneous mode and the two modes of the stripes for each field is enough and simplifies the problem allowing for an analytic treatment. The problem considering the whole infinite set of transverse modes in optical stripe patterns has been addressed numerically in [1]. At difference with the few modes approximation, the continuous problem makes evident the role of the so called soft modes in the fluctuations of the near field. However a very good agreement between the few modes approximation and the continuous treatment is still found for the correlations of the fluctuations of the far field mode intensities close to threshold.

Due to the additional complexity, fluctuations and correlations in hexagonal optical patterns have been much less studied [15,16]. Furthermore, these two papers use an approximation in few modes to describe the pattern. However hexagonal patterns generally appear subcritically, with a finite amplitude and therefore harmonics are not negligible even at threshold. Strictly speaking, an approximation in which only the homogeneous mode plus the six modes of the hexagons are considered is not fully justified.

In this paper we will treat the case of a subcritical hexagonal pattern using a continuous model, i.e., avoiding any restriction to a reduced number of spatial modes. In particular, we consider an optical cavity filled with a nonlinear isotropic Kerr medium. This situation is described by the Lugiato-Lefever model [10] in which a Turing instability was described for the self-focusing case. This pattern-forming instability leads to a hexagonal pattern in the 2D transverse plane. We find that the fluctuations of the near field are dominated by the two Goldstone modes associated to the translational invariance in the $x$ and $y$ directions, and by the soft modes arbitrarily close to them in infinitely large systems. We also show that the modes that dominate the near-field fluctuations do not contribute at all to the far-field intensity fluctuations. We identify the modes responsible for the far-field intensity correlations and we find: (a) strong correlations between arbitrary pairs of wave vectors of the pattern, but stronger between those forming a 120° angle; (b) anti-correlation between the zero wave vector of the spectrum of fluctuations and any wave vector of the pattern. While the anti-correlation of the homogeneous mode with the off-axis wave vectors can be understood in terms of energy conservations, the common microscopic interpretation of the far-field intensity correlations in terms of emission of twin photons would naively suggest that the strongest correlation is between the wave vectors forming a 180° angle. In fact, the total transverse momentum conservation involve always at least four modes simultaneously and give some hints about how the correlations should be, but does not identifies the pairs with stronger correlations. Our results here are obtained within a semiclassical approach in which specific features of quantum statistics are neglected.

The paper is organized as follows: In Sec. II we describe the model we are considering. In Sec. III we linearize around the hexagonal pattern and describe the linear response of the system to noise perturbations. In Sec. IV we discuss in detail the field fluctuations, and in Sec. V we describe the correlations of the field Fourier components. Finally, in Sec. VI we give some concluding
where \( \lambda \) with wave vector \( \vec{k} \) old is located at \( \vec{x}_0 \). At threshold \( \theta = \sqrt{3} \), the stationary hexagonal pattern is subcritical and the hexagonal pattern, once it is formed, is stable for values of the pump intensity within a quite large range which includes values below threshold.

Typically, the hexagons appear oscillating even at threshold a hexagonal pattern with a wave spectrum (far-field) \(|E(k)|^2\) of a stationary hexagonal solution. The presence in the far-field of high order harmonics. (c) Shows a cross section along a \( x \) axis of the intensity pattern and (d) a cross section along the \( k_y \) axis of the power spectrum.

III. LINEARIZATION AROUND THE HEXAGONAL PATTERN

The stationary hexagonal pattern can be written in the form

\[
E_h(\vec{x}) = \sum_{n=0}^{N} a_n e^{i \vec{k}_n^0 (\vec{x} - \vec{x}_0)},
\]

where \( a_n \) are complex coefficients, \( \vec{x}_0 \) determines the global position of the pattern (we take \( \vec{x}_0 = 0 \) in the following), \( \vec{k}_0^0 \) is the homogeneous mode and \( \vec{k}_n^0 \) for \( n = 1, \ldots, N \) are the off-axis wave vectors of the hexagonal pattern. Here we take \( N = 90 \) which corresponds to considering up to the fifth order harmonics in the far field. The six fundamental harmonics have modulus \( k_n \). For simplicity we first consider the case without noise. Linearizing Eq. (1) around the stationary solution (4) we obtain the following equation for the fluctuations \( \delta E(\vec{x}, t) = E(\vec{x}, t) - E_h(\vec{x}) \).

![Image of hexagonal pattern](image_url)
\[ \partial_t \delta E = -(1 + i\theta)\delta E + i\nabla^2 \delta E + i2[2|E_h|^2\delta E + E_h E_h^*\delta E^*]. \] (7)

As Eq. (7) is a linear differential equation with periodic coefficients, a general bounded solution can be found under a Floquet form (13):

\[ \delta E(\bar{x}, \bar{t}) = \int e^{i\vec{q} \cdot \vec{x}} A(\vec{q}, \bar{x}, \bar{t}) d\vec{q} \] (8)

where \( A(\vec{q}, \bar{x}, \bar{t}) \) are functions with the same spatial periodicity than the stationary pattern \( E_h \), and therefore can be written as

\[ A(\vec{q}, \bar{x}, \bar{t}) = \sum_{n=0}^{N} \delta a_n(\vec{q}, t)e^{i\vec{k}_n \cdot \vec{x}}. \] (9)

From (6), (8) and (9), we obtain for each perturbation wave vector \( \vec{q} \) a set of linear differential equations for the time evolution of the Fourier coefficients \( \delta a_n(\vec{q}, t) \).

\[ \partial_t \delta a_n(\vec{q}, t) = [-i(1 + i\theta) - i\vec{k}_n \cdot \vec{q}] \delta a_n(\vec{q}, t) + \]

\[ + i2\sum_{l=0}^{N} \sum_{m=0}^{N} a_l a_m \delta a_{n-l+m}(\vec{q}, t) + \]

\[ \sum_{l=0}^{N} \sum_{m=0}^{N} a_l a_m [\delta a_{-n+l+m}(\vec{q}, t)]^* \] (10)

where \( \delta a_{n-l+m}(\vec{q}, t) = \delta a_j(\vec{q}, t) \) with \( \vec{k}_j = \vec{k}_n - \vec{k}_l + \vec{k}_m \).

Introducing \( \tilde{\Sigma}(\vec{q}, t) = (\text{Re}[\delta a_0(\vec{q}, t)], \text{Im}[\delta a_0(\vec{q}, t)], \ldots, \text{Re}[\delta a_N(\vec{q}, t)], \ldots, \text{Im}[\delta a_N(\vec{q}, t)])^T \), Eqs. (10) can be written as

\[ \partial_t \tilde{\Sigma}(\vec{q}, t) = M(\tilde{E}_h, \vec{q}) \tilde{\Sigma}(\vec{q}, t). \] (11)

\( \tilde{\Sigma}(\vec{q}, t) \) includes perturbations with \(+\vec{q}\) and \(-\vec{q}\) since they are coupled in Eq. (11). The important point is that perturbations with different \( \vec{q} \) vectors are uncoupled. Any perturbation with a vector \( \vec{q} \) outside the first Brillouin zone of the hexagonal lattice defined by the wave vectors of the pattern \( \vec{k}_n \) (See fig. 9) is equivalent to another one with a vector \( \vec{q} = \vec{q}' + \vec{k}_n \) inside.

---

**Fig. 2.** First Brillouin zone (dashed hexagon) of the hexagonal lattice defined by the wave vectors of the pattern in the Fourier space.

Therefore the values of \( \vec{q} \) to be considered are only those inside of the first Brillouin zone. In this way one finds a set of \( 4(N + 1) \) eigenvalues and eigenvectors for each vector \( \vec{q} \) except for the cases \( \vec{q} = \vec{0} \) and \( \vec{q} = \vec{k}_n/2 \) where \( \tilde{\Sigma}(\vec{q}, t) \) has only \( 2(N + 1) \) components. The eigenvalues may be either real or complex conjugates and determine the linear response of the system when perturbations with \( \vec{k}_n \) \pm \vec{q} \) wave vectors are applied.

As the system is translationally invariant, \( E_h(\bar{x} + \bar{x}_0) \) is also a stationary solution for any fixed \( \bar{x}_0 \), the two modes \( \partial_x E_h \) and \( \partial_y E_h \) are eigenvectors of \( M(\tilde{E}_h, \vec{q} = 0) \) with zero eigenvalue. These neutrally stable modes of the linearized dynamics are the so-called Goldstone modes \([1, 7] \) and correspond to homogeneous perturbations that displace rigidly the pattern along the \( x \) or \( y \) directions

\[ \partial_x E_h(x) = \sum_n a_n h_{nx} e^{i\vec{k}_n \cdot \vec{x}} \] (12)

\[ E_h(x, y) + x_0 \partial_x E_h = \sum_n a_n (1 + i\vec{k}_n \cdot \vec{x}_0) e^{i\vec{k}_n \cdot \vec{x}} \]

\[ \approx \sum_n a_n e^{i\vec{k}_n \cdot \vec{x} + x_0} = E_h(x + x_0, y). \] (13)

For the hexagonal pattern considered here the Goldstone modes have the profile shown in Figs. 2 and 3. In the near field they have a larger amplitude at the borders of the hexagonal peaks, where the gradient is larger and show a sharp transition from negative to positive values just at the center of the peak (Fig. 3).

---

**Fig. 3.** Real part (left) and power spectrum (right) of the Goldstone modes \( \partial_x E_h \) (top) and \( \partial_y E_h \).

3
In a situation where the hexagonal pattern is stable the Goldstone modes are the only neutral modes while all the other eigenvectors have eigenvalues with strictly negative real part.

At this point we can study the linear response to noise perturbations. Decomposing the noise term of (11) as it has been done for the field [Eqs. (8) and (9)] we obtain an extra term in the rhs of equation (11)

\[ \partial_t \Sigma_i(q, t) = M(\vec{E}_h, q) \Sigma_i(q, t) + \tilde{\Sigma}(q, t), \]  

where \( \tilde{\Sigma}(q, t) = (\text{Re}[\xi(k_0^0 + \vec{q}, t)], \text{Im}[\xi(k_0^0 + \vec{q}, t)], \ldots, \text{Im}[\xi(k_{N_2}^0 - \vec{q}, t)], \ldots, \text{Im}[\xi(k_{N_2}^0 - \vec{q}, t)])^T. \) Then, we can write an Ornstein-Uhlenbeck process [14] for the amplitude \( \Theta_i(q, t) \) of each eigenvector of \( M(\vec{E}_h, q) \)

\[ \partial_t \Theta_i(q, t) = \lambda_i(q) \Theta_i(q, t) + \eta_i(q, t), \]  

where \( \lambda_i(q) \) is the \( i \)-th eigenvalue of \( M(\vec{E}_h, q) \) (ordered according to the value of its real part, \( \text{Re}[\lambda_i(q)] \geq \text{Re}[\lambda_{i+1}(q)] \)). \( \eta_i(q, t) = \sum_{n=0}^{4N+3} C^{-1}_{ij}(q) \Xi_j(q, t) \) is the noise expressed in the eigenvectors basis and \( C(q) \) is the matrix for the change of basis as obtained diagonalizing \( M(\vec{E}_h, q) \). The coefficients \( \delta a_n(q, t) \) are related to the amplitudes of the eigenmodes \( \Theta_i(q, t) \) by

\[ \text{Re}[\delta a_n(q, t)] = \Sigma_i(\Theta_i(q, t) C_{2n-1}(q) \]  

\[ \text{Im}[\delta a_n(q, t)] = \Sigma_i(\Theta_i(q, t) C_{2n}(q) \]  

\[ \text{Re}[\delta a_n(-q, t)] = \Sigma_i(\Theta_i(q, t) C_{2n-1+2N_2}(q) \]  

\[ \text{Im}[\delta a_n(-q, t)] = \Sigma_i(\Theta_i(q, t) C_{2n+2N_2}(q). \]  

The noises \( \eta_i(q, t) \) are Gaussian and white in time and have cross-correlations

\[ \langle \eta_i(q, t) \eta_j^*(q', t') \rangle = \frac{\epsilon}{2} D_{i,j}(q) \delta(t-t') \delta(q - q') \]  

\[ \langle \eta_i(q, t) \eta_j(q', t') \rangle = \frac{\epsilon}{2} D_{i,j}(q) \delta(t-t') \delta(q - q'). \]  

where

\[ D_{i,j}(q) = \sum_{k=0}^{4N+3} C_{ik}^{-1}(q) C_{jk}^{-1}(q), \]  

\[ \bar{D}_{i,j}(q) = \sum_{k=0}^{4N+3} C_{ik}(q) C_{jk}(q). \]  

The solution of the stochastic process is then

\[ \Theta_i(q, t) = e^{\lambda_i(q)t} \int_0^t e^{-\lambda_i(q)s} \eta_i(q, s) ds. \]  

The average value of the eigenmodes amplitude is \( \langle \Theta_i(q, t) \rangle = 0 \). The correlations between the amplitudes of the eigenvectors are given by:

\[ \langle \Theta_i(q, t) \Theta_j^*(q', t') \rangle = \frac{e^{\lambda_i(q)t}}{-4(\lambda_i(q) + \lambda_j(q'))}(1 - e^{(\lambda_i(q) + \lambda_j(q'))t}) \delta(q - q') \]  

\[ \langle \Theta_i(q, t) \Theta_j(q', t') \rangle = -4(\lambda_i(q) + \lambda_j(q')) \delta(q - q') \]  

In particular, the time evolution of the mean value of the squared amplitude of the eigenvectors with non zero eigenvalue is

\[ \langle |\Theta_i(q, t)|^2 \rangle = \frac{e^{\lambda_i(q)t}}{-8Re[\lambda_i(q)]}(1 - e^{2Re[\lambda_i(q)]t}). \]  

Eq. (24) does not apply to the Goldstone modes as they have zero eigenvalue \( \lambda_0(q = 0) = 0 \). Its time evolution is given by (from Eq. (20))

\[ \Theta_i(q, t) = \int_0^t \eta_i(q, s) ds. \]  

This is a purely diffusive motion which never reaches a stationary state. Its mean squared amplitude grows linearly in time

\[ \langle |\Theta_0(q = 0, t)|^2 \rangle = \frac{\epsilon}{8} D_{00}(q = 0) t. \]  

Therefore, the linearization fails for times \( t \sim 1/\epsilon \), when the amplitude of the Goldstone modes \( |\Theta_0(q = 0)|^2 \) reaches values comparable to one and nonlinear terms will come into play.
IV. FLUCTUATIONS IN THE NEAR FIELD

Starting from a stationary hexagonal solution of the system equations without noise, a typical evolution of the pattern fluctuations when the noise is switched on, obtained from numerical integration of the nonlinear equations Eq. (1) [15], is shown in Fig. 5.

FIG. 5. Near field (left: $Re[\delta E(\vec{x})]$, $\delta E(\vec{x}) = E(\vec{x}) - \langle E(\vec{x}) \rangle$) and far field (right: $|\delta E(\vec{k})|$, $\delta E(\vec{k}) = E(\vec{k}) - \langle E(\vec{k}) \rangle$) pattern fluctuations after switching on the noise. From top to bottom: $t = 2$, $t = 200$, and $t = 2000$. We have considered $\epsilon = 10^{-6}$.

From Eq. (23) we get that for short time all the modes $\Theta_i(\vec{q}, t)$ have a similar mean squared amplitude which is proportional to the noise intensity and grows linearly with time

$$\langle |\Theta_i(\vec{q}, t)|^2 \rangle = \frac{\epsilon}{4} D_{ii}(\vec{q}) t.$$  \hspace{1cm} (27)

All the modes will contribute with a similar weight to the field fluctuations and therefore there is a complete lack of structure in the field fluctuations at short times as shown in Fig. 5 (top).

As time goes on, following (23), the mean squared amplitude of the modes does not grow linearly any more. It reaches a steady state value given by (24) which is larger for the modes which have a smaller decaying rate $Re[\lambda_i(\vec{q})]$. According to the way the eigenvalues has been ordered, for a given $\vec{q}$, the smaller decaying rate is $Re[\lambda_0(\vec{q})]$. The eigenmodes with eigenvalue $\lambda_0(\vec{q})$ are the so-called soft modes [16] which are connected with the Goldstone modes and for which $\lambda_0(\vec{q} \gtrsim \vec{0}) \sim -|\vec{q}|^2$ (see Fig. 6).

FIG. 6. Left: $Re[\lambda_0(\vec{q})]$, darker color indicates smaller values. The white line shows the first Brillouin zone. The center of the figure corresponds to the Goldstone modes ($Re[\lambda_0(\vec{q} = \vec{0})] = 0$). Right: transverse cut of $Re[\lambda_0(\vec{q})]$ along $q_x$ (solid line) and $q_y$ (dotted line) axis.

While the Goldstone modes correspond to neutrally stable homogeneous perturbations, the soft modes correspond to weakly damped long-wavelength perturbations. For systems with a finite size $L$ the less damped of the soft modes are the ones with the smallest $\vec{q}$ vector allowed by the size of the system, $|\vec{q}| = 2\pi/L$. These modes have a decay rate proportional to $1/L^2$ and therefore a stationary mean squared amplitude proportional to $\epsilon L^2$. The shape of one soft mode is illustrated in Fig. 7.

FIG. 7. Soft mode $\vec{q} = (0, 2\pi/L_y)$ whose decay rate is $Re[\lambda(\vec{q} = (0, 2\pi/L_y))] = -0.0052$.

Its profile is similar to a Goldstone mode but with a long-wavelength modulation on top of it. The wavevector of the modulation is precisely the wavevector $\vec{q}$ that identifies the soft mode. While the Goldstone modes describe an overall rigid motion of the pattern, the soft modes add some distortion so the pattern moves in slightly different form at different locations.

For the numerical simulations shown in Fig. 5, at $t = 200$ the mean squared amplitude of most of the modes has already saturated at small values, while the amplitude of the soft modes is, in average, just reaching the stationary value. Therefore, as shown in the figure (center) the field fluctuations are dominated by the soft and
Goldstone modes and short range spatial structures start to appear. The typical correlation length of the fluctuations is determined by the wavelength of the soft modes.

According to (20), the mean square amplitude of the Goldstone mode keeps growing linearly in time and does not saturate in the linear approximation. The Goldstone mode amplitude only saturates due to nonlinearities at times of the order \( t \sim 1/\epsilon \) where the linear theory for fluctuations described in the previous section fails (this time is around \( 10^6 \) for the simulation shown in Fig. 3). Assuming linearization is valid, at times \( t \gg L^2 \), the mean squared amplitudes of the Goldstone modes (\( \sim \epsilon t \)) become much larger than the amplitude of any of the soft modes and dominate the fluctuations. In our system at time \( t \sim 2000 \) the profile of the field fluctuations is already determined only by the Goldstone modes as shown in Fig. 1 (bottom). In the far field the largest fluctuations are those of the wave vectors of the pattern, while in the near field fluctuations show a long range structure with strong correlation over all the system size. Integrating for longer times will not change the profile of the field fluctuations, the amplitude of the Goldstone mode will eventually saturate but nevertheless will completely determine the field fluctuations.

For systems with a larger system size, the soft modes will take a longer time to reach the stationary amplitude (and in fact its amplitude will be larger). However, provided that \( L^2 < 1/\epsilon \), the evolution will be basically the same, showing the three stages discussed before. If the system size is larger than \( 1/\sqrt{\epsilon} \) then the stationary amplitude of the soft modes and the Goldstone modes will be determined by the system nonlinearities and if \( L \) is large enough, both amplitudes may have similar sizes, in which case Goldstone and soft modes will contribute to the near field fluctuations even at \( t \to \infty \) and therefore the pattern of fluctuations may show a finite correlation length in the stationary regime.

\section*{V. FLUCTUATIONS AND CORRELATIONS IN THE FAR FIELD}

In the following three subsections, we address the fluctuations in Fourier space of the field, intensity and momentum.

\subsection*{A. Field fluctuations}

In the Fourier space the field fluctuations are also dominated by the Goldstone and soft modes. From Eqs. (12) and (13), we can see how the Goldstone modes, which have the same wave vectors than the hexagonal pattern, induce opposite and very large phase fluctuations in opposite Fourier components, which correspond to the rigid translation of the hexagons in the near field. The homogeneous component of the field is not affected by the Goldstone modes. The soft modes do not have exactly the same Fourier components than the hexagonal pattern but they are very close, therefore their main contribution is to broaden the spots of the far-field fluctuations (see the far-field for the intermediate time in Fig. 3).

\subsection*{B. Intensity fluctuations and correlations}

The intensity fluctuations of the far-field peaks are

\[ \delta I(\vec{k}) = I(\vec{k}) - I_0(\vec{k}), \]  

(28)

where \( I(\vec{k}) = |E(\vec{k})|^2 \) and \( I_0(\vec{k}) = |E_0(\vec{k})|^2 \). The correlation function of the far-field intensity fluctuations of a fundamental wave vector of the pattern, for instance \( \vec{k}_0^0 \), with the far-field intensity fluctuations of any other wave vector \( \vec{k} \) is given by

\[ C_1(\vec{k}_0^0, \vec{k}) = \frac{\langle \delta I(\vec{k}_0^0) \delta I(\vec{k}) \rangle}{\sqrt{\langle |\delta I(\vec{k}_0^0)|^2 \rangle \langle |\delta I(\vec{k})|^2 \rangle}}. \]  

(29)

From the numerical integration of Eq. (12) and averaging over two hundred realizations of the noise \([15]\), we find strong correlations between the intensity fluctuations of all the modes of the pattern, not only among the fundamental harmonics but also with the higher order ones (Fig. 3).

\begin{figure}[h]
\centering
\includegraphics[width=0.8\textwidth]{figure8.png}
\caption{Correlation function of the intensity fluctuations \( C_1(\vec{k}_3^0, \vec{k}) \). The brightest spot takes the value 1 corresponding to the autocorrelation of \( \vec{k}_0^0 \). Note the strong correlation with the other six fundamental wave vectors of the pattern and with the first rings of harmonics. The correlation decay as one consider higher and higher harmonics. Note also the anti-correlation with the homogeneous as a black spot at the center. The grey background is around 0.}
\end{figure}
this reasoning can not reveal which modes within these sets are more correlated in pairs. So, the stronger correlation between those modes forming a $\theta = \frac{2\pi}{3}$ angle, despite fulfill momentum conservation, can not be completely understood in this terms. We also find strong anti-correlations between the intensity fluctuations of the modes of the pattern and the homogeneous mode which are related to energy conservation (Fig. 8).

Neglecting terms of order $\epsilon^2$, the far-field intensity fluctuations can be approximated as

$$\delta I(\vec{k}) \approx 2Re[E^*_{\vec{k}}(\vec{k})\delta E(\vec{k})],$$

(30)

where $\delta E(\vec{k}) = E(\vec{k}) - E_h(\vec{k})$. As $E_h(\vec{k}) = \sum a_n(2\pi)^3\delta(\vec{k}_n - \vec{k})$ we have to consider only perturbations that have the same wave vectors of the pattern ($\vec{q} = \vec{0}$). Therefore, the soft modes ($\vec{q} \gtrsim \vec{0}$) do not contribute to the fluctuations of the far-field intensity peaks. The Goldstone modes are indeed $\vec{q} = 0$ perturbations, but the intensity fluctuations associated to the Goldstone modes are $\delta I(\vec{k}) = 2Re[E(\vec{k})^* \partial_\vec{k} E(\vec{k})]$ which from (9) and (12) is exactly zero. So, neither the Goldstone modes do contribute to the fluctuations of the far-field intensity peaks. They only contribute to phase fluctuations. Therefore, fluctuations of the far-field intensity peaks have to be described by the other eigenvectors of $M(E_h, \vec{q} = \vec{0})$. These eigenvectors have the same Fourier components than the hexagonal pattern and their eigenvalues $\lambda_i(\vec{q} = \vec{0})$, ($i = 1, \ldots N$) are shown in Fig. 9.

![Fig. 9. Eigenvalues of the eigenvectors with $q = 0$. There are two zero eigenvalues corresponding to the Goldstone modes. Note also the symmetry of the spectrum with respect to the axis $Re[\lambda] = -1$.](image1)

Using Eqs. (10), (21) and (22) we can compute the correlation function $C_1(\vec{k}_0^n, \vec{k}_m^0)$ analytically

$$C_1(\vec{k}_0^n, \vec{k}_m^0) = 2Re[E^*_{\vec{k}_n}^{\vec{k}_0}(\vec{k})]E_{\vec{k}_m}^{\vec{k}_0}(\vec{k})\langle \delta E(\vec{k}_n^0)\delta E(\vec{k}_m^0) \rangle + E_{\vec{k}_n}^{\vec{k}_0}(\vec{k})E_{\vec{k}_m}^{\vec{k}_0}(\vec{k})\langle \delta E(\vec{k}_n^0)\delta E^*(\vec{k}_m^0) \rangle,$$

(31)

where

$$\sum_i \sum_j \frac{\epsilon}{4(\lambda_i + \lambda_j^*)} (1 - e^{(\lambda_i + \lambda_j)^t}) \delta_{ij} (\vec{q} = \vec{0})$$

$$= \frac{i}{2} (C_{2n-1}C_{2m-1} - C_{2n}C_{2m} + i(C_{2n-1}C_{2m} + C_{2n}C_{2m})) \langle \delta E(\vec{k}_n^0)\delta E^*(\vec{k}_m^0) \rangle = 0$$

(32)

$$\sum_i \sum_j \frac{\epsilon}{4(\lambda_i + \lambda_j^*)} (1 - e^{(\lambda_i + \lambda_j)^t}) D_{ij} (\vec{q} = \vec{0})$$

$$= \frac{i}{2} (C_{2n-1}C_{2m-1} + C_{2n}C_{2m} + i(C_{2n-1}C_{2m} - C_{2n}C_{2m})) \langle \delta E(\vec{k}_n^0)\delta E^*(\vec{k}_m^0) \rangle = 0$$

(33)

Fig. 9 shows the stationary value ($t \to \infty$) of $\langle \delta E(\vec{k}^0_n)\delta E(\vec{k}^0_m) \rangle$ for the fundamental wave vectors of the pattern as a function of the angle $\theta$ between them. The results obtained from the linearized theory are in very good agreement with the correlations obtained from the numerical simulations of the nonlinear equation (1).

![Fig. 10. Correlations between the intensity fluctuations of the fundamental wave vectors obtained from the numerical integration of equation (1) (rhombi), and analytically form Eq. (31) (dots).](image2)

From Fig. 9 we can see that the most important eigenvectors are those associated to the complex conjugate eigenvalues with $Re[\lambda_2(\vec{q} = \vec{0})] = Re[\lambda_3(\vec{q} = \vec{0})] = -0.25$. This pair of eigenvectors give the strong correlation between all the Fourier components and a strong anti-correlation with the homogeneous field. The excitation of this eigenvectors implies also anti-correlations between the homogeneous mode and the off-axis Fourier components of the pattern (Fig. 11).
FIG. 11. Intensity fluctuations due to the eigenmodes with $\text{Re}\lambda = -0.25$.

Some eigenvectors with $\text{Re}\lambda_n(q = 0) = -1$ are finally the responsible for the differences between the correlations in the fluctuations of the six forth harmonics. The typical profile of one of these eigenmodes is shown in Fig. 12. The symmetry of the three peaks located at $120^\circ$ yields to larger correlations between the fluctuations of the corresponding far field intensity peaks.

FIG. 12. Intensity fluctuations due to one of the eigenmodes with $\text{Re}\lambda = -1$

We note that the modes that determine the correlations of the far-field intensity peaks reach stationary values in a much shorter time ($t \sim -1/\text{Re}\lambda_2(q = 0) = 4$) than the Goldstone and soft modes contributing to the near field fluctuations ($t \sim 1/\epsilon \sim 10^6$ as discussed in the previous section). As these correlations are determined by $\vec{q} = 0$ perturbations, these calculations can be performed in systems with relatively small size. Increasing the system size, may change the near field profile of the fluctuations, as discussed before, but nevertheless the dynamical evolution of the modes contributing to the far-field intensity fluctuations and their mean squared stationary amplitude will be basically the same.

C. Transverse momentum fluctuations

We finally address the fluctuations of the transverse momentum. Without noise the total transverse momentum of the pattern is $\vec{P} = \sum_n |a_n|^2 \vec{k}_n = 0$. The noise induce fluctuations given by $\delta \vec{P} = \sum_n 2 \text{Re}[a_n^* \delta a_n] \vec{k}_n$. One finds that all the eigenvectors that contribute to the far-field intensity fluctuations strictly fulfill momentum conservation except for two modes with $\lambda_{2N}(q = 0) = \lambda_{2N-1}(q = 0) = -2$, which are exactly those symmetric to the Goldstone modes respect to the line $\text{Re}\lambda = -1$ (Fig. 9). Therefore momentum fluctuations are determined by the two modes with maximum damping which are shown in Fig. 13, the on the top figure breaks the conservation of the $P_y$ momentum component while the one in the bottom breaks the conservation of $P_x$.

FIG. 13. Intensity fluctuations due to the two modes $\text{Re}\lambda_{2N}(q = 0) = \text{Re}\lambda_{2N-1}(q = 0) = -2$.

Alternatively it is possible to see from the classical field theory that the momentum fluctuations are damped with a coefficient $-2$. A Lagrange density can be defined for Eq. (1) [17]

$$L = e^{2t}[|\nabla E|^2 + i/2(\dot{E} \dot{E}^* - \dot{E}^* \dot{E}) + i(E_0 E^* - E_0^* E) + \theta |E|^2 - |E|^4]$$

(34)

Substituting (6) in (34) and integrating over all the space...
we get a Lagrangian for the amplitude of the modes \(a_n\) and for the position of the rolls in the near field \(x_0\)

\[
L = e^{2i\sum_n |a_n|^2 k_n^2} + i \sum_n (a_n^* \dot{a}_n - \dot{a}_n a_n^*) - \sum_n |a_n|^2 - \sum_n \sum_m a_n a_n^* a_m^* a_{n+m}^* \chi_{E_n^0 - E_0^0}^n + i \sum_n (E_0 a_n^0 - E_0^0 a_0) + \sum_n |a_n|^2 - \sum_n \sum_n' \sum_m a_n a_n^* a_m^* a_{n+n'}^* \chi_{E_n^0 - E_0^0}^n + \sum_n |a_n|^2 k_n^2 \chi_{E_n^0 - E_0^0}^n \]

\[ (35) \]

\(\tilde{x}_0\) is a cyclic coordinate, so its conjugate momentum

\[
\frac{\partial L}{\partial \dot{\tilde{x}}_0} = -i2e^{2i\sum_n |a_n|^2 k_n^2} = -2e^{2i\tilde{P}} \sum_n |a_n|^2 k_n^2 \]

\[ (36) \]
is constant. Therefore \(\dot{\tilde{P}} = -2\tilde{P}\). \(\tilde{P}\) is identically zero without noise. When noise is present momentum fluctuations should satisfy

\[
\delta \dot{\tilde{P}} = -2\delta \tilde{P} + \chi(t), \quad \text{ (37)}
\]

where \(\chi(t)\) is a Gaussian white noise. Therefore, momentum fluctuations have the maximum damping. The same damping coefficient for the momentum fluctuations has been found by Gatti and Mancini from a few modes quantum formulation \([9]\).

VI. CONCLUSIONS

We have analyzed the fluctuations and correlations in a hexagonal pattern of a prototypical model in nonlinear optics. In the near field fluctuations are dominated by the neutrally stable Goldstone modes associated to the translational invariance as well as by the soft modes connected with them. The soft modes destroy the long range correlation in the fluctuations, however in small systems these modes reach an stationary amplitude much earlier (and at a smaller value) than the Goldstone mode so that they are important only at intermediate times. At long times the fluctuations are dominated by the Goldstone modes which correspond to rigid displacements of the overall pattern. For very large systems, both the Goldstone and soft modes may have similar amplitudes and contribute to the fluctuations.

In the far-field, the most relevant effect of noise are the intensity fluctuations of the Fourier modes of the hexagonal pattern. At first order in noise intensity, these fluctuations are not affected neither by the Goldstone modes nor by the soft modes. They are dominated by damped modes, so they reach stationary values in relatively short times. Their main characteristics are: i) strong correlations between the intensity fluctuations of any arbitrary pair of the six fundamental wave vectors of the pattern, and also with their higher harmonics, ii) larger correlation between intensity fluctuations of the Fourier modes forming 120° angles than between modes forming 180°, and iii) strong anti-correlations between the zero wave vector and the pattern Fourier modes. Finally only the even modes with maximum damping contribute to the fluctuations of the total transverse momentum, therefore the total transverse momentum has the least possible fluctuations.

Our results are obtained from both semianalytical calculations based on linearization around the hexagonal pattern and from numerical simulations of the nonlinear system. Some of our results and predictions are very general, and depend only on basic symmetry properties of the system such as translational invariance. Thus we expect that similar structure and properties of the fluctuations and correlations can be found in other nonlinear systems displaying hexagonal patterns.

From a computational point of view, correlations in the far field intensity peaks are practically independent of the system size and therefore can be calculated accurately in relatively small systems, provided all the relevant harmonics of the pattern are considered. Good statistics can be obtained integrating the nonlinear equations over relatively short times (even though the near field fluctuations are quite far away from reaching a stationary value). Of course, alternatively a linear semianalytical approach as the one described in Sec. \[\text{[9]}\] can also be used to calculate far-field correlations.

[15] We integrate Eq. (1) using a pseudo-spectral method where the linear terms in Fourier space are integrated exactly while the nonlinear ones are integrated using a first-order in time approximation following the scheme described in M. San Miguel and R. Toral, in Instabilities and Nonlinear Equilibrium Structures, ed. by E. Tirapegui, J. Martinez and R. Tiemann, (Kluwer, 2000).
[16] The random number generator used is described in R. Toral and A. Chakrabarti, Compute Physics Communications, 74 327-334 (1993). A rectangular lattice of size 256 × 256 points was used. In Fourier space we took \( \Delta k_y = \frac{1}{8} \) and \( \Delta k_x = \sin(60^\circ)/6 \), which corresponds in real space to a system of size \( L_y \approx 50.3 \) and \( L_x \approx 43.5 \). The time step for integration was \( dt = 0.001 \).
