We propose a reconstruction of vortex beams based on the implementation of quadratic transformations in the orbital angular momentum. The information is encoded in a superposition of Bessel-like nondiffracting beams. The measurement of the OAM correlation distribution at different positions allows for the reconstruction of the Wigner function.

The goal of this Letter is to bring forward a feasible direct reconstruction of an optical vortex. We recall that efficient methods of state reconstruction are of the greatest relevance. Since the first theoretical proposals, this discipline has witnessed a significant growth and laboratory demonstrations of state tomography span a broad range of systems.

The canonically conjugate variable to OAM is the angle, so we shall need some basic concepts about this quantity. Since the first theoretical proposals, this discipline has witnessed a significant growth and laboratory demonstrations of state tomography span a broad range of systems.

as \( \Psi(r, \varphi, z) = \psi(r, \varphi, z) \exp(-i k z) \), where the envelope \( \psi(r, \varphi, z) \) is a slowly varying function of \( z \). In further consideration, we restrict ourselves to the paraxial regime and neglect polarization effects.

In the angle representation, \( L \) acts as \(-i \partial_\varphi \) and the OAM eigenstates (which constitute an appropriate basis) are conveniently expressed (in the plane \( z = 0 \)) by

\[
\psi_\ell(r, \varphi) = \left< r, \varphi | \ell \right> = A_\ell(r) \exp(i \ell \varphi),
\]

where \( A_\ell(r) \) is an arbitrary radial profile. Please, notice carefully that the polar angle \( \varphi \) in the transverse plane should not be confused with the rotor eigenstate \( \phi \). Next, we look at beams for which free propagation induces an \( L^2 \) transformation, as for them the tomography will be enormously facilitated. We thus require

\[
\psi_\ell(r, \varphi, z) = e^{i a z^2} \psi_\ell(r, \varphi).
\]

In this case the free propagation of the optical field corresponds to free evolution of the rotor. Since the free evolution of paraxial optical beams is determined by the wave equation \( \Delta_\perp \psi_\ell - 2 i k \partial_\varphi \psi_\ell = 0 \), where \( \Delta_\perp \) is the transverse Laplacian, we obtain

\[
r^2 \frac{d^2 A_\ell(r)}{dr^2} + r \frac{dA_\ell(r)}{dr} + (\ell^2 r^2 - 2 a k \ell^2) A_\ell(r) = 0,
\]

whose regular solution is given in terms of the Bessel function \( A_\ell(r) \propto J_\ell(\sqrt{2a k \ell} r) \). Consequently, the beams we look for turn out to have an envelope

\[
\psi_\ell(r, \varphi, z) = N_\ell J_\ell(\sqrt{2a k \ell} r) e^{i a z^2} e^{i \ell \varphi}. \tag{8}
\]

As it happens with paraxial waves, these beams require infinite energy, so their practical generation relies in a spatial apodization of some kind. We take this into account in the normalization factor \( N_\ell^2 = \frac{2 \pi}{\int_0^R dr r J_\ell(\sqrt{2a k \ell} r)^{-2}} \), \( R \) being the radius of this apodizing element.

Taking \( a \sim 1 \) guarantees that we are safely in the paraxial region \( |a| < 2/k \ell^2 \). In that case, the Bessel beams involved have central maxima of the size of a few millimeters and quadratic phases \( a \ell^2 \sim 10 \text{ rad/m} \) are induced in the free propagation. This confirms the feasibility of our proposal. We can also understand the form of the vortices \( \psi_\ell \) in an alternative way. The paraxial free-space transfer function is \( H(\rho, \theta) \propto \exp(-i \pi \lambda z \rho^2) \), where \( (\rho, \theta) \) are polar coordinates in the spatial-frequency space and \( \lambda \) is the wavelength. Let us assume that all the nonvanishing frequency components of our field lie on a circle of radius \( \rho_0 \), that is, \( \hat{\psi}(\rho, \theta) \propto \hat{\psi}(\theta) \delta(\rho - \rho_0) \), where \( \hat{\psi}(\rho, \theta) = F[\psi(r, \varphi)] \) denotes the Fourier transform. Then, free propagation contributes just by an unessential overall phase factor, \( \hat{\psi}(\rho, \theta) = H(\rho, \theta) \hat{\psi}(\theta) = \exp(-i \pi \lambda z \rho_0^2) \hat{\psi}(\theta) \), so the transverse intensity distribution becomes independent of the distance \( z \) (and hence represents a nondiffracting beam). The particular case of the family \( \psi_\ell \) is obtained by taking \( \rho_0 = \sqrt{2a k \ell} / (2 \pi) \).

A general input state can be encoded into an optical beam by creating a superposition of these basis waves \( \psi(r, \varphi) = \sum c_\ell \psi_\ell(r, \varphi) \), which can be easily accomplished by an amplitude spatial light modulator displaying a hologram computed as an interference pattern of the required field \( \psi(r, \varphi) \) and a reference plane wave.

After propagating a distance \( z \) the beam will evolve into a new superposition \( \psi(r, \varphi, z) = \sum c_\ell e^{i a z^2} \psi_\ell(r, \varphi) \). But according to Eq. (8), this is just the required \( L^2 \) action with \( \zeta = -a z \). This is the main result of this paper: by choosing a particular form of the OAM eigenstates, the highly nontrivial \( L^2 \) transformation is realized by a simple free beam propagation. This also provides an experimentally feasible and a reference plane wave.

After some simple calculations, the associated tomograms for the superposition field turns out to be

\[
\omega(\phi, \zeta) = \frac{1}{2\pi} \left| \sum_{\ell \in \mathbb{Z}} c_\ell e^{i \ell \phi} e^{-i a z^2/2} \right|^2. \tag{9}
\]

By scanning the values of \( \zeta \), the beam can thus be reconstructed according to Eq. (4). This completes our proposed scheme. Naturally, \( \zeta \) are independent of the rapid oscillating factor \( \exp(-i k z) \).

As a last experimental detail, we need to assess the measurement of the angular spectrum in Eq. (9). For the field \( \psi(r, \varphi) \) this reads as (taking for simplicity the plane \( z = 0 \))

\[
\omega(\phi, 0) = P(\phi) = \left| \int d\varphi d\ell r \psi_\ell^\ast(r, \varphi) \psi(r, \varphi) \right|^2, \tag{10}
\]

where \( \psi_\phi(r, \varphi) = \left< r, \varphi | \phi \right> \), and \( |\phi\rangle \) is a field with well-defined angle. Note in passing that the angular spectrum \( P(\phi) \) cannot be obtained, in general, by measuring the angular profile of the output beam, e.g., using a wedge-shaped aperture. In fact, as a consequence of the nontrivial radial profile of the OAM eigenstates, the states of \( \psi_\phi(r, \varphi) \) are given by

\[
\psi_\phi(r, \varphi) = \sum_{\ell \in \mathbb{Z}} e^{i \ell(\phi - \varphi)} J_\ell(\sqrt{2a k \ell} r). \tag{11}
\]

Finally, using the cross-correlation theorem of Fourier analysis, one gets \( P(\phi) = \left| F^{-1}[\hat{\psi}_\phi(\rho, -\theta) \hat{\psi}(\rho, \theta)] \right|^2_{|\rho=0} \). This result provides a simple interpretation of the tomographic setup. The angular states \( |\phi\rangle \) are defined in such a way that by placing a transparency \( \psi_\phi(\rho, -\theta) \) in the Fourier plane, the unwrapping of azimuthal phase modulations occurs simultaneously for all the vortices in the superposition \( \psi(r, \varphi, 0) \). As a result, the on-axis interference observed at the output plane of the optical processor yields phase information about the coefficients \( c_\ell \). Different angular components can be readily accessed by rotating the filter transparency with respect to the optical axis.

The proposed experiment thus consists of the following four steps: (i) The input state is encoded into a superposition of Bessel-like beams \( \psi_\ell(r, \varphi) \). (ii) This superposition is propagated a distance \( z \). (iii) The angular distribution \( \omega(\phi, z) \) is determined by measuring the intensity in the middle of the output plane of the optical processor as a function of the
Fourier filter orientation $\phi$. The last two steps are repeated for a set of distances $z$. (iv) The Wigner function of the input state is reconstructed with the help of Eqs. (2) and (4).

As an illustration, we apply our reconstruction procedure to the state $\psi(r, \varphi) = [\psi_1(r, \varphi) + \psi_2(r, \varphi)]/\sqrt{2}$. The calculated transverse intensity of this state is shown in the left panel of Fig. 1 while a typical CCD scan of the state generated in the laboratory by an amplitude spatial light modulator (CRL Opto 1024 × 768 pixels) is shown on the right for comparison. As an illustration, we apply our reconstruction procedure to the state $\psi(r, \varphi) = [\psi_1(r, \varphi) + \psi_2(r, \varphi)]/\sqrt{2}$. The calculated transverse intensity of this state is shown in the left panel of Fig. 1 while a typical CCD scan of the state generated in the laboratory by an amplitude spatial light modulator (CRL Opto 1024 × 768 pixels) is shown on the right for comparison.

The tomograms are calculated from Eq. (9), whence we obtain the Fourier coefficients as $\phi(\ell, \phi) = e^{i\delta \phi/2}(\delta_{\ell,1} + \delta_{\ell,-1})/(4\pi)$. This leads to the Wigner function

$$W(\ell, \phi) = \frac{1}{4\pi}(\delta_{\ell,1} + \delta_{\ell,2}) + \frac{(-1)^{\ell+1}}{\pi^2(3-2\ell)} \cos \phi. \quad (12)$$

We can see three contributions: two flat slices, coming from the fields $\psi_1$ and $\psi_2$, located at $\ell = 1$ and $\ell = 2$, respectively, and an interference term that contains contributions from all the values of $\ell$, although damped as $1/\ell$. These features are illustrated in Fig. 2 which shows the reconstructed Wigner function on the unit cylinder and its wrapped counterpart in Cartesian axes.

In practice, one cannot scan infinite values of $\zeta$ (i.e., of $z$), and only some discrete version of the Eq. (4) is available in the laboratory. We have checked that with 50 equispaced values, the reconstruction is still fairly stable.

In summary, we have carried out a full program for a complete reconstruction of vortex beams. In our scheme, the information is encoded in a superposition of Bessel-like non-diffracting beams for which free propagation is equivalent to the $L^2$ operation. At the same time, our formulation provides a theoretical framework on the action of angle and angular momentum on these beams.
