Key words: membrane traffic, rab proteins, Rab7b, Rab7, toll like receptor, epidermal growth factor receptor, cation independent-mannose-6-phosphate receptor

Abbreviations: CI-MPR, cation independent-mannose phosphate receptor; DCs, dendritic cells; EGF, epidermal growth factor; EGFR, epidermal growth factor receptor; LPS, lipopolysaccharide; MVBS, multivesicular bodies; TGN, trans Golgi network; RILP, rab interacting lysosomal protein; TLR, toll like receptor

Rab proteins are key-regulators of intracellular membrane trafficking. Rab7b is a recently identified Rab protein that may downregulate TLR4 and TLR9-mediated inflammatory responses. Rab7b, believed to have similar function as Rab7, controls however vesicular trafficking from endosomes to the TGN. It is localized to late endosomes/lysosomes as well as the TGN. Rab7b interferes with enzymes delivery to lysosomes and with the retrograde Shiga toxin transport to the Golgi. Furthermore, Rab7b depletion alters CI-MPR and TGN46 trafficking. In conclusion, Rab7b, by regulating the transport from late endosomes to the TGN, is fundamental for trafficking of several receptors, opening for a revised scenario for its influence on signaling of toll-like receptors (TLRs) and other receptors.

Eukaryotic cells are organized complexes of subcellular membranous compartments that, in order to function properly, needs to be tightly controlled by specific transport systems. Some proteins, such as Rab proteins, are the responsible for regulating the trafficking between the different compartments. Rab proteins (Ras-related proteins in brain) are small GTPases, members of the Ras superfamily.1 Although more than 60 human Rab proteins have been identified to date, only about half of them has been functionally characterized.2,3 Each Rab protein interacts with several downstream effectors: motor proteins that transport vesicles along actin or tubulin cytoskeleton,3 tethering factors, as well as SNARES, that help to target the vesicular carrier to the appropriate membrane promoting membrane fusion,4,5 adaptors, lipid kinases and phosphatases to control budding and fusion of vesicles.4,5 Furthermore Rab proteins are also essential for proper signaling and control of cell proliferation and differentiation.10,11

Rab7 regulates the transport to late endosomes and lysosomes (Fig. 1), and is important for lysosomal and phagosomal biogenesis, and for maturation of late autophagic vacuoles.12-14 The active form of Rab7, recruits RILP onto Rab7-positive compartments, and RILP recruits dynein-dynactin motor complexes.13,15 Recruitment of motors causes the movement of Rab7-containing vesicles toward the microtubule-organizing center.

The localization and function of a new Rab7 like protein called Rab7b has recently been investigated.16-19 In this review we will discuss the role of Rab7b in membrane traffic and we will highlight the implications of its functions in receptor trafficking and signaling.

Role of Rab7b in Membrane Traffic

Rab7b is a small GTPase first identified by Cao and coworkers in 2004.16 It shares approximately 68% similarity with Rab7 and it is highly expressed in monocytes (CD14+ cells), monocyte-derived immature dendritic cells (DCs), and promyeloid or monocytic leukemia cell lines.16 Rab7b expression is downregulated in DCs after stimulation with lipopolysaccharide (LPS), while it is upregulated when monocytes are activated by LPS treatments or when acute promyelocytic leukemia (APL) cell lines are differentiated with phorbol myristate acetate (PMA).16

Cao and coworkers demonstrated that Rab7b is localized on late endosomes and lysosomes, and suggested that, similarly to Rab7, Rab7b could control transport to late endosomes and lysosomes in the endocytic pathway.16 When we investigated the intracellular localization of Rab7b, we confirmed that Rab7b, similarly to Rab7, is localized to late endosomes and lysosomes. However, we also found that, at variance with Rab7, Rab7b is also localized to the Golgi apparatus and to the TGN19 (Fig. 1). In particular, the constitutively active mutant Rab7b Q67L almost completely co-localizes with Golgi and TGN markers, at variance with Rab7 Q67L that is present solely on the late endosomal and lysosomal compartment.19

EGFR, after binding its ligand (EGF) at the plasma membrane, is activated and dimerizes; dimerization induces auto-phosphorilation of the receptor, followed by ubiquitination and internalization.20 On early endosomes, the ubiquitinated receptor is directed by the endosomal sorting complexes required for

Role of Rab7b in Signal Transduction

High level expression of Rab7b downregulates the TLR4 and TLR9-mediated inflammatory response whereas depletion leads to upregulation, and suggests that Rab7b function was essential for receptor degradation.\(^{17,18}\) This hypothesis was based on the assumption that Rab7b regulated transport to degradative compartments along the endocytic pathway similarly as Rab7.\(^{17,18}\) However, considering that Rab7b controls transport from endosomes to the TGN, data on TLRs should be reinterpreted.

TLRs are type I transmembrane receptors that initiate the immune responses following the binding with microbial molecules.\(^{26}\) TLR4 is present on the plasma membrane and binds molecules that are on the surface of pathogens (LPS), whereas TLR9 is expressed intracellularly in acidic compartment where it recognizes microbial nucleic acids.\(^{27}\) Although there is a good knowledge about the TLRs-triggered signaling cascade, very little is known about their intracellular trafficking.
LPS, after binding CD14 on the cell surface, is presented to TLR4 and initiates the intracellular signaling cascade, resulting in the release of proinflammatory cytokines. The LPS/TLR4/MD-2 complex is internalized by endocytosis in early endosomes, but it is then delivered to different destinations, as recycling endosomes, TGN and Golgi for recycling, and lysosomes for degradation (Fig. 1).18-33 Notably, the receptor complex has been detected in Rab7b-positive compartments.18 In Rab7b-silenced cells, after LPS treatment, it was observed a prolonged persistence of the receptor in both early and late endocytic compartments.18 Since Rab7b regulates the transport from endosomes to the TGN, when Rab7b is depleted TLR4 cannot recycle to the TGN efficiently and therefore it is forced to stay in the early endocytic route longer and this could increase its signaling.

It has been also observed that Rab7b overexpression inhibits its unspecifically both the MyD88-dependent (occurring at the plasma membrane and terminating with TLR4 endocytosis) and TRIF-dependent (occurring in the endosomes and terminating with the receptor degradation) signaling cascade.18,32,33 However, if Rab7b was controlling early endosomes to late endosomes and lysosomes transport one would expect that only TRIF-dependent signaling would be affected. In addition, in cells overexpressing Rab7b there is a low protein level of the receptor even in unstimulated conditions. Therefore, the inhibition of TLR4-mediated signaling in presence of Rab7b could be caused by decrease of the receptor synthesis or, assuming that the receptor complex is not able to signal when localized to the TGN, by increased transport to this compartment from endosomes.

TLR9 localizes to endoplasmic reticulum in unstimulated cells; after activation, it traffics to endolysosomes passing through the Golgi (Fig. 1).34 The ectodomains of TLR9 is cleaved in the endolysosome by cathepsins, and it interacts with endocytosed CpG DNA at acidic pH.35 After DNA binding, TLR9 activates immune response against microbial pathogens, leading to the induction of proinflammatory cytokines.36 Although both full-length and processed forms of the receptor can bind ligand, only the cleaved form of TLR9 is competent for signal transduction.34,35 Rab7b colocalizes with TLR9 on late endosomes/lysosomes after CpG stimulation.

Overexpression of Rab7b inhibits TLR9-mediated activation and expression of proinflammatory cytokines and type I IFN in macrophages, while Rab7b silencing has the opposite effect.17 Interestingly, Rab7b overexpression inhibits TLR9 expression in macrophages even when the macrophages are unstimulated.17 Considering that Rab7b controls trafficking between endosomes and the TGN, it is tempting to speculate that overexpression of Rab7b cause re-routing of the receptor to the TGN thus causing the suppression of TLR9-triggered production of proinflammatory cytokines.37 In addition, it is known that TLR9 is degraded by proteasomes after ubiquitination by the Triad3A ubiquitin ligase, thus ending the signaling.36

Emerging evidence demonstrates the functional significance of compartmentalized signaling by cell surface receptors. Therefore, the endocytic Rab proteins (and in particular of Rab7b) are essential for regulating the kinetics and dynamics of membrane traffic and thereby receptor signaling. Indeed, modulation of endocytic Rab proteins functions could help to regulate signal transduction enabling control of proliferation and differentiation, with important implications for the development of cancer therapies and stem cell-based therapy for genetic and acquired diseases.
