The high osmolarity glycerol (HOG) pathway in yeast serves as a prototype signalling system for eukaryotes. We used an unprecedented amount of data to parameterise 192 models capturing different hypotheses about molecular mechanisms underlying osmo-adaptation and selected a best approximating model. This model implied novel mechanisms regulating osmo-adaptation in yeast. The model suggested that (i) the main mechanism for osmo-adaptation is a fast and transient non-transcriptional Hog1-mediated activation of glycerol production, (ii) the transcriptional response serves to maintain an increased steady-state glycerol production with low steady-state Hog1 activity, and (iii) fast negative feedbacks of activated Hog1 on upstream signalling branches serves to stabilise adaptation response. The best approximating model also indicated that homeostatic adaptive systems with two parallel redundant signalling branches show a more robust and faster response than single-branch systems. We corroborated this notion to a large extent by dedicated measurements of volume recovery in single cells. Our study also demonstrates that systematically testing a model ensemble against data has the potential to achieve a better and unbiased understanding of molecular mechanisms.

Keywords: adaptation; ensemble modeling; Hopf bifurcation; model discrimination; osmotic stress

Introduction

The high osmolarity glycerol (HOG) pathway in the yeast Saccharomyces cerevisiae is one of the best-studied mitogen-activated protein kinase (MAPK) pathways and serves as a prototype signalling system for eukaryotes. This pathway is necessary and sufficient to adapt to high external osmolarity. A key component of this pathway is the stress-activated protein kinase (SAPK) Hog1, which is rapidly phosphorylated by the SAPK kinase Pbs2 upon hyper-osmotic shock, and which is the terminal kinase of two parallel signalling pathways, subsequently called the Sho1 branch and the Sln1 branch, respectively. Either of these branches is necessary for adaptation (Hohmann, 2002) and they converge on Pbs2. In the Sln1 branch, Pbs2 acts in a classical three-tiered stress or MAPK pathway, where the MAPK kinase kinases Ssk2 and Ssk22 are activated by an upstream phospho-relay system controlled by the sensor Sln1 (Posas et al., 1996). In the Sho1 branch, Pbs2 acts as a scaffold, involving membrane-associated Sho1 and the MAPK kinase kinase Ste11 (Tatebayashi et al., 2003, 2007; Yamamoto et al., 2010). Why two parallel redundant pathways have been conserved through evolution remains elusive, even more so because components of the Sho1 branch are also involved in two other MAPK pathways and crosstalk seems to be actively prevented (O’Rourke and Herskowitz, 1998; Nelson et al., 2004; Schwartz and Madhani, 2004; Yamamoto et al., 2010).

It is generally agreed that the main mechanism of short-term adaptation to osmotic shock in yeast is through the accumulation of the osmolyte glycerol (Nevoigt and Stahl, 1997; Rep et al., 1999; Hohmann, 2002; O’Rourke et al., 2002; Klipp et al., 2005; Muzzey et al., 2009), which balances the internal and external water potential differences and therefore re-establishes pre-stress volume (Schaber and Klipp, 2008; Schaber et al., 2010), effectively terminating the signal. However, it is debated which are the main processes regulating glycerol accumulation. Some argue in favour of glycerol production (Rep et al., 1999; Dihazi et al., 2004; Muzzey et al., 2009), whereas others also see an important role in glycerol retention by closing the glyceroporin Fps1 (Luyten et al., 1994; Tamas et al., 1999; Klipp et al., 2005; Mettetal et al., 2008). In addition,
the important mechanisms regulating those two main processes of glycerol accumulation remain poorly understood. Increase in glycerol production is classically viewed to be a function of the abundance of the glycerol-3-phosphate dehydrogenases Gpd1 and Gpd2, which in turn are regulated at the transcriptional level by Hog1 (Albertyn et al., 1994; Rep et al., 1999; Hohmann, 2002). However, there is also evidence that activated Hog1 might directly or indirectly redirect the glycolytic flux from ethanol towards glycerol, possibly at the post-transcriptional level (Dihazi et al., 2004). Loss of glycerol through Fps1 is at least partly controlled by Hog1, either by direct or indirect interaction or both (Tamas et al., 2003; Beese et al., 2009). There is also evidence for a Hog1-independent mechanism regulating closure of Fps1, possibly activated directly by a reduction in the cell’s volume and/or its turgor pressure (Tamas et al., 2000; Reiser et al., 2003; Schaber et al., 2010).

Glycerol accumulation may be viewed as an integral feedback control mechanism, which integrates the difference between the desired steady-state and the actual state of the system, measured by Hog1 activation, over time (Mettetal et al., 2008). However, it remains unclear what the feedback acts upon. Again, it seems to be related to volume and/or turgor pressure (Tamas et al., 2000; Reiser et al., 2003; Schaber et al., 2010). Apart from this general integral feedback control mechanism, which undoubtedly is the main determinant of osmo-adaptation in yeast, other transient feedback mechanisms mediated by activated Hog1 have been proposed to act on the signal transduction pathway.

In the Sho1 branch, Hao et al. (2007) showed that Hog1 binds and phosphorylates the membrane protein Sho1. They proposed that this phosphorylation acts as a rapid transient negative feedback responsible for the rapid attenuation of the Hog1 activity. However, a recent model discrimination analysis suggested that the experimental data in Hao et al. (2007) did rather support a model with an integral feedback through glycerol accumulation, rendering the role of the suggested transient feedback unclear (Schaber et al., 2011). It was also shown that Hog1 phosphorylates Ste50 (Hao et al., 2008; Yamamoto et al., 2010) and thereby shortens the duration of Hog1 activation (Yamamoto et al., 2010), which further supports the notion of a transient negative feedback within the Sho1 branch.

In the Sin1 branch, Macia et al. (2009) proposed the existence of a fast transient negative feedback mechanism. They suggested that the role of this feedback regulation was to increase efficiency and reduce response time. However, the data in Macia et al. could also be explained by alternative mechanisms. It also seems likely that the importance of the various regulatory mechanisms may vary over the course of the response (Klipp et al., 2005; Klipp and Schaber, 2008) and probably with the intensity of the shock.

Therefore, we systematically addressed the question of which of the many possible regulation and feedback mechanisms or combinations thereof are best supported by the available data. To this end, we compiled an unprecedented amount of published and comparable dynamic data on the HOG pathway activation. We fitted an extensive set of parsimonious models representing different hypotheses about the underlying biological regulatory mechanisms to one part of the data. Another part of the data was used to test the predictive properties of the various models. Subsequently, models were ranked according to both their goodness of fit and their predictive properties. Then, the highest scoring models were used to generate new predictions, which were partly tested by dedicated additional experiments. In this way, we obtained a model that was well supported by the data and that provided new insights into the importance of several regulatory and feedback mechanisms acting during osmo-adaptation, which might be of general importance in adaptation mechanisms.

The model suggested that (a) the main adaptation mechanism is through the increase in glycerol production by fast transient post-translational mechanisms, rather than translational mechanisms or glycerol retention as previous studies had suggested; (b) glycerol retention is the second mechanism in importance, which is also fast and acts through closure of the glycerol channel; (c) the slow mechanism, via induction of gene expression, serves predominantly to reset the steady state of the system after adaptation to near pre-stress levels, replacing the short transient mechanisms by a slower but less Hog1-dependent and sustained process; and (d) we found that transient negative feedback mechanisms acting on the upstream signalling branches have only a minor role for adaptation. The models rather suggested that fast transient negative feedbacks serve to stabilise the integral feedback response in terms of preventing oscillatory behaviour, which may occur in systems with delayed negative feedback. The first three mechanisms directly act upon the accumulation of glycerol thereby modulating the integral feedback response, which terminates the signal and re-establishes homeostasis. Therefore, in the following, we refer to such mechanisms as homeostatic feedbacks.

The model also provided an explanation for why there are two redundant parallel signalling pathways. Simulation studies suggested that the mean adaptation time for the wild-type yeast is faster and more robust to variations in initial state and parameters than for the single-branch mutants, especially for weak stress. By dedicated experiments, we could corroborate the prediction that wild-type yeast adapts faster than single-branch mutants. The notion that adaptation in wild-type yeast is also more robust could only be corroborated for low osmotic stress, which might be more relevant in the natural environment.

Results

The best approximating models have excellent explanatory as well as predictive properties

We constructed an ensemble of 192 models, their differences reflecting uncertainties about molecular mechanisms underlying osmo-adaptation and representing different hypotheses thereof (Figure 1, Supplementary Tables S1–S7 and see Materials and methods section for details on model construction). The free kinetic parameters of the models were fitted to an unprecedented amount of dynamic data (Figure 2), including time series for Hog1 phosphorylation, mRNA, protein, glycerol and volume for a range of different conditions and mutants. In addition, the predictive properties of the
models were tested with another data set (Figure 3A and B), that was not used to parameterise the models. Models were ranked according to goodness of both fit and predictive properties using the Akaike Information Criterion (AIC) (see Materials and methods section and Supplementary Tables S8–S10). Both with and without taking into account predictions (Figure 3A and B), the same model was consistently selected as best approximating model (Model Nr. 22, Supplementary Tables S9 and S10). However, there were three models with an Akaike weight (AIC\_w) < 0.05 (see Materials and methods section) considering both ranking methods (Model Nr. 22, 30 and 78, Supplementary Tables S9 and S10). These three best approximating models exhibited only marginal differences in both fits and predictions (see SSRs in Supplementary Tables S9 and S10). These models differed in the way they modelled the total amount of Fps1. Model Nr. 30 and Model Nr. 78 included Fps1 production and degradation reactions (reactions v\_17 and v\_18 in Figure 1), the latter modified by activated Hog1 and protein, respectively. However, Fps1 degradation was negligible, because the fitted degradation rates were very small. Therefore, in the following, we show only results for the best approximating model Nr. 22, even though most results also hold for the other two models. Model Nr. 22 had 20 free parameters, which constitutes to our knowledge the lowest ratio of parameters to data points of all published HOG models. In Figure 1, the best approximating model (Nr. 22) is indicated by solid and dashed lines. An implementation of Model Nr. 22 in COPASI format (Hoops et al., 2006) and SBML format (F Hucka et al., 2003) together with the data used for fitting and prediction can be found in the online Supplementary Material. COPASI is a free and open source software available from www.copasi.org. The SBML model can also be downloaded from the Biomodels database (accession number MODEL1209110001).

In general, the selected models exhibited an excellent parsimonious data representation, especially for the fitted single-branch Hog1 phosphorylation time series for different conditions (Figure 2A, B and D) and wild-type Fps1ΔI mutant (Figure 2E). Also wild-type mRNA, Gpd1 and glycerol data (Figure 2C) could be well fitted. Only the artificial volume data (see Materials and methods) for 0.2 M NaCl shock could not be well fitted, showing an accelerated simulated volume recovery (Figure 2F, green line). However, the best approximating models excelled at predicting wild-type Hog1 phosphorylation time series for different conditions (Figure 3A and B), even though we mostly used the single-branch mutants to parameterise the models (Figures 2A, B and D). These predictions were also used for the model selection procedure.

We further tested the predictive properties of the models with three additional experiments from Macia et al. (2009) (Figure 3C and D) that were not used for model selection. The models were able to predict well Hog1 phosphorylation time series when (a) Pbs2 kinase activity is inhibited, assuming that an inhibitor concentration of 1, 3 or 5 μM corresponds to a decrease in Pbs2 phosphorylation activity (reactions v\_6 and v\_7 in Figure 1) of 0%, 75% or 99%, respectively (Figure 3C), (b) Hog1 kinase activity is inhibited in the Fps1ΔI mutant (Figure 3D, brown line) and (c) Hog1 kinase activity is inhibited and simultaneously transcription is blocked by thiolutin (Figure 3D, blue line).

The HOG pathway was shown to act as a low-pass filter regarding the frequency of salt shocks (Hersen et al., 2008). We simulated the response of the best approximating model Nr. 22 to square-wave stimuli of 0.2 M NaCl with periods ranging...
Using Fourier analysis, we approximated the simulations by sine wave oscillations with a period of $P_0 = \frac{2\pi}{\omega}$ and calculated frequency-dependent output amplitude $A(\omega)$, which is represented in a Bode plot (Supplementary Figure S3) as in Mettetal et al (2008). We also compared our simulated frequency-dependent amplitude $A(\omega)$ with re-analysed data from Mettetal et al. (2008) (Supplementary Figure S2). The model simulations show an increasing frequency-dependent amplitude $A(\omega)$ with decreasing frequency $\omega$, like both the results from Hersen et al (2008) and the re-analysed data from Mettetal et al (2008). Thus, the best approximating model can well reproduce the reported low-pass filter characteristics of the HOG pathway (for details refer to the Supplementary Material).

A sensitivity analysis of the adaptation time (assessed as the time to recover pre-stress volume) showed that the model is in general robust to changes in both kinetic parameters and initial conditions. All absolute sensitivities were $< 1$, except for the rate constant of reaction $v_{13}$ (glycerol production) and initial turgor pressure, both having a maximal absolute sensitivity of 2.4 (Supplementary Table S13). A sensitivity of 1 indicates a
direct proportional change of adaptation time with respect to a certain parameter (see Supplementary Material).

In the course of model analysis, reaction \( v_{13} \), that is, Hog1-modified glycerol production (Figure 1), turned out to be important for our conclusions (see below). As Hog1 modification of glycerol production was modelled by a simple heuristic approach owing to the lack of a detailed mechanism, we also tested other possible kinetic rate laws for reaction \( v_{13} \) in the three best approximating models Nr. 22, Nr. 78 and Nr. 30 that had an AIC \( w^2 < 0.05 \) (see Materials and methods section, Supplementary Tables S11 and S12). The kinetic rate law for reaction \( v_{13} \) used in the original model formulation was best supported by the data and, thus, the ranking of at least the three best approximating models was robust to changes in this kinetic rate law. The large difference in the performance between the original and the other tested kinetics suggests that this result is also valid for the other models (Supplementary Table S12).

Seven out of 20 parameters were not identifiable within the tested range, especially concerning the upper confidence limit, as revealed by an identifiability analysis calculating one-dimensional likelihood profiles (Raue et al, 2009; Schaber 2012) (Supplementary Figure S4). This is due to lack of data, especially shortly after shock, a time when the system is highly dynamic. However, all fitted parameters were at a local minimum and more than half of them were identifiable (Supplementary Figure S4).

The model correctly predicts effect of wild-type and single-branch inhibition

Hao et al (2007) proposed a transient negative feedback mechanism in the Sho1 branch, showing that Hog1 directly interacts with and phosphorylates Sho1, and that this phosphorylation attenuates Hog1 activation. We mimicked their experiments in a simulation with or without feedback, and with a Hog1-independent constitutive feedback on the Sho1 branch. Despite the simplistic model formulation, the best approximating model (Nr. 22) shows the same dynamic behaviour as measured by Hao et al (2007) (see Figure 5B therein), where blocking the feedback increases Hog1 phosphorylation levels and a constitutive feedback decreases Hog1 phosphorylation levels upon osmotic shock (Supplementary Figure S6).

Thus, the best approximating model is not only able to recapitulate a large amount of data, but it is also able to predict an unprecedented range of mutants and experimental conditions both qualitatively and quantitatively. This gave us confidence that the model captures the main mechanism of osmo-adaptation in yeast and that we could use it to further study these mechanisms.
Direct non-transcriptional modification of glycerol production by Hog1 is the main mechanism responsible for Hog1 phosphorylation upon inhibition of Hog1 activity

Macia et al (2009) observed an increase in phosphorylation of Hog1 following chemical inhibition of its kinase activity, even under non-stressed conditions (Figures 2D and 3B). They attributed this behaviour to a rapid and transient negative feedback of Hog1 on the signalling branch activated by the Sln1 branch, as the Sho1 branch mutant did not show this behaviour (Figure 2D, green line). They discarded two homeostatic negative feedbacks (closure of Fps1 and induction of Gpd1 expression) by showing that a mutant with a constitutively open Fps1 channel or with blocked transcriptional activity still exhibited the same increase in Hog1 phosphorylation after its inhibition (Figure 3D). However, we were not satisfied with their conclusions, because they disregarded the possibility of other Hog1-mediated homeostatic feedback mechanisms.

Thus, we decided to further investigate the importance of the individual mechanisms responsible for the measurements done by Macia et al using our best approximating model (Nr. 22), which could reproduce and predict well all these data (Figures 2D, 3B and D). To this end, we again simulated Hog1 phosphorylation time series during a Hog1 kinase inhibition experiment as shown in Figures 2D, 3B and D. However, this time instead of removing (setting the appropriate parameters to zero) all modifying influences of activated Hog1, which would mimic complete inhibition of the kinase, we removed all but one of these feedbacks at a time. This way, we could selectively test which of the proposed feedback mechanisms is responsible for the observed Hog1 phosphorylation upon kinase inhibition, because if the responsible feedback would still be active despite of other feedbacks being blocked, no Hog1 activation should be observed. Specifically, we tested situations where all Hog1-mediated feedbacks were deleted except one of the following four: (a) upstream signalling branch feedback (branch FB only), (b) Hog1-mediated induction of transcription (transcriptional FB only), (c) direct activation of glycerol production (Hog1–glycerol FB only) or (d) closure of Fps1 channel (Fps1 FB only). The results are shown in Figure 4.

Sln1 branch mutant (disabled Sho1 branch)

When only the Hog1 feedback on upstream signalling remains functional (reactions \( v_1 \) and \( v_5 \) in Figure 1, “branch FB only”), after addition of Hog1 kinase inhibitor, Hog1 still becomes phosphorylated, though to a lesser extent than in the simulation with all feedbacks blocked (all FBs off).
(Figure 4A, compare blue and red lines). A similar simulation output is observed when Hog1 activity remains functional only towards Fps1 closure (reaction $v_6$ in Figure 1, Figure 4A, 'Fps1 FB only', grey line). When only Hog1-dependent induction of gene expression remains enabled in the model, we see initially the same behaviour as if all feedbacks were blocked, but at later times Hog1 phosphorylation decreases again, reflecting increasing protein production and subsequent increased glycerol production (Figure 4A, transcriptional FB only, green line). Thus, our model indicates that the above mentioned feedbacks can only partly explain the observed behaviour. In contrast, there is almost no simulated Hog1 phosphorylation when the direct Hog1-mediated modification of glycerol production is the only remaining functional feedback upon kinase inhibition (Figure 4A, 'Hog1 glycerol FB only', orange line). This demonstrates that in our model, and for the Snl1 branch, the main mechanism leading to Hog1 phosphorylation upon addition of inhibitor is inhibition of direct (non-transcriptional) Hog1-mediated glycerol production. Accordingly, simulations of the dynamics of intracellular glycerol concentration and corresponding branch activation (Figure 4C, Supplementary Figure S7) further support this mechanism, as inhibition of Hog1 activity leads to a rapid downregulation of steady-state glycerol production, leading to a decrease in the simulated internal glycerol. This reduction leads to an osmotic stress, which in turn leads to pathway activation.

Sho1 branch mutant (disabled Snl1 branch)

For the Sho1 branch mutant, the model shows almost no Hog1 phosphorylation for the simulated scenarios (Figure 4B). This is what Macia et al (2009) observed experimentally (Figure 2D). They interpreted this result as evidence for a lack of feedback of Hog1 on the Sho1 branch. Here, our model suggests that the reason is not the lack of such feedback, which was experimentally confirmed to exist (Hao et al, 2007; Yamamoto et al, 2010), but the low sensitivity of the Sho1 branch to mild osmotic stresses. In this mutant, the drop in internal glycerol caused by inhibition of Hog1 is comparable to that in the Snl1 branch mutant (Figure 4D), but it is insufficient to activate the Sho1 branch (Supplementary Figure S7).

Direct non-transcriptional modification of glycerol production by Hog1 is the main adaption mechanism to osmotic stress

Our modelling analysis of the mechanisms leading to Hog1 phosphorylation after inhibition of its kinase activity suggests that rapid non-transcriptional modification of glycerol production by Hog1 is the main mechanism of adaption. This notion is further supported by an analysis of activated Hog1 and volume time series under osmotic stress conditions (Figure 5).

Abrogating direct non-transcriptional Hog1-mediated activation of glycerol production substantially prolongs adaptation to 0.4 M NaCl osmotic shock (Hog1-PP modification of $v_3$ in Figure 1, red lines in Figure 5) compared with the wild type (blue lines in Figure 5) both in terms of Hog1 phosphorylation and volume recovery. Disabling other mechanisms having a direct role in glycerol accumulation (Fps1 channel closure, i.e., Hog1-PP and turgor modifications of reaction $v_{15}$ and $v_{16}$ in Figure 1, grey lines in Figure 5) increased the maximal Hog1 phosphorylation level and had almost no effect on the timing of volume recovery.

Taken together, the analyses of the best approximating model suggest that the main mechanism for Hog1 and volume adaptation is a fast and transient non-transcriptional Hog1-glycerol feedback. Concerning Fps1 channel closure, the effects of activated Hog1 and turgor are additive, where turgor has a more pronounced role in channel closure. Interestingly, the effect of disabling transcription is an increase in the final steady-state level of activated Hog1 rather than prolonged adaptation time (see green lines for volume and Hog1-PP in Figure 5). Disabling the direct feedback of Hog1 to the Snl1 and the Sho1 branch (Hog1-PP modification reaction $v_3$ and $v_4$ in Figure 3, orange lines in Figure 5) increased the maximal Hog1 phosphorylation level and had almost no effect on the timing of volume recovery.

Transcriptional modification of glycerol production by Hog1 serves to sustain adaptation and prepares for subsequent shocks

The analysis above suggests that the role of the transcriptional feedback is to control the steady-state level post adaptation rather than adaptation dynamics. Indeed, when protein levels related to glycerol production stay constant in our model instead of being upregulated upon osmotic shock, Hog1 steady-state activation is elevated after adaptation relative to normal conditions (Figure 5). Moreover, upon simulation of consecutive increases of the external osmolarity the cell is less able to adapt in terms of both volume and Hog1 activity.

**Figure 5** Simulated Hog1 phosphorylation and volume dynamics for 0.4 M NaCl osmotic shock for cases where several feedback mechanisms are selectively shut off. W/o denotes without. FB denotes feedback. Blue line: wild type. Brown line: without Hog1-mediated feedback on both upstream signalling branches. Orange line: without Hog1-mediated feedback on the Sho1 branch. Light orange line: without Hog1-mediated feedback on the Snl1 branch. Dark grey line: without Fps1 closure. Grey line: without Hog1-mediated Fps1 closure. Light grey line: without turgor-mediated Fps1 closure. Green line: without transcription. Red line: without Hog1-mediated glycerol production.
(Figure 6A), whereas under normal transcriptional activity, the response remains the same upon each consecutive shock. For the case of three consecutive shocks, this has been observed experimentally (Schaber et al., 2011).

We observe a similar behaviour upon simulating multiple hyper–hypo-osmolarity shock cycles (Figure 6B). When Hog1-mediated gene expression is functional, after each hyper–hypo-osmolarity shock pair of the same strength, the simulated cell needs less and less time to adapt to the following hyper–hypo shock and the volume changes less and less, as well. This is because of the increasing internal glycerol production capacity. Accordingly, Hog1 phosphorylation amplitude decreases (see also Supplementary Figure S1). When the increase in glycerol production capacity is disabled, cells are less able to prepare to a subsequent shock and need correspondingly more time to adapt. Such a behaviour has been reported before (Mettetal et al., 2008), which further supports our model. However, this result should be taken with care, because the hypo-shock response, which activates the cell wall integrity pathway, might interfere with the hyper-shock response regulated by the HOG pathway.

### Rapid feedback on signalling branches stabilises adaptation response

We observed that disabling the Hog1-PP-mediated feedback on the upstream signalling branches did not have a marked effect on adaptation dynamics (orange lines in Figure 5). In fact, without these feedbacks, Hog1 activation levels returned even faster to steady-state levels than with feedback, because of the higher maximal Hog1 activation and the corresponding boost of glycerol production. This prompted the question as to why the best approximating model included these feedbacks at all and, the related question, as to what they are good for. First, we observed that the best approximating model without the branch feedbacks displayed slightly damped oscillations (orange lines in Figure 5). Second, as mentioned in the Materials and methods section, we excluded models that showed oscillatory behaviour after adaptation from the model selection procedure (Supplementary Table S8). This is because we assumed that the real system does not exhibit this behaviour, as even careful single-cell analyses did not reveal oscillatory behaviour (Mettetal et al., 2008; Muzzey et al., 2009). We analysed the percentage of models with oscillatory behaviour among models with or without transient feedbacks on the signalling branches and with or without non-transcriptional Hog1-PP-mediated glycerol production. We noticed that including either of these feedbacks reduced the percentage of oscillating models in the respective category (Figure 7). Thus, models including transient feedbacks had a higher chance of being part of the discrimination procedure, because they were less prone to oscillatory behaviour.

More than 70% of models with only transcriptional feedback (Figure 7, Gpd1) and less than two feedbacks on the signalling branches (Figure 7, < 2 BFB) showed oscillatory behaviour. Including both transient feedbacks on the signalling branches (2 BFB in Figure 7) or the rapid (non-transcriptional) Hog1-PP-mediated glycerol production (Hog1 in Figure 7) decreased the percentage of oscillating models.
Using this model, we systematically studied the stability of oscillating models. Gpd1+<2BFBs: transcriptional feedback (Gpd1) with less than two Hog1-mediated upstream signalling branch feedbacks (2BFBs). Gpd1+2BFBs: transcriptional feedback (Gpd1) with both Hog1-mediated upstream signalling branch feedbacks (2BFBs). Gpd1→Hog1+<2BFBs: transcriptional feedback (Gpd1) with Hog1-mediated glycerol production (Hog1) and less than two Hog1-mediated upstream signalling branch feedbacks (2BFBs). Gpd1→Hog1+2BFBs: transcriptional feedback (Gpd1) with both Hog1-mediated glycerol production (Hog1) and both Hog1-mediated upstream signalling branch feedbacks (2BFBs).

(10.5) Finally, only 25% of models including the three fast mechanisms (both branch feedbacks and the rapid Hog1 control on glycerol production) showed oscillatory behaviour. Taken together, it seems that transient feedbacks stabilise the adaptation response in terms of avoiding or making it less prone to oscillatory behaviour, at least for our parameterised models.

We hypothesised that this might be a more general feature of delayed negative feedback systems, including fast transient feedbacks. To further investigate this hypothesis, we developed a simple and more general model (Figure 8A). This generic model consisted only of four components and included the main features and feedback mechanisms of the complete model, that is, a non-zero steady state, Hog1 activation, transcription, translation, glycerol production, an integral feedback control via glycerol accumulation, and two fast transient Hog1-PP-mediated feedbacks: one on Hog1 activation itself and one on glycerol production. The model had only three kinetic parameters (See Supplementary Material for a detailed description). With arbitrary parameters and initial conditions, the model exhibited general adaptation behaviour upon osmotic shock (Figure 8B); however, without either of the two transient feedbacks (dashed lines in Figure 8A), the model showed stable oscillations after adaptation (Figure 8C).

Using this model, we systematically studied the stability of the steady state after adaptation as a function of the base signal $T_o$ and the input signal NaCl (Figure 9). Assuming mass-action kinetics and the same reaction parameters for reactions $v_1$, $v_2$, $v_3$ and $v_7$, there were only one to three free kinetic parameters, depending on the model, which had only minor influence on the stability behaviour (see Supplementary Material).

In Figure 9, we plot the sign of the real part of the maximum eigenvalue of the linearised system at steady state. If negative, that is, white squares in Figure 9, the steady state is stable and no sustained oscillations are possible. A computational analysis revealed that when the real part of the maximum eigenvalue changes from negative to positive, that is, grey squares in Figure 9, there is a single pair of complex conjugated eigenvalues crossing the imaginary axis and the remaining two eigenvalues remain negative. This is the hallmark of a Hopf bifurcation giving rise to, in our case, stable oscillations. We illustrate this by bifurcation diagrams of Hog1PP equilibria as a function of $T_o$ for selected values of NaCl (See Supplementary Figure S5). We observed that including one or both of the transient feedbacks drastically reduced the region in the $T_o$-NaCl plane where the steady state was unstable and oscillations occurred, rendering the model including both transient feedbacks stable for the whole range of tested input conditions (Figure 9).

In combination with our observation from the model fits of the complete models, this provides support to the hypothesis that a potential biological role of those proposed transient feedbacks is the stabilisation of the adaptation response by avoiding oscillatory behaviour, which can occur in delayed negative feedback systems (Khodolenko, 2000).

Both branches synergistically elicit a swifter and more robust osmo-adaptation than a single branch alone

One of the purposes of this study was to address the question of why yeast maintained two redundant signalling pathways in the course of evolution. We addressed this question using our model. Specifically, we tested a hypothesis inspired by recent work stating that it is extremely costly for cells to increase noise suppression in signalling networks owing to molecular fluctuations (Lestas et al., 2010). One possible way to improve noise suppression is to evolve parallel signalling systems, because each signalling pathway contributes independent information about the upstream state (Lestas et al., 2010). We reasoned that the adaptation time is one of the main components that cells optimised throughout evolution, because it brings a selective advantage. Cells that are able to adapt faster and more robustly may resume normal growth and cell division faster and out-compete cells that recover more slowly. Therefore, we tested robustness of the adaptation time for single-branch mutants and the wild type by a Monte–Carlo simulation approach. This stochastic approach mimics the natural cell to cell variability observed in a population (Colman-Lerner et al., 2005, Gaudet et al., 2012). We simultaneously perturbed free parameters and initial conditions within a window of 25% plus or minus of their original value and calculated the time the system needs to regain 98% or 95% of their original volume after an external shock.

For all simulated conditions, the wild-type model had a significantly shorter mean and median adaptation time than each branch alone ($P<0.01$, using two robust tests for location, i.e., U-test and Kolmogoroff–Smirnov test) (Tables I and II and Supplementary Table S14). This effect was especially pronounced for low and intermediate osmotic shocks (0.1 and 0.2 M NaCl), and it is a consequence of the partly additive effects of the two branches during the response to low stress (Supplementary Figures S6 and S9). Moreover, the wild type was significantly more robust than the single-branch mutants to changes in parameters and initial...
conditions ($P<0.01$, using two robust tests for scale, i.e., Siegel–Tukey test and Conover test), which was evidenced by its smaller interquartile ranges and s.d.’s (Tables I and II and Supplementary Table S14).

We sought to corroborate these simulations by dedicated measurements (Figures 10 and 11, Tables I and II). In order to do so, we needed not only to measure average volume recovery times for wild-type and branch mutants but also single-cell information to assess cell to cell variability in the response. As cells are expected to be in different states at the time of the shock, low cell to cell variation in volume recovery time would imply high robustness of the HOG pathway to those differences. Thus, we followed single cells of wild-type, Sln1 branch ($\text{sho1}^{\Delta}$) or Sho1 branch ($\text{ssk1}^{\Delta}$) yeast by time-lapse microscopy during their response to 0.1 and 0.2 M NaCl. Then, we measured from the acquired images the volume of individual cells over time. As predicted by our model, wild-type cells recovered significantly faster than single-branch mutants ($P<0.01$, Tables I and II).

In terms of interquartile ranges, a robust measure of population variability, we observed that for an osmotic shock of 0.1 M NaCl the wild-type exhibits significantly less variability ($P<0.01$) than the single-branch mutants (Table I). For an osmotic shock of 0.2 M NaCl, however, the Sho1 branch showed least variability ($P<0.01$), whereas the variability between wild type and Sln1 branch was not significantly different (Table II).

Our Monte–Carlo analysis of adaptation times using the parameterised model support the hypothesis that a major consequence of maintaining two redundant signalling pathways is that they provide an advantage in recovery from hyper-osmotic shock, both in terms of speed and robustness. The advantage in speed was corroborated by our measurements, whereas the advantage in robustness was only supported for low osmotic shock (0.1 M NaCl).

**Discussion**

The HOG pathway in yeast is one of the best-studied signalling pathways and, therefore, serves as a prototype for eukaryotic stress response MAP kinase pathways. Nevertheless, there is still substantial uncertainty about the relative importance of different regulation and feedback mechanisms and their interaction in time. Moreover, it is still unclear why yeast has maintained two redundant signalling pathways.

In order to answer which of the many hypothesised regulation and feedback mechanisms are best supported by the available data, and what are two parallel redundant signalling branches good for, we systematically tested an extensive set of different hypotheses against an unprecedented amount of available data that mostly have not yet been used for modelling. By a rigorous model discrimination approach, we identified a parsimonious model that was best supported.
by the data. To our knowledge, there was no model proposed yet with a lower ratio of number of parameters to number of fitted data points (20/390). Comparable models based on biological knowledge and fitted to data had ratios of, for example, 70/33 (Klipp et al., 2005) and 10/41 (Gennemark et al., 2006). Most of the parameters of the best approximating model were identifiable and the model showed excellent explanatory, as well as predictive, properties over a wide range of mutants and conditions. Owing to the excellent interpolating as well as extrapolating properties of the model, we are confident that we

Figure 9 Real parts of the maximum eigenvalues of the Jacobian matrix of the simplified HOG model from Figure 8 at steady state including different feedback mechanisms. Grey squares indicates maximum eigenvalues > 0, that is, unstable steady states, white squares indicate maximum eigenvalues < 0, that is, stable-steady states. Unstable steady states coincide with stable oscillations owing to a Hopf bifurcation, which was checked by a computational bifurcation analysis (see Supplementary Material and Supplementary Figure S5).

Table I Adaptation time (min) for 0.1 M NaCl

have captured a formal well-parameterised description of the most important mechanisms underlying osmo-adaption in yeast under the studied conditions.

Addressing the above questions with this model yielded various novel insights into osmo-adaption, which might also be important for other homeostatic adaptive systems in eukaryotes. First, the model suggested that the main adaptation mechanism is not via a feedback involving transcription of glycerol-producing enzymes, but rather a fast, possibly post-translational, Hog1-mediated feedback on the glycerol production machinery. This is in contrast to previous studies, which also proposed a fast non-transcriptional Hog1-mediated feedback having an important role for short-term osmo-adaptation, but speculated that it is rather mediated via fast Fps1-channel closure and resulting glycerol retention (Klipp et al., 2005; Mettetal et al., 2008). Such a mechanism had a less pronounced role in our model. The feedback acting on glycerol production proposed by our model can act by, for example, redirecting the glycolytic flux from ethanol to glycerol (Dihazi et al., 2004) or by increasing the glycolytic flux in general by stopping the cell cycle progression and growth (Adrover et al., 2011). The transcriptional feedback takes over at later time and serves to reset the basal level of Hog1 by replacing the transient Hog1-mediated increase in glycerol production by a more sustainable increase in Gpd1-mediated glycerol production. Resetting a low steady state of Hog1 activity is important in order to be able to quickly respond to possible future shocks, which was suggested by our simulation results (Figure 6). Given that Hog1 activation leads to cell cycle arrest (Adrover et al., 2011), low steady-state Hog1 activity after adaptation may also be important to allow normal cell cycle progression, a feature that was not considered in the model.

The concept of signalling and glycerol production homeostasis under non-stress conditions is important in order to come to a new understanding of osmo-adaptation. This concept has not been sufficiently appreciated by earlier models (Klipp et al., 2005; Macia et al., 2009). It has been noted before that there is a constitutive signal maintaining a low Hog1 activity under non-stress conditions (Wurgler-Murphy et al., 1997; Macia et al., 2009). However, that low constant Hog1 activity may also serve to maintain a constitutive enzyme and glycerol production was not rigorously appreciated. It is exactly this notion that provides a new explanation for the data from Macia et al., that is, that Hog1 activation upon inhibition of Hog1 kinase activity is not due to releasing a negative feedback on upstream signalling, but rather due to an osmotic stress, induced by a drop in steady-state intracellular glycerol levels that can no longer be maintained.

Several recent studies support the notion that there are post-translational Hog1-mediated rapid negative feedback mechanisms within the signalling branches of the HOG pathway. Two studies demonstrated experimentally that phosphorylated Hog1 negatively regulates the Sho1 branch at different sites (Hao et al., 2007; Yamamoto et al., 2010), and Macia et al (2009).
proposed a rapid Hog1-mediated negative feedback within the Sln1 branch, which was indirectly supported by experimental data, but whose physical nature remains elusive. It should be noted that all three cited studies used different strains, and Macia et al. (2009), whose data we used to parameterise our models, did not propose a transient negative feedback in the Sho1 branch. Thus, it is still unclear whether there are Hog1-mediated post-translational feedbacks within both branches of the HOG pathway in the strain our data refers to (W303). Nevertheless, our model discrimination analysis shows that the data support the existence of such feedbacks. Opposed to Macia et al. (2009), we suggest that these transient feedbacks have only a minor role for adaptation per se, but rather serve to stabilise the response in terms of avoiding oscillatory behaviour, which may occur in delayed negative feedback systems. A similar effect was described before for models without transcriptional feedback (Tsai et al., 2008). Basically, fast transient feedbacks decrease the delay in the systems and thereby avoid oscillatory behaviour. The stabilisation effect in our model, however, seems to be stronger for the transient Hog1-mediated feedback on the glycerol production rather than for transient feedbacks on the signalling branches.

In contrast to the perfect adaptation in Hog1 nuclear localisation reported by Muzzey et al. (2009), Macia et al. (2009) reported elevated Hog1 activity after adaptation (Figures 2A and B, and 3A). As the model was fitted to the Macia et al. data and could explain these data well, it also implies a role for model components that were not observed during adaptation response. Thereby, the model provides a more complete picture of the system in case of imperfect adaptation. In the model, elevated Hog1 activity leads to higher steady-state glycerol production, which serves to maintain an increased glycerol gradient, which has to be actively maintained, at least in part, because Fps1 reopens after adaptation (Supplementary Figure S10).

Having, for the first time, a well-parameterised model that includes the two branches at hand, we pursued the hypothesis that the two branches render the system more robust to internal variations in cellular states and to molecular noise (Lestas et al., 2010). Indeed, a Monte–Carlo analysis using the best approximating model showed that the wild-type elicits a faster and more robust response to changes in parameters and initial conditions than the single-branch mutants. We could confirm by dedicated experiments that the wild-type cells indeed recover significantly faster than the single-branch mutants for low and intermediate osmotic shocks (0.1, 0.2 M NaCl). In addition, as evidenced by the interquartile ranges of the adaptation times, we could show that the single-branch mutants showed a significantly higher variability than the wild-type for the low osmotic shock of 0.1 M NaCl. For intermediate osmotic shock, the Sho1 branch seems to be more robust than both wild-type and Sln1 branch mutant, indicating other possible roles of Sho1 branch under this condition and the existence of additional processes, which are not considered by our model.

There are technical limitations to the precision with which the small changes in volume that occur in mild osmotic shocks can be measured. However, recovery of the wild type was up to 5 minutes faster than in the single-branch mutants, which constitutes more than 5% of the cell cycle time under good

![Figure 11](image-url) Volume adaptation simulations and measurements after 0.2 M NaCl osmotic shock. For the time series, shaded coloured regions indicate respective interquartile ranges. We show measured volume curves of one representative experiment, whereas adaptation times are pooled over five independent experiments (Table II). In the box plot, solid lines are median, dashed lines mean, boxes indicate the interquartile range, whiskers minimum and maximum, and point are outliers beyond upper quartile \( +1.5 \times \text{interquartile range} \). Source data is available for this figure in the Supplementary Information.
growth conditions. This advantage might be sufficient to evolutionary conserve two parallel redundant signalling branches. Besides the hypothesis that parallel signalling pathways have evolved to improve noise suppression, which is partly supported by this study, there are, of course, other possible explanations, which we did not investigate here. It is known that, for example, the Sho1 branch is also involved in the activation of the Fus3 and Kss1 MAP kinases, which regulate the response to pheromone and starvation, respectively. Therefore, it seems clear that possible noise suppression is not the sole reason for the existence of the Sho1 branch.

There are other reports on parallel signalling pathways that are activated by a single stimulus in eukaryotic systems. One example is the ERK MAP kinase cascade, which is activated at high doses of epidermal growth factor by both a phosphoinositide 3-kinase (PI3K)-dependent and a PI3K-independent pathway (Sampaio et al., 2008). Another example is NF-kB activation upon genotoxic stress. In this case, at least two partially redundant parallel signalling pathways, one PI3ASy dependent and another ATM dependent, converge on NEMO/IKK activation (McCool and Miyamoto, 2012). In these examples, stabilisation or acceleration of response time might be important. However, as in the HOG system, parallel signalling pathways probably serve additional purposes, for example, crosstalk to other connected signalling pathways.

This study also demonstrates the potential of an ensemble modelling approach in discriminating rivalling hypotheses. It may lead to biased conclusions, when only one favourite hypothesis is investigated. The inherent uncertainty about the molecular mechanisms underlying biological phenomena inevitably leads to alternative mathematical model formulations, which should all be challenged with available data (Schaber et al., 2009). In combination with a model discrimination analysis, this is a comprehensible way to find the hypothesis that is best supported by data. A model that is selected by this approach has more credibility than fitting and analysing one single model.

Materials and methods

Data

We made extensive use of published data to parameterise dynamic models of the HOG pathway. The core dataset used for model parameterisation and discrimination was taken from Macia et al. (2009), which was kindly provided by Sergi Regot in a digital version. This data set consists of time series of phosphorylated Hog1 under several hyper-osmotic shock conditions, for wild-type and different mutant yeast, for up to 2 h after hyper-osmotic shock (Figures 2A and B, and 3A). Only the Snl1 branch data for stimulation with 0.1, 0.4 and 0.6 M NaCl have been used before to parameterise mathematical models (Macia et al., 2009) (Figure 2A). The data in Figures 2D and E, and 3B, C and D were also taken from Macia et al. (2009), but digitised from the original figures therein. In addition, we used time series of mRNA, Gpd1 and glycerol published in Klipp et al. (2005) (Figure 2C). These data sets, although coming from different sources, were comparable, because they were produced using the same genetic background and under the same culture conditions. Initially, we did not have volume recovery data for these strains and conditions. Therefore, we generated artificial volume data using the observation that change in volume over time during adaptation to a hyper-osmotic shock mirrors Hog1 activation profile in wild-type yeast (Muzzey et al., 2009). We combined this idea with measured minimal volumes (the minimal volume to that a cell can shrink) for different conditions (Schaber et al., 2010) (Figure 2F).

Retrospectively, this approach is justified, because at a later stage of the project we did measure volume recovery for single cells for the same strain and under similar conditions (see Figures 10 and 11 and Supplementary Material). The artificial volume data lie within the interquartile range of the measured volumes for the initial phase of adaptation (there was no measurement for the shrinkage phase after shock). As the model does not include growth, the artificial and simulated volumes level off below 100% of the initial volume, whereas the measured volume surpasses the initial volume. Therefore, and in the light of the excellent predictive properties, we refrained from refitting all models including the measured volumes.

Model development and candidate models

Model development was guided by the principle of parsimony. In most published models of the HOG pathway that we are aware of and that have been fitted to data, the number of parameters exceeds the number of data points used to fit those parameters (Kuhn and Klipp, 2012). This leads to over-parameterised models with non-identifiable parameters. Over-parameterised models tend to show spurious effects and artefacts and may lead to wrong conclusions, especially concerning quantitative aspects (Burnham and Anderson, 2002; Schaber et al., 2011). Therefore, we aimed at a model that had substantially less parameters than data points.

Given an appropriate experimental design this increases the possibility of obtaining at least some identifiable parameters (Raue et al., 2009; Schaber and Klipp, 2011).

There are no data available on the dynamics of pathway components upstream of Hog1. This part of the model was, therefore, kept as simple as possible, basically only consisting of two different possibilities of how the MAPK kinase Pbs2 can be activated. First, it can be activated by direct phosphorylation through a volume-dependent signal, representing the Sln1 branch activation ($v_1$ in Figure 1), and, second, by volume-dependent binding to Sho1, representing scaffolding properties of the Sho1 branch ($v_3$ in Figure 1). Both the phosphorylated form of Pbs2 as well as the Sho1–Pbs2 complex are capable of double phosphorylating Hog1 independently of each other ($v_6$ and $v_7$ in Figure 1). For characterising processes downstream of Hog1, there were data available for mRNA, Gpd1 and glycerol, which were explicitly included in the model. The data for Gpd1 were also considered as a proxy for other Hog1-regulated proteins. Fps1 closure (by phosphorylation) was optionally dependent on volume, turgor or active Hog1 ($v_{12}$ and $v_{16}$ in Figure 1). As there was a report on Fps1 degradation and/or internalisation (Mollapour and Piper, 2007), we included two possible degradation mechanisms, one dependent on activated Hog1 and one dependent on some hypothetical protein induced by activated Hog1. A balancing reaction producing Fps1 was included as well (reactions $v_{13}$ and $v_{14}$ in Figure 1), because the model was assumed to be in steady state before stimulation. Internal and external osmotic pressures, turgor and volume dynamics were described with an established parameterised biophysical model (Klipp et al., 2005; Schaber and Klipp, 2008; Schaber et al., 2010).

According to our guiding principle of parsimony, not only the structure of the model but also the kinetic rate law formulations were kept as simple as possible, but as complex as necessary. In almost all rate laws, the most simple rate law, that is, mass-action kinetics, was sufficient. However, in the course of model development, we realised that assuming simple mass-action kinetics for reactions $v_9$ and $v_{13}$ could not explain the data well, making a more complex kinetic necessary. In these two reactions, we used a simple saturation kinetic, which gave good results, implying that saturation seems to be an important feature of these reactions. In the Supplementary Material, we describe a detailed derivation of such saturation kinetics (Alon, 2007). Owing to the lack of knowledge about a mechanism of how Hog1 may potentially modify glycerol synthesis, we used a simple heuristic approach. As this modifying influence of Hog1 turned out to be not significant for our results, we also tested more complex rate formulations for reactions $v_{13}$ for the three best approximating models (see Result section and Supplementary Tables S11 and S12). See Supplementary Tables S1–S8 for a detailed list of all reactions, their respective rationale and parameters. Figure 1 gives an overview of all reactions considered in the candidate models.
Several reactions and modifying influences in the model were left optional, reflecting uncertainty about the biological processes and representing different hypotheses. These are marked with dashed and dotted lines in Figure 1. Specifically, there were (i) four options for the transient feedback of Hog1-PP on the two branches (\(v_1\) and \(v_2\)); without, with both or with either one of the feedbacks; (ii) two options for glycerol production: only protein (Gpd1, 2) dependent or with additional stimulation by phosphorylated Hog1; (iii) two options for Fps1 closure (\(v_{15}\), putative phosphorylation); stimulated by a volume-dependent function (Fps1 activation) or inhibited by turgor; (iv) four options for Fps1 opening (\(v_{16}\)); without regulation (constitutive), inhibited by Hog1, stimulated by turgor or both; and (v) three options for degradation/internalisation of open Fps1 (\(v_{17}, v_{18}\)) stimulated by phosphorylated Hog1, protein-stimulated or without. The combination of these alternative model formulations resulted in 4\(^2\)\(2^2\)\(3 = 192\) different models.

We used a steady-state assumption valid before osmo-stress in order to reduce the number of free parameters. Starting point was the observation that Hog1 shows a basal (non-zero) steady-state activation (Figures 2A and B, and 3A). Therefore, at steady state, activation of these alternative model formulations resulted in a volume-dependent function (Fps1 activation) or inhibited by turgor; (iv) four options for Fps1 opening (\(v_{16}\)); without regulation (constitutive), inhibited by Hog1, stimulated by turgor or both; and (v) three options for degradation/internalisation of open Fps1 (\(v_{17}, v_{18}\)) stimulated by phosphorylated Hog1, protein-stimulated or without. The combination of these alternative model formulations resulted in 4\(^2\)\(2^2\)\(3 = 192\) different models.

The combination of these alternative model formulations resulted in 4\(^2\)\(2^2\)\(3 = 192\) different models.
Image processing with CellID and data analysis with RCell
To extract quantitative information from the images, we processed them with VCell-ID as previously described (Gordon et al, 2007; Chernomoretz et al, 2008) using the parameters max_dist_over_waist = 4.00, max_pixels_per_cell = 2000, min_pixels_per_cell = 400, background_reject_factor = 1.10 and standard parameters otherwise.
In order to select the image from the stack where cells are slightly out of focus, we used a simple observation. We noticed that the image corresponding to the in-focus slice had the minimum total pixel intensity of all slices in the stack. Therefore, we selected for VCell-ID processing the images that were three and four slices below the image with minimum pixel intensity. We analysed single-cell data extracted from VCell-ID using R (http://www.r-project.org) with Cell-ID-specific analysis package Rcell (http://cran.r-project.org/web/packages/Rcell/index.html). After quantification, we removed irregular shaped analysis package Rcell (http://cran.r-project.org/web/packages/Rcell/index.html). After quantification, we removed irregular shaped analysis package Rcell (http://cran.r-project.org/web/packages/Rcell/index.html). We thank Sergei Regov and Francesco Posas for supplying digital data versions of the data in Figures 2A, B, D and E, and 3A and B. We also thank Soheil Rastgou Talemi for digitising the data used in Supplementary Figure S2. This study was supported by the European Commission (QUASI (Contract No. 503230), CELLCOMPUT (Contract No. 043310) to EK), the German Ministry of Science and Education (BMBF projects 0135779 and 01DN12003 to JS), and the Argentine Ministry of Science and Productive Innovation (MYNCYT and Education (BMBF projects 0135779 and 01DN12003 to JS), and the German Ministry of Science (Contract No. 503230), CELLCOMPUT (Contract No. 043310) to EK), the German Ministry of Science (Contract No. 503230), CELLCOMPUT (Contract No. 043310) to EK), the German Ministry of Science (Contract No. 503230), CELLCOMPUT (Contract No. 043310) to EK), the German Ministry of Science (Contract No. 503230), CELLCOMPUT (Contract No. 043310) to EK)

Author contribution: JS designed and conducted the research, data analysis and modelling; RB and AB did single-cell volume measurements and conducted volume data analysis; and EK and ACL designed the research. JS, EK and AC-L wrote the paper.

Conflict of Interest
The authors declare that they have no conflict of interest.
