Cog3p depletion blocks vesicle-mediated Golgi retrograde trafficking in HeLa cells

The conserved oligomeric Golgi (COG) complex is an evolutionarily conserved multi-subunit protein complex that regulates membrane trafficking in eukaryotic cells. In this work we used short interfering RNA strategy to achieve an efficient knockdown (KD) of Cog3p in HeLa cells. For the first time, we have demonstrated that Cog3p depletion is accompanied by reduction in Cog1, 2, and 4 protein levels and by accumulation of COG complex-dependent (CCD) vesicles carrying v-SNAREs GS15 and GS28 and cis-Golgi glycoprotein GPP130. Some of these CCD vesicles appeared to be vesicular coat complex I (COPI) coated. A prolonged block in CCD vesicles tethering is accompanied by extensive fragmentation of the Golgi ribbon. Fragmented Golgi membranes maintained their juxtanuclear localization, cisternal organization and are competent for the anterograde trafficking of vesicular stomatitis virus G protein to the plasma membrane. In a contrast, Cog3p KD resulted in inhibition of retrograde trafficking of the Shiga toxin. Furthermore, the mammalian COG complex physically interacts with GS28 and COPI and specifically binds to isolated CCD vesicles.

Introduction

The Golgi apparatus is a hub for membrane trafficking pathways, organizing both the anterograde exocytic trafficking of newly synthesized proteins that travel from the ER to the plasma membrane and retrograde endocytic trafficking of cell surface molecules that travel back to the ER (for review see Shorter and Warren, 2002). COP I coat proteins function in intra-Golgi trafficking and in maintaining the normal structure of the Golgi complex (Duden, 2003). We and others have previously shown that the Golgi vesicular coat complex I (COPI)-modulated membrane trafficking used conserved oligomeric Golgi (COG) vesicle tethering complex (Ram et al., 2002; Suvorova et al., 2002; Oka et al., 2004).

COG complex consists of eight subunits (COG1-8; Kingsley et al., 1986; Whyte and Munro, 2001; Suvorova et al., 2001, 2002; Ram et al., 2002; Ungar et al., 2002). A COG role in Golgi membrane trafficking was suggested by biochemical and genetic studies in yeast (VanRheenen et al., 1998, 1999; Suvorova et al., 2002). Yeast COG complex interacts genetically and physically with Rab protein Ypt1p, intra-Golgi SNARE molecules, as well as with COPI (Suvorova et al., 2002).

Mutations in COG subunits disturb both structure and function of the Golgi in eukaryotic cells (Podos et al., 1994; Ram et al., 2002; Suvorova et al., 2002; Ungar et al., 2002; Farkas et al., 2003), but the exact cellular function of the COG complex remained elusive. It was recently shown that mammalian cells that carried either deletion of COG1 and 2 or truncated version of Cog7p are defective in Golgi glycosylation (Wu et al., 2004) and maintain slightly dilated Golgi cisternae with reduced levels of resident proteins GS15 and GS28 and GPP130 (Oka et al., 2004). These mutant phenotypes may reflect either the primary COG malfunction or secondary manifestations that occur in cells after a prolonged adaptation period. Deletion of either COG1 or COG2 in yeast cells is virtually incompatible with membrane trafficking and normal cell growth (VanRheenen et al., 1998; Ram et al., 2002), whereas ΔCOG1 and ΔCOG2 CHO cells are not compromised in growth or protein secretion. One possibility is that the primary COG deletion phenotype in these cells is masked and/or suppressed by secondary mutations in cell genome. To better understand the initial defects associated with the COG complex malfunction it is important to acutely interfere with its activity. Transfection with small interfering RNAs (siRNAs) and microinjection with inhibitory antibodies are two efficient methods for acute protein knockdown (KD) in mammalian cells.

We rationalized that the most evolutionarily conserved COG subunit would be the best candidate for the KD. Yeast and mammalian Cog1 and Cog2 proteins do not share significant
similarities, whereas the protein sequence of yeast Cog3p is 41% similar to mammalian Cog3p (Suvorova et al., 2001). In this work, we used siRNA strategy for the efficient KD Cog3p in HeLa cells. Cog3p depletion is accompanied by reduction in Cog1, 2, and 4 protein levels and rapid accumulation of intracellular vesicles carrying v-SNAREs GS15 and GS28 and cis-Golgi glycoprotein GPP130. A prolonged COG3 KD induced extensive Golgi fragmentation. Fragmented Golgi membranes were deficient in retrograde trafficking of the Shiga toxin. Native immunoprecipitations (IPs) revealed that the COG complex physically interacts with Golgi SNARE molecules and COPI and specifically binds to isolated GPP130-containing vesicles in vitro. For the first time, we have demonstrated that the acute depletion of the mammalian COG complex results in specific inhibition of tethering of retrograde vesicles and that the efficient targeting of these vesicles is essential for the maintenance of the Golgi structure.

Results

**Cog3p KD induces Golgi fragmentation**

To interfere with the COG complex function in HeLa cells we depleted Cog3p by using RNA interference technique (Elbashir et al., 2001). Three different COG3-specific RNA duplexes were tested initially and one of them (sense, AGACUUGUG-CAGUUUAACA) efficiently induced reduction of the Cog3 protein level (Fig. 1 A). The expression of other lobe A COG subunits Cog1p, Cog2p, and Cog4p was also reduced 72 h after COG3 KD, whereas protein level of the lobe B Cog5-8p subunits remained unchanged. Similarly, cellular levels were unchanged for other tested cell proteins: protein disulphide isomerase (PDI), actin, GS28, syntaxin 5, GPP130, and p115 (Fig. 1 and unpublished data). Cell transfection with a nonspecific siRNA did not change the levels of COG subunits expression (unpublished data).

Because the level of the lobe B COG subunits was not affected by the Cog3p depletion we have determined their intracellular localization by both immunofluorescence (IF) and Western blot (WB) assays. We have found that significant amounts of both Cog5p and Cog8p were still associated with the membrane fraction (Fig. 1 B). IF analysis of COG3 KD cells revealed that Cog6p (Fig. 1 C) and other lobe B subunits (unpublished data) were localized on large structures in juxta-nuclear region that were colocalized with resident Golgi enzyme GFP-tagged β1,4-galactosyltransferase (GalT-GFP; Fig. 1 C). Detailed analysis of COG3 KD cells revealed that Cog6p (Fig. 1 C) and other lobe B subunits (unpublished data) were localized on large structures in juxta-nuclear region that were colocalized with resident Golgi enzyme GFP-tagged β1,4-galactosyltransferase (GalT-GFP; Fig. 1 C). Detailed analysis of COG3 KD cells revealed that GallT-GFP and a Golgi tethering factor GM130 were found on fragmented Golgi membranes (Fig. 2).

To test the specificity of COG3 siRNA KD, we took advantage of the fact that human and mouse Cog3 proteins show 95% identity and, therefore, most likely would functionally substitute each other. In the same time, human and mouse COG3 siRNA target region share only 74% of homology with five miss-matched nucleotides (Fig. 3 A) and this difference can be used in gene-replacement siRNA experiments (Puthenveedu and Linstedt, 2004). In good agreement with our prediction, in HeLa cells, that were cotransfected with both hCOG3 siRNA and the plasmid that expressed mouse Cog3p,
the Golgi fragmentation was completely or partially prevented (Fig. 3B). Similar results were obtained when cells were transfected with mCOG3-containing vector 24 h after hCOG3 siRNA transfection (unpublished data). We concluded that the COG3 KD is specific and that the Cog3p depletion directly induces a reversible Golgi fragmentation.

To independently confirm an essential role for the COG complex in Golgi structure maintenance, we used affinity-purified antibodies against Cog3p (Suvorova et al., 2001). These antibodies were previously used for both IF and IP of the endogenous COG complex in mammalian cells (Suvorova et al., 2001; Ungar et al., 2002). We rationalized that upon microinjection into cells anti-Cog3p IgGs would specifically bind to the Cog3p and interfere with the COG complex function. Indeed, we have observed that 4 h after the antibodies microinjection the Golgi ribbon structure was converted into multiple mostly juxtanuclear localized small fragments (Fig. 4). This Golgi phenotype was persistent for up to 20 h after antibody microinjection without any visible signs of cell death. Microinjection with control antibodies did not change the morphology of the Golgi (unpublished data). We have concluded that anti-Cog3p antibodies like the COG3 siRNA act by blocking Cog3p function, which is necessary for the Golgi structure maintenance.

**Loss of Cog3p expression results in accumulation of Golgi v-SNAREs and cis-Golgi resident protein GPP130 in nontethered vesicles**

Detailed IF analysis of different Golgi resident proteins in COG3 KD cells revealed that the majority of integral and peripheral membrane Golgi proteins, including cis-Golgi tethering factors p115 (Nelson et al., 1998) and GM130 (Nakamura et al., 1995), cis-Golgi t-SNARE syntaxin 5 (Hay et al., 1998), cis/medial Golgi tethering protein giantin (Linstedt and Hauri, 1993), and trans-Golgi tether p230 (Brown et al., 2001), were present almost exclusively on relatively large (1–3 μm in size) fragmented Golgi membranes (Fig. 5A; unpublished data).
Surprisingly, we have found that a subset of Golgi proteins, intra-Golgi v-SNAREs GS15 (Xu et al., 2002) and GS28 (Hay et al., 1998), and cis-Golgi phosphoprotein GPP130 (Linstedt et al., 1997) were localized preferentially to multiple small vesicle-like structures distributed throughout the cytoplasm of COG3 KD cells (Fig. 5 B). In control cells all these three proteins were primarily localized to a juxtanuclear Golgi.

Small GPP130-positive structures in COG3 KD cells presumably represent nontethered vesicles, because, in cells permeabilized with the mild detergent digitonin, these structures were efficiently washed away from cells, whereas large Golgi cisternae remained inside the cells (Fig. 6 A). Similar digitonin sensitivity was previously observed for Golgi-derived vesicles that are transiently accumulated during mitosis (Jesch and Linstedt, 1998).

To verify our IF findings we performed a subcellular fractionation of both COG3 KD and mock-treated HeLa cells (Fig. 6 B). We have found that in COG3 KD cells >50% of both GPP130 and GS28 proteins are present in a 10K supernatant, whereas in lysates obtained from control cells these proteins are almost exclusively cofractionated with large membranes. Noticeably, the long syntaxin 5 isoform and the ER resident protein PDI did not significantly change their subcellular distribution in a COG3 KD cells.

To characterize membranes in 10K supernatant we have first used gel-filtration analysis on a Sephacryl S-1000 column (Fig. 6 C). This analysis revealed that in COG3 KD cells the peak of GPP130 was eluted in fractions 11 and 12, whereas in control cells GPP130 was mostly found in fractions 9 and 10. We have concluded that in COG3 KD cells the GPP130 was mostly associated with small vesicles.

To test GPP130 localization by another separation technique we used a glycerol velocity gradient. Post-nuclear supernatant (PNS) from COG3 KD cells was loaded on 10–30% glycerol gradient and membranes were separated by size (Fig. 6 D). WB analysis of collected fractions revealed that majority of GPP130 signal was peaked in a vesicular fraction 3, whereas large ER membranes (PDI lane) were concentrated at the bottom of the gradient. A small fraction (~25%) of GPP130 was also found at the bottom of the gradient and may represent a fraction of the protein that was associated with large Golgi fragments or vesicle aggregates. Because these vesicles were accumulated as a result of Cog3p depletion, we have named them a COG complex-dependent (CCD) vesicles. GPP130-containing Golgi membranes from identically fractionated control cells were rapidly pelleted to the bottom of the glycerol gradient (Jesch and Linstedt, 1998; unpublished data).

GPP130 is a heavily glycosylated cis-Golgi protein (Linstedt et al., 1997) that cycles through trans-Golgi and endosomal compartments (Puri et al., 2002) and rapidly degrades in...
both ΔCOGI and ΔCOG2 CHO cell lines (Oka et al., 2004). We have found that both the protein level and the electrophoretic mobility of GPP130 were identical in both control and COG3-KD cells. Therefore, it can be concluded that in HeLa cells acute Cog3p depletion did not, at least initially, result in GPP130 down-regulation and did not alter its glycosylation.

To further analyze the content of CCD vesicles we prepared lysates from COG3 KD and control cells that stably express GFP-tagged N-acetylgalactosaminyltansferase-2 (GalNAc-T2). Both lysates were subjected to glycerol velocity gradient centrifugation, membranes from vesicle peak fractions 3 and 4 were concentrated and relative concentrations of Golgi and ER proteins were assessed by WB (Fig. 6 E). In an agreement with our IF data, we have found that in COG3 KD cells the amount of GPP130 in the CCD vesicle pool was increased by approximately fourfold. The concentrations of two other Golgi proteins, GS28 and GalNAc-T2-GFP were also increased by approximately twofold, whereas the amount of ER marker PDI remained unchanged. Small but detectable amounts of GPP130, GS28, and GalNAc-T2 in vesicular fractions prepared from control cells may represent a constitutive pool of recycling vesicles.

We also tested whether accumulated CCD vesicles could be recognized by the COG complex in vitro. The COG complex was purified from HeLa cells that transiently express YFP-Cog3p (Suvorova et al., 2001). Protein G–Agarose beads loaded with the COG complex were incubated with PNS fraction obtained from the COG3 KD cells. As a positive control for vesicle binding we used beads loaded with anti-GS15 antibodies and as a negative control for nonspecific binding we used protein G–Agarose beads. As expected, anti-GS15 beads efficiently pulled down GPP130-containing (Fig. 6 F, GS15 lane) and GS28-containing (unpublished data) vesicles. Importantly, the COG beads were also capable to precipitate GPP130-containing CCD vesicles (Fig. 6 F, compare lanes COG and control). We have concluded that CCD vesicles may directly bind to the COG complex and this interaction may be a first step in vesicle tethering to the cis-Golgi.

Results of the subcellular fractionation experiments confirmed the IF data that showed accumulation of CCD vesicles in COG3 KD cells. It also raised an intriguing possibility that not only recycling SNARE proteins and GPP130, but also Golgi resident proteins like GalNAc-T2 may recycle in the COG complex-dependent manner. To test this hypothesis, we used HeLa cells that stably express VSVG-tagged GalNAc-T2. It was shown previously that unlike the GFP-tag the small VSV-tag does not interfere with the GalNAc-T2 folding, function and localization (Storrie et al., 1998). Double IF labeling experiments revealed that the vesicular pool of GalNAc-T2-VSV increased significantly in COG3 KD cells (Fig. 6 G).

In the same time, vesiculization of GalNAc-T2–containing Golgi region was not as dramatic as for GPP130-containing membranes and only a few vesicular profiles were double labeled with both Golgi markers. This may reflect different kinetics of GPP130 and GalNAc-T2 recycling as well as a possibility that different Golgi proteins may cycle in different membrane carries.

Does accumulation of CCD vesicles occur before or after COG3 KD-induced Golgi fragmentation? To answer this question we analyzed COG3 KD cells every 12 h after the initial COG3 siRNA transfection. We have found that 48 h after transfection both GS15 (Fig. 7) and GPP130 (unpublished data) were mostly found in CCD vesicles, whereas overall Golgi structure labeled with GalT-GFP has not yet been disturbed in a subpopulation of the COG3 KD cells. These data support the idea that accumulation of CCD vesicles may occur independently and before the Golgi fragmentation.

**Fragmented Golgi membranes are capable in supporting anterograde but not retrograde protein trafficking**

Although siRNA-induced COG3 KD induced both accumulation of CCD vesicles and Golgi fragmentation, cells were able to multiply and their growth rate was not severely affected (unpublished data). Moreover, fragmented Golgi membranes maintained their juxtanuclear localization (Fig. 5 A). Detailed IF analysis revealed that cis-Golgi p115 (Nelson et al., 1998), and the medial Golgi GalNAc-T2 (Storrie et al., 1998), maintained their overlapping but distinct distribution on both control Golgi ribbon-like structure and Golgi fragments in COG3 KD cells (Fig. 8 A, GalNAcT2/p115 frames). Similarly, localization of two medial Golgi proteins GalNAcT2 and giantin (Linstedt and Hauri, 1993) almost completely overlapped in both control and COG3 KD-treated cells (Fig. 8 A, GalNAcT2/Giantin frames). And finally trans-Golgi localized p230 (Brown et al., 2001) maintained its relative localization in COG3 KD cells (Fig. 8 A, GalNAcT2/p230 frames). We concluded that Cog3p KD resulted in Golgi fragmentation into multiple mini-Golgi stacks.

To confirm this conclusion the EM analysis of control and COG3 KD cells (Fig. 8) was performed. We found that in COG3 KD cells Golgi ribbon was disrupted onto multiple fragments, comprising three to four stacked cisternae (Fig. 8 B, ii). In addition to the Golgi fragments, a large number of ~60-nm vesicles were observed in COG3 KD cells (Fig. 8 B, iii). Thus, Cog3p depletion leads to both vesiculization of Golgi and break up of the ribbon to multiple mini-stacks.

To test whether these Golgi mini-stacks can support two basic Golgi functions, anterograde and retrograde proteins flow, we used GFP-tagged vesicular stomatitis virus G protein (VSVG) as a cargo marker for anterograde protein trafficking (Suvorova et al., 2001) and Cy3-labeled subunit B of the Shiga toxin (STB-Cy3) as a marker for the retrograde trafficking (Johannes et al., 1997).

2 d after siRNA treatment both control and COG3 KD cells were transfected with the vector that directs synthesis of the temperature-sensitive VSVG-GFP protein (Beckers et al., 1987). VSVG was accumulated in the ER for 16 h at the restrictive temperature (39.5°C). After that cells were transferred to the permissive temperature (32°C) to allow VSVG to travel toward plasma membrane and fixed 2 h later. This time frame is sufficient for VSVG delivery from the ER to PM in HeLa cells (Suvorova et al., 2001). Indeed, we have observed that the majority of both control and COG3 KD cells accumulated sig-
Figure 6. Characterization of CCD vesicles. (A) Apparent release of GPP130-containing vesicles upon digitonin permeabilization. Control or COG3 KD cells were either treated with buffer (−digitonin) or treated with 0.04 mg/ml digitonin, fixed, and analyzed by IF. Note that disperse vesicle-like staining of GPP130 in COG3 KD cells was eliminated after digitonin treatment. Bars, 10 μm. (B) WB analysis of total cell lysates and subcellular fractions prepared from COG3 KD and mock-treated HeLa cells. Cell lysates were fractionated on heavy membranes (P10) and light vesicle-containing fraction (S10). Equal amount of protein (10 μg) was loaded per lane and analyzed by WB with antibodies to GPP130, GS28, syntaxin 5, and PDI. A portion of marker proteins that was found in a vesicular fraction (n = 2) was determined by semi-quantitative WB. (C) Separation of GPP130-containing membranes by gel filtration. PNS from both control and COG3 KD cells was loaded on a Sephacryl S-1,000 column; 0.5-ml fractions were collected and analyzed by WB.
significant amounts of VSVG on the cell surface (Fig. 8 C, merged images, arrowheads). Some VSVG was also found on GS28-positive Golgi membranes in control cells and on Golgi fragments in COG3 KD cells. In COG3 KD cells the major pool of GS28 was localized on VSVG-negative CCD vesicles (Fig. 8 C, inset).

Detailed analysis of >200 VSVG-GFP-positive cells revealed some minor trafficking defects and/or kinetic delays in the ER-PM delivery of VSVG in COG3 KD cells (Fig. 8 D). Significantly, more cells in a control group demonstrated complete delivery of VSVG to the plasma membrane (22% vs. 6% in COG3 KD cells) and twice as many cells in the COG3 KD group accumulated VSVG in the ER (16% vs. 7% in COG3 KD cells). Nevertheless, because the absolute majority (84%) of the COG3 KD cells were able to deliver at least some VSVG molecules to the cell surface, we concluded that fragmented Golgi is, at least partially, competent to support anterograde protein trafficking. This result is in agreement with previous findings (Ram et al., 2002; Suvorova et al., 2002; Bruinsma et al., 2004) that demonstrate the COG complex defects in yeast cells do not interfere directly with the anterograde protein trafficking.

To investigate if Cog3p-depleted Golgi mini-stacks can function in retrograde plasma membrane to ER protein trafficking we have analyzed STB-Cy3 trafficking by using fluorescent live cell microscopy. In agreement with the data obtained in many different labs (Sandvig et al., 1994; Johannes et al., 1997) STB was rapidly internalized. In the majority of control cells STB signal was detected in a juxtanuclear region 2 h after beginning of initial internalization (Fig. 8 E). In control cells 12 h later STB was entirely distributed between the ER and the Golgi cisternae, marked by GalNAc-T2-GFP, (Fig. 8 F, control row). In the COG3 KD cells, even at the 12 h time point, the majority of internalized STB was localized in punctate structures on cell periphery (Fig. 8 F, COG3 KD row). Some STB was detected in a perinuclear region of transfected cells but these STB-labeled membrane structures were clearly distinct from the GalNAc-T2-GFP–containing Golgi fragments. None of the STB was detected in the ER of COG3 KD cells (Fig. 8, E and F, ER frames) indicating that retrograde trafficking through the Cog3p-depleted Golgi was blocked.

**COG complex physically interacts with the Golgi SNARE molecules and the COP I vesicular coat**

We have previously demonstrated that the yeast COG complex regulates intra-Golgi retrograde trafficking and interacts with the essential components of core machinery of vesicular Golgi traffic, i.e., intra-Golgi SNARE proteins and COPI vesicular coat (Suvorova et al., 2002). To test if the mammalian COG complex may also interact with both SNARE and COPI components, we isolated Golgi from the rat liver and performed an IP of the COG complex, v-SNARE GS28, and PDI from detergent-solubilized membranes. WB analysis of coIP proteins revealed that both GS28 (~5% from total) and small amounts of t-SNARE Syntaxin5 were coprecipitated with the Cog3p (Fig. 9 A, lane 1; unpublished data). It was previously shown that Syntaxin5 and GS28 form a Golgi-localized SNARE complex (Hay et al., 1997) and our findings suggest that the COG complex can interact with either individual SNARE proteins or with the entire SNARE core complex. In the reciprocal precipitation, Cog3p was coIP by anti-GS28 antibodies (Fig. 9 A, lane 4). Neither Cog3p nor the Golgi SNARE molecules were precipitated with control beads (Fig. 9 A, lane 3). We have also determined that the β subunit of the COPI coat was specifically precipitated with anti-Cog3p antibodies (Fig. 9 B, lane 2). These results indicated that the mammalian COG complex like its yeast homologue

could physically interact with both vesicular and Golgi-localized components of membrane transport machinery.

IF experiments indicated that CCD vesicles are distinct from both ER (Fig. 9 D) and early endosomes (Fig. 9 E). To test whether CCD vesicles are COPI-coated we performed double-IF in COG3 KD VSVG-GFP expressing cells (Fig. 9 C). A number of vesicle profiles were labeled with CCD vesicle marker GS15 and some were colabeled with antibodies against the epsilon subunit of COPI coat (Fig. 9 C, inset, arrowheads). In contrast, VSVG was colocalized with the GS15 only on a fragmented Golgi membrane (Fig. 9 C, inset, membranes marked with an asterisk). These data indicated that CCD vesicles do not carry anterograde cargo molecules and most likely represent COPI-coated retrograde intra-Golgi vesicles that bud from distal Golgi compartments and subsequently tether to the cis-Golgi in a COG complex-dependent manner.

Discussion

Although both genetic and biochemical analysis indicated that the COG complex primarily regulates retrograde intra-Golgi membrane trafficking in budding yeast (Ram et al., 2002; Suvorova et al., 2002), the cellular role of the mammalian COG complex is less clear. COG has been implicated in the anterograde intra-Golgi trafficking (Walter et al., 1998), ER to Golgi protein delivery (Loh and Hong, 2002), glycoconjugate synthesis, intracellular protein sorting, and protein secretion (Kingsley et al., 1986; Chatterton et al., 1999; Wu et al., 2004). The most evolutionary conserved COG subunits bear 21–23% identity between yeasts and humans (Whyte and Munro, 2002). Therefore, it is hard to make any functional predictions that are simply based on protein similarities.

In this study, we report that the acute depletion of the Cog3p subunit of the human COG complex results in accumulation of nontethered transport vesicles, dramatic changes in overall Golgi structure and block of Shiga toxin retrograde trafficking. We have also obtained microscopic evidences that in COG3 KD cells the fragmented Golgi maintains its cisternal organization and that these Golgi mini-stacks are capable, at least partially, to support anterograde protein delivery from the ER to the plasma membrane. Finally, our data suggest that the COG complex can directly interact with the CCD retrograde vesicles via binding to both vesicular COPI coat and integral components of vesicular SNARE machinery.

The COG3 KD differentially influences the protein level of other COG subunits. Although the level of Cog1p, Cog2p, and Cog4p is reduced more than twofold, the expression of the other four subunits is not affected. Moreover Cog5-8p continue to localize properly to membranes in a juxtanuclear region. These data support our original model proposing two-lobed COG complex structure (Ungar et al., 2002; Loh and Hong, 2004) and suggests that Lobe B (COGs 5–8) may be attached to the Golgi membrane by its own receptor.

COG3 KD-induced Golgi fragmentation is specific and reversible because either simultaneous or subsequent introduction of the mouse siRNA-insensitive version of the Cog3p is able to restore a wild-type Golgi appearance. We have also demonstrated that the disruption of the Golgi structure is observed in cells microinjected with anti-Cog3p IgGs. The most likely explanation of this phenomenon is that the antibody microinjection induces the proteolytic degradation of the Cog3p similarly to the recently described antibody-induced degradation of the Golgi tethering factor p115 (Puthenveedu and Linstedt, 2001).

Observed Golgi fragmentation phenotype induced by the COG3 KD is distinct from the Golgi appearance in ΔCOG1 and ΔCOG2 CHO cells (Ungar et al., 2002) and indicate that the acute COG3 KD, at least transiently, disrupts normal structural organization of the Golgi complex. In the majority of COG3 KD cells fragmented Golgi membranes retain their juxtanuclear localization and their cisternal organization appear to be normal both at the light microscopy and the EM levels. The Golgi mini-stacks are capable to carry out a plasma membrane delivery of VSVG, though with reduced efficiency compared with a normal Golgi apparatus. This observation sharply differs from the effect of p115 KD on VSVG trafficking (Puthenveedu and Linstedt, 2004); it may reflect different roles of two cis-Golgi localized tethering factors in membrane trafficking. Moreover, in COG3 KD cells p115 is properly expressed (unpublished data) and its localization on the Golgi membranes is virtually undisturbed. Only a small fraction of the COG3 KD cells accumulates VSVG in the ER. These results agree with our previous data that yeast COG mutants do not show any primary anterograde trafficking defects (Suvorova et al., 2002) and that protein secretion in both ΔCOG1 and ΔCOG2 CHO cells is not compromised (Kingsley et al., 1986).

Specific vesicle accumulation is a most striking phenotype observed after the COG3 KD. These CCD vesicles seem to carry at least two different Golgi SNARE molecules, GS15 and GS28, and GPP130, a 130-kD, cis-Golgi protein that continuously cycle between the early Golgi and distal compartments (Linstedt et al., 1997). Significantly, it has been shown that these proteins are rapidly degraded in both ΔCOG1 and ΔCOG2 CHO cells (Oka et al., 2004). The most likely explanation is that after the acute COG3 KD, all three markers are...
transiently accumulated in nontethered recycling vesicles that are rapidly degraded. We have found that 90 h after COG3 KD the protein level of both GPP130 and GS28 was decreased (unpublished data). A number of Golgi resident proteins, including MG160 (Johnston et al., 1994), GP73 (Puri et al., 2002), GlcNAc T-1, and α-1,2 mannosidase II (Opat et al., 2001a,b) are shown to cycle through the trans-Golgi region. The prediction is that in COG3 KD cells all these proteins will, at least transiently, be accumulated in CCD vesicles.

What is the origin of CCD vesicles? IF data indicated that the major pool of CCD vesicle is clearly distinct from both ER and early endosomes. Some of CCD vesicles are likely to originate from the trans-Golgi because both GS28 and GS15 are SNARE molecules that function in the intra-Golgi trafficking (Xu et al., 2002; Volchuk et al., 2004). Alternatively, some CCD vesicles could originate from TGN/sorting endosomal/recycling compartments. GPP130 was shown to cycle through the trans-Golgi/early endosomal membranes (Linstedt et al., 1997) and both GS28 and GS15 could participate in the early endosomal SNARE complex (Tai et al., 2004). Current models of Golgi trafficking involving cisternal maturation (Pelham, 2001) predict that all Golgi residents move down the stack to the late Golgi. Indeed, a number of cis-Golgi residents in both yeast (Harris and Waters, 1996) and mammalian cells (Johnston et al., 1994; Bachert et al., 2001; Opat et al., 2001a) have been shown to rapidly acquire specific modifications of the late Golgi. The rapid rate of trans-Golgi modifications (Opat et al., 2001a) and relatively slow rate of the recycling through the ER (Miles et al., 2001) suggest that cis- and medial-Golgi resident proteins are recycled directly from the trans-Golgi and/or TGN to the corresponding early Golgi compartment. The COG complex localizes on cis/medial Golgi membranes (Suvorova et al., 2001; Ungar et al., 2002) and most likely regulates recycling of different resident Golgi proteins. We and others have shown that mutations in yCOG3 resulted in abnormal Golgi recycling of yeast Golgi proteins Sec22p and Och1p (Suvorova et al., 2002; Bruinsma et al., 2004).
Materials and methods

CCD carriers are most likely to be formed in a COPI-dependent reaction. COPI vesicles bud from all Golgi cisternae and COPI is required for intra-Golgi transport in vitro (Orci et al., 1997). In the in vitro assay, Golgi resident proteins mannose II and GS28, were found to be concentrated in COPI vesicles (Lanoix et al., 1999, 2001), and these transport intermediates were able to fuse with cis-Golgi compartment (Love et al., 1998). The COG complex is a good candidate to orchestrate COPI vesicle tethering. Indeed, genetic and biochemical connections between yeast COG and COPI complexes (Ram et al., 2002; Suvorova et al., 2002) have been shown. Oka et al. (2004) reported recently that synthetic phenotypes arose in mutants deficient in both epsilon-COPI and either COG1 or COG2. During the investigation, we have found significant accumulation of COPI-positive vesicular profiles in COG3 KD cells (unpublished data) and demonstrated that some of these vesicles are double-labeled with the CCD vesicle cargo GS15. Finally we have shown that the COG complex binds to CCD vesicles in vitro and could be coIP with the β-COPI.

In conclusion we propose a model (Fig. 10) in which the cis-Golgi localized COG complex acts as a tether for retrograde COPI coated CCD vesicles that originate from distal trans-Golgi/endoosomal compartments. The acute COG3 KD and corresponding defects in the Lobe A of the COG complex discontinue normal vesicle recycling. Non-tethered vesicles are transiently accumulated in cell cytoplasm as membrane-depleted Golgi ribbon is fragmented in multiple Golgi mini-stacks. Detailed biochemical analysis of CCD vesicles and the elucidation of exact roles of both lobes of the COG complex should help in our understanding of mechanisms of Golgi maintenance and function.

Reagents and antibodies

Most laboratory reagents were purchased from Sigma-Aldrich. Antibodies used for WB and IF studies were obtained from standard commercial sources and as gifts from generous individual investigators or generated by us (see below). Antibodies (and their dilutions) were as follows: rabbit pAbs: anti-Cog1 (Ungar et al., 2002), anti-Cog2p (Podos et al., 1994; Ungar et al., 2002), anti-Cog3p (Suvorova et al., 2001), anti-Cog4p (Ungar et al., 2002), anti-Cog5p (Walter et al., 1998), anti-Cog6p, anti-Cog7p, anti-Cog8p (Ungar et al., 2002), anti-GPP130 (Covance), anti-GM130 (BD Biosciences), anti–GS-28 (BD Biosciences), anti–GS15 (BD Biosciences), mAbs: anti-GPP130 (A1-118; a gift from A. Linstedt), anti-GM130 (BD Biosciences), anti–p230 (BD Biosciences), and anti–PDI (Affinity BioReagents).

For analysis of anterograde transports both COG3 KD and mock-treated HeLa cells 60 h after siRNA treatment were transfected with a vector that encoded VSVGtso45-GFP protein and were kept at the 39.5°C. Cells were plated in 24-well dishes, grown to a confluency of ~70%, transfected with siRNA for 24–72 h, and lysed in the SDS-PAGE sample buffer.

For analysis of retrograde transport Cy3- Shiga toxin B subunit (STB-Cy3; Mallard et al., 1998) was used. STB-Cy3 was a gift from B. Storrie. 60 h after the start of COG3 KD HeLa cells that stably express the Golgi markers GalT-GFP or GalTAct2-GFP were incubated with STB-Cy3 for 30 min at 4°C, washed, refueled with fresh DME medium without phenol red, and incubated for 2 or 12 h at 37°C and 5% CO2 in a humidified chamber. ER was visualized with the ER-Tracker blue-white PDX (Molecular Probes). Images were obtained as described above.

EM

Cells were fixed with 3% glutaraldehyde in PBS for 2 h at 4°C. Cells were washed three times with PBS, fixed with 2% OsO4 in PBS, washed again, and mCOG3 sequence was verified by sequencing. Transfections were performed using TransIT-HelaMONSTER Kit (Mirus Corporation).

RNA interference experiment

Human COG3 was targeted with a siRNA duplex (target sense, AGACTTGTCAGTGTAAAC), siRNAs were obtained as purified duplexes obtained from Dharmacon Research. Transfection was performed using Oligolectamine (Invitrogen) following the protocol recommended by Invitrogen. For WB, cells were plated in 24-well dishes, grown to a confluency of ~70%, transfected with siRNA for 24–72 h, and lysed in the SDS-PAGE sample buffer.

Live cell fluorescence microscopy

For live cell fluorescence microscopy, cells were cultured in Lab-Tek Chambered Coverglass System (Nalge Nunc). Cells were maintained on the stage of a microscope at RT in DME/F12 without phenol red and sodium pyruvate (Invitrogen).

For analysis of anterograde transports both COG3 KD and mock-treated HeLa cells 60 h after siRNA treatment were transfected with a vector that encoded VSVGtso45-GFP protein and were kept at the 39.5°C for 16 h (Suvorova et al., 2001). After that the temperature was reduced to permissive one (32°C) to allow the VSVG to travel toward the plasma membrane. After 2 h of chase, cells were fixed and stained for GS28.

For analysis of retrograde transport Cy3- Shiga toxin B subunit (STB-Cy3; Mallard et al., 1998) was used. STB-Cy3 was a gift from B. Storrie. 60 h after the start of COG3 KD HeLa cells that stably express the Golgi markers GalT-GFP or GalTAct2-GFP were incubated with STB-Cy3 for 30 min at 4°C, washed, refueled with fresh DME medium without phenol red, and incubated for 2 or 12 h at 37°C and 5% CO2 in a humidified chamber. For analysis of anterograde transports both COG3 KD and mock-treated HeLa cells 60 h after siRNA treatment were transfected with a vector that encoded VSVGtso45-GFP protein and were kept at the 39.5°C for 16 h (Suvorova et al., 2001). After that the temperature was reduced to permissive one (32°C) to allow the VSVG to travel toward the plasma membrane. After 2 h of chase, cells were fixed and stained for GS28.

For analysis of retrograde transport Cy3- Shiga toxin B subunit (STB-Cy3; Mallard et al., 1998) was used. STB-Cy3 was a gift from B. Storrie. 60 h after the start of COG3 KD HeLa cells that stably express the Golgi markers GalT-GFP or GalTAct2-GFP were incubated with STB-Cy3 for 30 min at 4°C, washed, refueled with fresh DME medium without phenol red, and incubated for 2 or 12 h at 37°C and 5% CO2 in a humidified chamber. Materials and methods

Reagents and antibodies

Most laboratory reagents were purchased from Sigma-Aldrich. Antibodies used for WB and IF studies were obtained from standard commercial sources and as gifts from generous individual investigators or generated by us (see below). Antibodies (and their dilutions) were as follows: rabbit pAbs: anti-Cog1 (Ungar et al., 2002), anti-Cog2p (Podos et al., 1994; Ungar et al., 2002), anti-Cog3p (Suvorova et al., 2001), anti-Cog4p (Ungar et al., 2002), anti-Cog5p (Walter et al., 1998), anti-Cog6p, anti-Cog7p, anti-Cog8p (Ungar et al., 2002), anti-GPP130 (Covance), anti-giantin (a gift from A.D. Linstedt, Carnegie Mellon University, Pittsburgh, PA), anti-p115 (a gift from M.G. Waters, Merck Research Laboratories, Rahway, NJ), anti-ε-COP (a gift from R. Dudden, Royal Holloway University of London, Egham, Surrey), rabbit pAb and monoclonal (18C8) anti-synaptin 5 (a gift from J. Hay, University of Michigan, Ann Arbor, MI), anti-β-COP (Sigma-Aldrich), anti-VSVG tag (E11; Delta Biosabs); murine mAbs: anti-GPP130 (A1-118; a gift from A. Linstedt), anti-GM130 (BD Biosciences), anti-GS-28 (BD Biosciences), anti-GS15 (BD Biosciences), anti-p230 (BD Biosciences), and anti-PDI (Affinity BioReagents).

Mammalian cell culture, plasmids, and transfection

Monolayer HeLa cells were cultured in DME/F-12 media supplemented with 15 mM Hepes, 2.5 mM L-glutamine, 5% FBS, 100 U/ml penicillin G, 100 μg/ml streptomycin, and 0.25 μg/ml amphotericin B. Cells were grown at 37°C and 5% CO2, in a humidified chamber. HeLa cells that stably expressed Gα1α-N17 fused to GFP or to a VSVG-tag and GalT fused to GFP were provided by B. Storrie (University of Arkansas for Medical Sciences, Little Rock, AR; Storrie et al., 1998). The plasmid encoding VSVGtso45-GFP was obtained from M.A. McNiven (Mayo Clinic, Rochester, MN). The plasmid pYFP-hCOG3 was described previously (Suvorova et al., 2001), pCMV-SPORT6 with cDNA of mCOG3 (clone ID 4020725; NCBI Accession BC038030) was obtained from Invitrogen.
dehydration in a graded ethanol series, and embedded in Epon 812. Ultrathin sections were obtained using an LMC MT-7000 ultramicrotome, double stained with uranyl acetate and lead citrate. Specimens were examined using a JEOL JEM-1010 electron microscope at 80 kV with magnification ranging from 15,000 to 75,000×.

Microinjection of anti-COG3 antibodies
Hela cells that stably expressed GaIT-GFP were microinjected with anti-Cog3p IgGs with the N-rasgiiuee Micromanipulator and imaged immediately and 4 h after the injection using a 40×, 1.3 NA Fluor objective fitted to a confocal microscope (model LSM410; Carl Zeiss Microla-Imaging, Inc.). The antibody concentration was 2 mg/ml, Texas red was used as an injection marker. Microinjection of the preimmune IgGs was used as the control.

Cell fractionation and preparation of CCD vesicles
Hela cells were cultured to ~80% confluence in 60-mm dishes and transfected with COG3 siRNA. 78 h after transfection (KD efficiency of ~80%), cells were washed three times with PBS and then scraped in 0.3 ml of 20 mM Hepes-KOH buffer, pH 7.4, supplemented with a protease inhibitor cocktail (Roche Diagnostics Corporation) on ice. The cells were disrupted using a Potter homogenizer. Subcellular fractions were obtained by standard differential centrifugation. The PNS was obtained at 500 g (5 min, 3°C). Heavy membranes, including ER and the Golgi were pellet at 10,000 g (10 min, 3°C). Light mem-

Glycerol velocity centrifugation and gel filtration
Gradient fractionation was prepared as described previously (Jesch and Linstedt, 1998) with some modification. To prepare the lysate, 72 h COG3 KD Hela cells from one 10-cm plate were collected by trypsinization, pelleted (500 g for 5 min), then washed once in PBS, and once in STE buffer (250 mM sucrose, 10 mM triethyamine, pH 7.4, 1 mM EDTA, with protease inhibitors), homogenized by 20 passages through a 25-gauge needle in 0.5-ml buffer STE without sucrose, and then centrifuged at 1,000 g for 2 min to obtain PNS. This supernatant was used for both gradient fractionation and gel filtration. PNS [1 × 1 ml] was layered on linear 10–30% (wt/vol) glycerol gradients [12 ml in 10 mM triethyamine, pH 7.4, and 1.4 mM EDTA on a 0.5 ml 80% sucrose cushion] and centrifuged at 280,000 g for 60 min in a SW40 Ti rotor (Beckman Coulter).

Interaction of the COG complex with CCD vesicles
The COG complex was isolated from HeLa cells that express YFP-Cog3p infected with COG3 siRNA. 78 h after transfection (KD efficiency of ~95%), cells from two 10-cm plates were homogenized by 20 passages through a 25-gauge needle in 0.5-ml buffer STE without sucrose, and then centrifuged at 1,000 g for 5 min. The supernatant was transferred to a new tube, resuspended in 30 µl of 2 × sample buffer, heated for 5 min at 95°C, loaded on SDS-PAGE, and analyzed by WB.

IP experiments using rat liver Golgi membranes
Rat liver Golgi membranes were purified as described by Hamilton et al. (1991) and frozen in aliquots in liquid nitrogen. All of the following operations were performed in a cold room. Membranes were thawed on ice in an equal volume of cold CDT buffer and incubated for 30 min. 50 µl of protein A Sepharose in TBS was added and incubated on a tube rota- tor for 1 h. Insoluble protein A Sepharose and beads were pelleted at 20,000 g for 10 min at 3°C. The supernatant was transferred to a new tube and di-

SDS-PAGE and Western blotting
SDS-PAGE and WB were performed as described by Suvorova et al. (2002). A signal was detected using a chemiluminescence reagent kit (PerkinElmer Life Sciences) and quantitated using ImageJ software (http://rsb.info.nih.gov/iij/).

We thank B. Storrie and R. Karten for help with IF and microinjections and M. Crocker for great help with EM. We are very grateful to O. Pavlov for excellent technical assistance and to A. Shestakova for valuable comments on this manuscript. We also thank R. Duden, J. Hay, F. Hughson (Princeton Univer-
sity, Princeton, NJ), M. Krieger (Massachusetts Institute of Technology, Cam-
bridge, MA), A. Linstedt, D. Ungar (Princeton University), and others who pro-
vided antibodies and other valuable reagents.
This work was supported by grants from the National Science Foundation (MCB-0234822) and the Department of Defense (DAMD17-03-1-0243).
