(Dated: February 4, 2005)

We present experimental and theoretical studies of Pd/Cu(100) and Cu/Pd(100) heterostructures in order to explore their structure and misfit strain relaxation. Ultrathin Pd and Cu films are grown by pulsed laser deposition at room temperature. For Pd/Cu, compressive strain is released by networks of misfit dislocations running in the [100] and [010] directions, which appear after a few monolayers already. In striking contrast, for Cu/Pd the tensile overlayer remains coherent up to about 9 ML, after which multilayer growth occurs. The strong asymmetry between tensile and compressive cases is in contradiction with continuum elasticity theory, and is also evident in the structural parameters of the strained films. Molecular Dynamics calculations based on classical many-body potentials confirm the pronounced tensile-compressive asymmetry and are in good agreement with the experimental data.

Heteroepitaxy with different thicknesses ranging from monoatomic layers up to micrometers produces various structures, and is one of most important routes to artificially obtain functional materials and devices. Stress and its relaxation due to an interface lattice mismatch are an essential problem in the heterostructures. Classical continuum theory defines the concept of an equilibrium critical thickness $h_c$, above which the lattice stress relaxes with the introduction of a misfit dislocation (MD) [1]. The critical thickness is determined by energy balance between strain energy buildup and strain relief due to dislocation nucleation in the mismatched structure. The value of $h_c$ predicted by the continuum theory, however, often does not agree with experiments. Moreover, the critical thickness in the continuum elasticity theory is independent on the strain type, be it tensile or compressive. Atomic details of the interface structure such as surface steps and surface roughness, are usually ignored. Actual stress relaxation of coherent strained films is kinetically limited, typically with high barriers. Recently, atomistic studies on model systems have been done to determine the transition paths and energy barriers from coherent to incoherent states in real epitaxial films [2,3,4]. One of the main findings has been a striking asymmetry between the tensile and compressive cases, due to the anharmonicity and asymmetry of the atomic interactions [3,4]. Further, the concept of a size-dependent mesoscopic mismatch has been proposed to explain strain relaxations in the early stage of homo- and heteroepitaxial metal growth on the atomic scales [5].

In this Letter, we present results from a combined experimental and theoretical study on a model system of Cu-Pd heteroepitaxy grown by pulsed laser deposition (PLD). The bulk lattice parameters of Cu and Pd are $a_{Cu} = 3.61\text{Å}$ and $a_{Pd} = 3.89\text{Å}$, respectively. The lattice misfit induces a large compressive ($m = -7.2\%$) strain in the Pd overlayer on Cu(100) and a tensile ($m = 7.8\%$) strain for the Cu overlayer on Pd(100). The Pd films on Cu(100) and the Cu films on Pd(100) were grown by pulsed laser deposition (PLD) in a multi-chamber ultrahigh vacuum (UHV) system with a base pressure $p < 5 \times 10^{-11} \text{mbar}$, and $p < 2 \times 10^{-10} \text{mbar}$ during deposition. Prior to deposition the copper and palladium substrates were cleaned by cycles of Ar$^+$ sputtering followed by annealing at 873 K for Cu substrate or 950 K for Pd substrate until clean Auger electron spectroscopy (AES) spectra, sharp low-energy electron diffraction (LEED) spots, and atomically smooth terraces under scanning tunneling microscopy (STM) were observed. The substrate temperature was kept at room temperature during deposition. The substrate was placed about 100 ~ 130 mm away from targets. A KrF excimer laser beam (wavelength 248 nm, pulse duration 34 ns, typical pulse energy 300 ~ 350 mJ and pulse repetition rate of 3 ~ 5 Hz) was focused onto targets. During deposition the growth process was monitored by a reflection high energy electron diffraction (RHEED). All STM measurements were performed in the constant current mode at a 0.2 ~ 0.5 V positive tip bias and a 0.1 ~ 0.5 nA tunneling current. Compared to thermal deposition (TD), an extremely high instantaneous flux of atoms in PLD favors much larger nucleation density [6,7]. This helps to suppress the formation of Cu(001)(2 × 2)-Pd ordered alloy in the initial growth stage for Pd/Cu(100) [8] and the phase transition
systems. It persists up to at least 5 ML. The RHEED coverages, as determined from STM images, are always consistent with the coverage from RHEED. The RHEED data confirm the layer-by-layer growth mode for both systems. It persists up to at least 5 – 6 ML in Cu-Pd multilayer growth mechanism. A typical image for 9.0 ML is given in Fig. 2(f). Four layers appear simultaneously on the surface. Moreover, only 70% of the ninth layer is completed while the remaining 30% appears as the tenth and eleventh layers. It should be pointed out that the height or depth of all (ir)regular islands and pits is about 1 Å until 9.0 ML as shown in the inset of Fig. 2(d). This vertical magnitude corresponds to the interlayer spacing for both systems. In the case of Pd/Cu(100) films, the interlayer distance is about 1.65 Å up to 3 ML, very close to the value of Cu substrate, and increases rapidly above 3 ML to reach the value of bulk Pd. For Cu on Pd(100) up to 10 ML, the value stays constant (≈ 1.64 Å). This agrees well with the measured height of monolayer islands by STM. Above 10 ML the interlayer spacing gradually increases close to the value of bulk fcc Cu at a coverage of 20 ML.

IV-LEED measurements of the specularly scattered electron beam were done to obtain structural information on the films. The average interlayer spacing of PLD films was calculated from LEED intensity of the (00) diffraction beam vs. energy curves based on a kinetic model [11]. Fig. 3 gives the layer thickness dependence of the interlayer distance for both systems. In the case of Pd/Cu(100) films, the interlayer distance is about 1.82(5) Å up to 3 ML, very close to the value of Cu substrate, and increases rapidly above 3 ML to reach the value of bulk Pd. For Cu on Pd(100) up to 10 ML, the value stays constant (≈ 1.64 Å). This agrees well with the measured height of monolayer islands by STM. Above 10 ML the interlayer spacing gradually increases close to the value of bulk fcc Cu at a coverage of 20 ML.

The actual in-plane lattice constant of deposited films was obtained in situ by measuring the spacing between the reciprocal lattice rods in the RHEED image. The RHEED spacing of substrates serves as a reference. The

Figure 1: STM images for (a) 0.5 ML Pd (200 × 200 nm²); (b) 1.6 ML Pd (200 × 200 nm²); (c) 4.8 ML Pd (100 × 100 nm²); (d) 6.0 ML Pd (100 × 100 nm²) deposited at 300 K.

Figure 2: STM images for (a) clean Pd(100) substrate (500 × 500 nm²); (b) 0.85 ML Cu (100 × 100 nm²); (c) 2.1 ML Cu (100 × 100 nm²); (d) 3.05 ML Cu (100 × 100 nm²); (e) 6.0 ML Cu (100 × 100 nm²); (f) 9.0 ML Cu (100 × 100 nm²) deposited at 300 K.
Figure 3: Perpendicular interlayer distance calculated based on a kinetic model from LEED intensity of the (00) diffraction beam vs. energy curves. The change of the interlayer distance occurs at about 3–4 ML for Pd/Cu(100) films and at about 10 ML for Cu/Pd(100) films. Assuming a pseudomorphic growth up to 3 ML for Pd on Cu(100) and 10 ML for Cu on Pd(100), PLD films can be identified as fcc Pd and fct Cu structures. The results from experimental and theoretical work at 300 K are indicated by open and solid symbols, respectively. The lines are guides to eye.

The in-plane lattice strain is defined as \(\frac{a_{\text{bulk}} - a_{\text{film}}}{a_{\text{bulk}}}\) (%). Fig. 4 gives the measured data. For Pd/Cu(100), the measured in-plane strain exhibits a gradual decrease with increasing thickness of the Pd film. The compressive strain is nearly fully relaxed at 9 ML. In contrast, the in-plane tensile strain shows a very different thickness dependence in the case of PLD Cu films on Pd(100). Until 9 ML only 0.6 % reduction in the tensile strain is found. Above 9 ML a step-like decrease is visible and a residual strain is observed until 20 ML.

The most striking discovery in our data is the strong asymmetry in the strain relaxation behavior between the tensile and compressive strained films. This result is in direct disagreement with the continuum elasticity theory, which predicts a symmetrical behavior for tensile and compressive systems.

In any growth mode, there is always the question whether the final configuration is dictated by kinetic considerations or it corresponds to a true thermodynamic equilibrium state. Given the lack of precise characterization of the PLD growth conditions, a full theoretical modeling of the kinetic growth process under the experimental conditions is unfeasible. Instead, we have chosen to perform equilibrium molecular dynamics simulations of the epitaxial layer after deposition. The object here is to study the thermal excitation and nature of dislocations in the epitaxial film and to see whether they can account for the observed stress relaxation and tensile compressive asymmetry in Cu-Pd heterostructures. Our atomistic model contains five layers of substrate and varying number of film layers. Two bottom layers of the substrate were fixed. Periodic boundary conditions were applied in the plane parallel to the surface. The lateral size of the systems studied varied between 20 × 20 to 40 × 40. Interatomic forces between particles in the system were computed using Embedded Atom Model (EAM) potentials for Cu and Pd [12]. The initial configuration of the film has adatoms occupying fcc positions in registry with substrate.

For Pd/Cu(100), after thermal equilibrium is reached at 300 K, the system relaxes and gains partial strain relief through generation of misfit dislocations starting at 2 ML and above. To facilitate a direct comparison with the experimental data in Fig. 3, we computed from our simulations the average interlayer distance for the top layers of the film (up to three to take into account the surface sensitivity of LEED). We also computed the average in-plane lattice constant for the top three surface layers, and then evaluated the in-plane strain using the bulk value of the adsorbate as a reference. The depen-
dence of these values on the film thickness is shown in Fig. 8. There is a good qualitative agreement between the theoretical results with the experimental observation showing continuous relief of in-plane strain through the misfit dislocations. The exact nature of the misfit dislocations is rather complicated, varying both as a function of film thickness and lateral size. In Fig. 5 we show a typical configuration for a film of 7 ML thickness and lateral size 20 × 20 obtained by molecular dynamics annealing through heating to 500 K, followed by cooling to 0 K. This shows a Pd film with misfit dislocations visibly aligned along the (100) direction of the substrate, in agreement with the experimental observations.

Simulation studies were also performed for Cu/Pd(100). Here, in agreement with the experimental observation, the theory shows a striking difference from the Pd/Cu(100) system. The pseudomorphic strained fct structure for the Cu film remains stable up to about 9 ML. Then strain is gradually released through localized surface defect such as vacancies and adatoms, rather than the misfit dislocation mechanism observed in Pd/Cu(100). The theoretical results for the average interlayer distance of the film and the in-plane strain for the top surface layers as a function of the film thickness are shown in Figs. 8 and 9 respectively. The theory again is in good agreement with the experimental data, indicating a stable highly strained epitaxial state below 9 ML.

In conclusion, we have studied the stress relaxation mechanism in Cu-Pd heteroepitaxy both through PLD experiments and numerical simulations. The experimental data show that for Pd/Cu(100), the in-plane stress is relaxed almost immediately above 1 ML, whereas Cu/Pd(100) remains coherent up to about 9 ML. While these observations contradict predictions from the continuum theory, they are confirmed by our atomistic simulations using EAM potentials for the Pd and Cu interactions. The good agreement between the experimental data and the equilibrium simulation study leads us to conclude that the observed configurations of the film at different thicknesses correspond to equilibrium state with thermally generated misfit dislocations as the strain relief mechanism. The microscopic nature of the misfit dislocation observed here for the Pd/Cu(100) system is rather complicated and does not fit into the simple model postulated previously [10].

On a microscopic level, the tensile-compressive asymmetry originates from the asymmetry of the interatomic interactions. The general feature of interatomic potentials is a steeply rising repulsive part at small separations as opposed to a very slowly decreasing attractive part at large separations. This strong asymmetric feature of the interaction is what leads to the observed macroscopic tensile-compressive asymmetry. We have performed additional studies using very different potentials (of Lennard-Jones type) with the same general feature, and the results indeed remain qualitatively unchanged. Interestingly, we find that geometry and dimension play an important role in the tensile-compressive strain relief asymmetry. For the 2D model, misfit dislocations are favored for tensile rather than compressive strained systems [11]. Clearly, there is much more to learn in strain relief in heteroepitaxy through further theoretical and experimental investigations.
