(Dated: January 15, 2014)

The formation of Mach cones is studied in a full (3 + 1)-dimensional setup of ultrarelativistic heavy-ion collisions, considering a transverse and longitudinal expanding medium at RHIC energies. For smooth initial conditions and central collisions the jet-medium interaction is investigated using high-energy jets and various values of the shear viscosity over entropy density ratio, $\eta/s$. For small viscosities, the formation of Mach cones is proven, while for larger viscosities the characteristic structures smear out and vanish eventually. The formation of a double-peak structure both in a single and a multiple jet event is discussed.

I. INTRODUCTION

Collisions of heavy nuclei both at the Relativistic Heavy-Ion Collider (RHIC) [1–4] and the Large Hadron Collider (LHC) [5,8] indicate the formation of a new state of strongly-interacting matter, the quark-gluon plasma (QGP). The large value of the measured elliptic flow coefficient, $v_2$, suggests that the QGP behaves like an almost perfect fluid as demonstrated by various calculations of viscous hydrodynamics [9,12] and microscopic transport models [13–15]. The values determined for the shear viscosity over entropy density ratio are approximately $\eta/s = 0.1 - 0.2$ and thus close to the conjectured lower bound, $\eta/s = 1/4\pi$, derived via the correspondence between conformal field theory and string theory in an Anti-de-Sitter space [16].

High-energy jets traversing the expanding medium deposit energy and momentum. Due to this interaction with the bulk medium, those jets are (strongly) suppressed, a phenomenon that is called jet quenching [1–4,17–21]. Its explicit mechanisms of the jet-medium interaction are still a matter of research. The two- and three-particle correlations extracted from experiment show a complete suppression of the away-side jets for $3 < p_T < 6$ GeV and due to energy and momentum conservation the signal appears again in a lower-$p_T$ range, showing a double-peak structure [22–26]. The origin of the double-peak structure was discussed to be connected to Mach cones generated by fast partons traversing the strongly-coupled medium [25,27]. However, recent studies on the triangular flow and hot spots [24,28–31] issue a further, probably more satisfactory explanation for the appearance of the double peak structure.

Up until today, however, the contribution of jet-induced Mach cones to the double-peak structure remains unclear. To gain a better understanding of the contribution of Mach cones to the double-peak structure in two-particle correlations, we investigate the evolution pattern of jet-induced Mach cones and their particle distribution in a relativistic, (3 + 1)-dimensional expanding system of a heavy-ion collision for various values of the shear viscosity over entropy density ratio, $\eta/s$, using the microscopic transport model BAMPS (Boltzmann Approach of MultiParton Scatterings) [32].

In an earlier publication, [33], we already studied the formation of Mach cones using the above mentioned kinetic transport model applying a static box scenario and thus neglecting all effects from expansion. We showed that, considering a source term depositing both energy and momentum, the double-peak structure is overshadowed by the strong contribution of the head shock and diffusion wake, while the double-peak structure appears for a source term (that lacks physical motivation from any theoretical model) which leads to only energy but no momentum deposition. These results are consistent with an investigation based on an AdS/CFT calculation [34] and a hydrodynamic model [37,38]. The comparison with the latter publications proofs once more BAMPS can model a hydrodynamic expansion [39,40]. Using the same non-expanding scenario, we studied the effect of dissipation in box scenario [56] and found that dissipation tends to destroy any Mach cone signal.

However, as discussed in Ref. [61], the flow-velocity profile created by jets in the transverse plane interacts with the radial flow of the background medium, changing e.g. the effective angle of a Mach cone. This effect of transverse expansion on Mach cones has also been studied in Refs. [46]. It was found that a double-peak structure can be created by averaging over different jet paths. The main contribution to the double-peak structure originates from jets which are deflected by radial flow. In the rare case that a jet traverses into the opposite direction of the radial flow, the interplay between radial flow and jets reduces the strong contribution of the diffusion wake and head shock and results in a double-peak structure for this single event.

In the following, we investigate a similar setup as in [46], but including not only transverse but also longitudinal expansion, exploring in particular the influence of viscosity. In this work, the units are $\hbar = c = k = 1$.

II. NUMERICAL SETUP

We use the framework of BAMPS in a fully $(3+1)$-dimensional setup designed for ultrarelativistic heavy-ion collisions \cite{55}. Here, we treat a massless gluon gas as classical Boltzmann particles with a degeneracy factor of $g = 16$. Particles only collide via binary collisions with an isotropic cross section, i.e., a cross section with an isotropic distribution of the collision angle. We perform the numerical calculations using a constant value of the shear viscosity over entropy density ratio, $\eta/s$. For isotropic binary collisions, the shear viscosity is given by $\eta = 0.4 \rho / (n \sigma) \rho$ \cite{62}, where $\rho$ is the local rest frame energy (particle) density.

As we intend to focus on the impact of transverse radial and longitudinal flow on jets, we neglect additional effects from density fluctuations. Likewise, we neglect any effects originating from elliptic flow and only consider central collisions. We apply smooth Glauber initial conditions in the transverse direction \cite{53} and a Gaussian rapidity distribution in longitudinal direction as it was found at RHIC \cite{54} that the rapidity distribution of charged hadrons can be described by a Gaussian. In beam ($z$) direction, we determine the width of the nuclear overlap region based on the Lorentz-contrasted nuclear thickness that is approximated by a Gaussian as well. (Please note that we initialize the system with a finite width. The system, however, will behave boost-invariant near $z = 0$ at times $< 1$ fm.) For the high-$p_T$ region we apply a power law which approximately fits the $p+p$ data \cite{65,66}. Thus, we apply the following parametrization for the initial non-thermal single-particle distribution function

$$f(\vec{x}, \vec{p}) = K \frac{Q^n}{Q^n + p_T^n} \exp \left(-\frac{y_{\text{rap}}^2}{\sigma_y^2}\right) \times$$

$$\exp \left(-\frac{z^2}{\sigma_z^2}\right) T_A \left(x + \frac{b}{2}, y\right) T_B \left(x - \frac{b}{2}, y\right),$$

where $p_T = \sqrt{p_x^2 + p_y^2}$ denotes the transverse momentum, $y_{\text{rap}}$ the momentum rapidity, and $b$ the impact parameter. The nuclear thickness function \cite{67}

$$T_A (x, y) = \int_{-\infty}^{+\infty} dz \rho_A(x, y, z)$$

is integrated in $z$-direction. $\rho_A(\vec{x})$ denotes the Woods-Saxon distribution for the nucleus $A$,

$$\rho_A(\vec{x}) = \frac{\rho_0}{1 + \exp \left(\frac{|\vec{x}| - R_A}{D}\right)}. \quad (3)$$

Here, $R_A = 1.12A^{1/3} - 0.86A^{-1/3}$ and the mean density of the nucleus is $\rho_0 = 0.17$ fm$^{-3}$. For the thickness parameter we use $D = 0.54$ fm. As we are studying RHIC energies, we exclusively use gold nuclei with a mass number of $A = 197$ and choose $Q = 1.3$ GeV, $n = 4$, $m = 1.5$, $\sigma_y = 0.13$ fm, and $K = 0.0135$.

In the following we investigate scenarios where the jet is set on top of the bulk medium. Please note that the jet interacts with the same cross section as the medium particles.

Similar to the numerical setup discussed in \cite{46} we initialize the starting points of the jet on a semi-circle displayed in Fig. 1 with a radius of $r = 4$ fm at mid-rapidity,

$$\vec{x}_{\text{jet}} = r \begin{pmatrix} \cos \phi_{\text{jet}} \\ \sin \phi_{\text{jet}} \\ 0 \end{pmatrix}. \quad (4)$$

While in the experiment back-to-back correlated jets are created due to momentum conservation, we assume that the near-side jet escapes rapidly to the vacuum and thus, we neglect the near-side jet contribution. In contrast, the away-side jet traverses the hot and dense medium of the collision.

Due to reasons of symmetry, the possible jet paths that need to be studied in a central collision (see left panel of Fig. 1) reduces drastically (as shown in the right panel of Fig. 1). All jets studied here have an initial momentum only in the $z$-direction of $p_z = E_{\text{jet}} = 20$ GeV.

Although performing a full $(3+1)$-dimensional simulation, we restrict the following discussion on the midrapidity region. Thus, we extract all quantities and azimuthal particle distributions for a small space-time rapidity of $|y_{\text{rap}}| < 0.1$. Since the parton cascade BAMPS has no effective hadronization process implemented yet, the final particle distribution is obtained by stopping the simulation at a certain time and extracting the macroscopic quantities as well as the azimuthal particle distribution from the final gluon-momentum distribution.

III. RESULTS

In the following we study the evolution of jet-induced Mach cones in ultrarelativistic heavy-ion collisions for
three different scenarios in order to gain a better understanding of the contribution of transverse and longitudinal expansion on the evolution of Mach cones induced by high-energy jets, considering various values of the shear viscosity over entropy density ratio, $\eta/s$.

### A. Scenario I

In a first scenario we consider a jet starting at a fixed-angle position of $\phi_{\text{jet}} = 180^\circ$ on a semi-circle. In this particular case the jet initially propagates in opposite direction to the radial flow generated in a heavy-ion collision. We examine different values of the shear viscosity over entropy density ratio, reflecting different possible interaction strengths with the medium. To illustrate the results we depict a time evolution of the local-rest frame energy-density profile around mid-rapidity, $|y_{\text{rap}}| < 0.1$, in Fig. 2, overlaid with a velocity profile represented by scaled arrows.

At early times, $t \sim 1 \text{ fm}/c$, the energy density reaches very high values and a Mach cone has not yet built up. The energy behind the jet, however, is significantly lowered for an $\eta/s = 0.08$, indicating that matter is pushed in forward direction. This effect is reduced with increasing values of $\eta/s$.

At later times, the energy density decreases drastically due to the longitudinal and the transverse expansion. A conical structure induced by the jet has developed at $t = 5 \text{ fm}/c$ for $\eta/s = 0.08$. In contrast, for larger values of $\eta/s$, such a structure has not built up (yet). The differences in the shape of the Mach cone for various $\eta/s$ becomes more evident at later times, $t = 9 \text{ fm}/c$ and $t = 12 \text{ fm}/c$. In case of $\eta/s = 0.08$, the energy density in the region of the developed shock front is much more increased than for larger values of $\eta/s$. Interestingly enough, the maximal energy density reached in the head-shock region for an $\eta/s = 0.2$ is smaller than for an $\eta/s = 0.5$. The reason is that the interaction of the jet with the medium is weakened for $\eta/s = 0.5$, i.e., the jet is almost not quenched. In turn this means that the jet propagates faster for larger values of $\eta/s$. For the case with $\eta/s = 0.08$ the initial jet has already lost almost all of its energy, i.e., has thermalized, within a very short time in the beginning of the simulation. As mentioned above we do not distinguish between bulk medium and jet particles, which implies that for $\eta/s = 0.08$ the mean free path of the jet is very small. It is clear, that considering perturbative QCD based elastic and inelastic processes would change significantly the jet energy loss. However, such a treatment remains a future task.

The results in Fig. 2 indicate that a single jet propagating through the middle of the medium creates a Mach cone for moderate values of $\eta/s$ and sufficiently large times. The shock front, however, is strongly curved due to the interaction of the jet with the medium. The diffusion wake is not directly visible as it is superimposed by the radial flow of the background medium, indicating that the contribution of the diffusion wake and head shock is possibly reduced in the final particle distribution. After passing the center of the collision, however, the radial flow broadens the jet-induced shock front region.

In Fig. 3 we show the extracted normalized azimuthal particle distribution $dN/(N d\phi)$. The plot demonstrates that a double-peak structure can develop for a small value of the shear viscosity over entropy density ratio, $\eta/s$, and a $p_T$-cut of $p_T > 0.5$ GeV. For $\eta/s = 0.08$ and $0.5 < p_T < 1$ GeV a double-peak structure is observed at $\phi \approx \pm 70^\circ$, suggesting that the contribution of head shock and diffusion wake is indeed compensated by the radial flow. For larger transverse momenta, however, [see e.g. Fig. 3 panel (d)] the double-peak structure appears around $\phi \approx \pm 120^\circ$. Here, this conical structure is due to the fact that matter flows into region of lower pressure and energy density behind the jet and is thus not directly a signal of the Mach cone. Finally, for $\eta/s = 0.5$ the contribution from the head shock and diffusion wake is very strong, leading to a single peak in forward direction.

The above discussion reveals that a Mach cone can only develop if the energy of the jet is neither too high nor too low. In the former case, the strong contribution of the head shock and diffusion wake leads to a single peak in jet direction, while in the latter case the radial flow of the background medium distorts a Mach cone signal.

Please note that the local energy density in Fig. 2 at $t = 12 \text{ fm}/c$ is much smaller than typically expected $e_{\text{crit}} \approx 0.6$ GeV/fm$^3$ in the deconfined phase. We mentioned above that BAMPS has no effective hadronization procedure, thus we extract all observables from the final gluon distribution. However, Fig. 4 proves that the extracted azimuthal two-particle correlations do not change significantly after $t = 5 - 6 \text{ fm}/c$. While the cross-section increases to unphysical values for energy densities smaller than the critical energy density $e_{\text{crit}} \approx 0.6$ GeV/fm$^3$, those energy densities are thus small that the interaction rate of the system decreases rapidly. This implies that the further evolution of the deconfined phase with the same $\eta/s$ after $t = 5 - 6 \text{ fm}/c$ is reasonable.

### B. Scenario II

In a second scenario, we consider a single jet with a fixed-angle position of $\phi_{\text{jet}} = 135^\circ$ on the semi-circle to study the effects of deflection on the jet due to radial flow. The time evolution for different values of the shear viscosity over entropy density ratio, $\eta/s$, is depicted in Fig. 5. Due to the relative position on the semi-circle and the strong radial flow, the single jet is deflected, especially for small $\eta/s$. This deflection, however, reduces for large $\eta/s$ as the jet-medium interaction weakens, keeping the jet on its initial propagation direction.

A direct comparison to scenario I indicates that the
FIG. 2. Time evolution of a Mach cone in a central heavy-ion collision. The local rest frame energy density around midrapidity ($|\eta_{\text{rap}}| < 0.1$) is shown, overlaid by the velocity profile, indicated by scaled arrows. The results are depicted at various time steps and different values of the shear viscosity over entropy density ratio, $\eta/s$. The jet is initialized at fixed-angle position of $\phi_{\text{jet}} = 180^\circ$ on the semi-circle with an initial momentum of $p_x = E_{\text{jet}} = 20$ GeV.
The jet is initialized at fixed-angle position of $\phi_{\text{jet}} = 180^\circ$ on the semi-circle (see Fig. 2). The results are shown for a fixed time $t = 12 \text{ fm}/c$.

Averaging over all possible jet trajectories with randomly chosen starting positions on the semi-circle, i.e., $\phi_{\text{jet}} = 90^\circ - 270^\circ$, Scenario III gets closest to the experimental situation. Here, in contrast to scenario I and scenario II, we consider many different jet events. Fig. 4 displays the normalized azimuthal particle distribution determined for this multiple-jet scenario. A double-peak structure appears for sufficiently high $p_T$ and low $\eta/s$ with peaks around $\phi \approx 50^\circ$. This result is in line with the Ref. [46] applying a hydrodynamic evolution.

C. Scenario III

Averaging over all possible jet trajectories with randomly chosen starting positions on the semi-circle, i.e., $\phi_{\text{jet}} = 90^\circ - 270^\circ$, Scenario III gets closest to the experimental situation. Here, in contrast to scenario I and scenario II, we consider many different jet events. Fig. 4 displays the normalized azimuthal particle distribution determined for this multiple-jet scenario. A double-peak structure appears for sufficiently high $p_T$ and low $\eta/s$ with peaks around $\phi \approx 50^\circ$. This result is in line with the Ref. [46] applying a hydrodynamic evolution.

IV. DISCUSSION

The above results provide evidence that Mach cones can form in heavy-ion collision if the medium created has a small viscosity. However, as compared to an ideal, zero-viscosity medium, the pattern of the Mach cone is more curved. If a jet gets deflected by radial flow, the shape of the induced Mach cone is distorted. We demonstrate that the radial flow in a heavy-ion collision affects both, the final pattern of the Mach cone [61] and the observed particle distribution.

Considering a single jet event for a sufficiently small value of $\eta/s = 0.08$, the interplay of jet-induced Mach cones and radial flow may lead to a double-peak structure, as shown in scenario I. In this scenario the double-peak structure originates from the Mach cone since the contributions of head shock and diffusion wake are cancelled by the radial flow.

For a single jet not traversing the medium in opposite direction to the radial flow, however, the double-peak structure does not appear, c.f. scenario II. Here, the jet traverses a significantly lower energy-density region, thus reaching only much lower values for the energy density in the shock-front region, especially for $\eta/s = 0.08$. For lower energy-density regions, however, the mean free path of the jet is larger and results in a reduced jet quenching. On the other hand, a medium with $\eta/s = 0.08$ is characterized by a strong collective behavior. The radial flow leads to a strongly distorted Mach cone pattern which is significantly reduced in a medium with $\eta/s = 0.5$.

These results indicate that the generated diffusion wake and head shock are less compensated by the radial flow in scenario II due to the fact the jet does not propagate in opposite direction to the radial flow. The deflection of the jet for $\eta/s = 0.08$ leads to only one peak in the two-particle correlations as displayed in Fig. 6. This peak originates from the head shock and diffusion wake of the distorted Mach cone and becomes sharper and more pronounced for larger $p_T$. We also see that the position of the induced peaks in Fig. 6 changes with viscosity. The larger the value of $\eta/s$, the smaller the peak angle, reflecting the fact that the jet is less deflected for larger values of $\eta/s$.

Although the two-particle correlations determined for this specific single-jet scenario only exhibit one single peak, a double-peak structure is possible when considering in a second jet event in the lower semi-circle [46] [70] [72]. In this case, however, the double-peak is mainly generated due to the superposition of several deflected and distorted jet-induced Mach cones. I.e., the origin for the double-peak structure is not the Mach cone itself but the deflected head shocks and diffusion wakes of the distorted Mach cones as demonstrated below in scenario III.
FIG. 5. Time evolution of a Mach cone in a central heavy-ion collision. We show the local-rest frame energy density within a mid-rapidity range of $|\eta_{\text{rap}}| < 0.1$, overlaid by the velocity profile indicated by scaled arrows. The results are depicted at various time steps and for different values of the shear viscosity over entropy density ratio, $\eta/s$. The jet is initialized at fixed-angle position of $\phi_{\text{jet}} = 135^\circ$ on the semi-circle with an initial momentum of $p_x = E_{\text{jet}} = 20 \text{ GeV}$. 
the radial flow leads to a deflection of the jet, resulting in a single peak arising in the two-particle correlations. Nonetheless, considering a multiple-jet scenario as in scenario III, a double-peak structure occurs as well which is mainly generated by the superposition of the deflected and distorted head shocks and diffusion wakes of the jet-induced Mach cones [46, 70].

We demonstrate above that a sufficiently large value of $\eta/s$ tends to destroy the characteristic structure of a Mach cone in a 3-dimensional expanding heavy-ion collision and results in a single peak in the two-particle correlation. Here, the contributions from both head shock and diffusion wake are less cancelled by the radial flow than in case of a smaller value of $\eta/s$. Moreover, larger dissipation reduces the deflection of jets. However, not only viscosity tends to destroy the double-peak structure, but also the strength of the jet. A jet with a large initial energy punches through the medium and the effect of the radial flow weakens. For such a high-energy jet, the diffusion wake and head-shock contribution in scenario I would overshadow the double-peak structure, while in scenario III most of the jets would get less deflected. On the other hand, a jet with a very small initial energy density would not lead to a double-peak structure either as in this case the strong radial flow observed in a heavy-ion collision does not allow a Mach cone to be developed.

Our results imply that the influence of the radial flow is most important for the observation of a double-peak structure. A large dissipation and/or large initial jet energy lead to a smaller influence of the radial flow. The effect of longitudinal flow is studied here in a qualitative way and was not considered previous studies [46]. We conclude that the longitudinal flow does not affect the results significantly.

The Mach-cone angle extracted from two-particle correlations is certainly not connected to the equation-of-state [61]. Scenario III provides evidence that the contribution of this double-peak structure mainly originates from the head shocks and diffusion wakes of the jet-induced Mach cones. To extract the Mach angle and thus determine the speed of sound of the medium would require the measurement of a single jet event as shown in scenario I which remains an extremely tough experimental challenge.

V. CONCLUSION

In conclusion, we have shown that Mach cones can form in a longitudinal and transverse expanding heavy-ion collision. Considering multiple jet-events, a double-peak structure evolves if the energy over entropy-density ratio is $\eta/s < 0.5$. Please note that the peak position does not change significantly with $\eta/s$. However, this double-peak structure does not originate from Mach cones but arises due to the contribution of the head shock and diffusion wake originating from the deflected jets [46] [61].

Although initial-state fluctuations certainly provide a large contribution to the experimentally observed double-peak structure [48] [51] [73] [76] it will be important to quantify the contribution from jets. The double-peak signal might not be an appropriate observable to disentangle both contributions [50] as it is mainly medium-driven. However, allocating a more appropriate signature remains an open challenge.
