ABSTRACT

To increase the accumulation of atmospheric carbon dioxide is due to the anthropogenic activity, natural fire and industrialization induced climate change. To increase the pressure regarding reduce the concentration of CO₂ in the environment, sequestration of carbon is the trend to improve the carbon sink and environmental health in soil. The maintenance of a threshold level of organic matter in the soil is crucial for maintaining physical, chemical and biological integrity of the soil and also for the soil to perform its agricultural production and environmental functions. The application of biochar to the soil is proposed as a novel approach to establish a significant long term sink for atmospheric carbon dioxide in terrestrial ecosystems. For rising interest regarding carbon sequestration and soil sustainability field experiment was conducted to determine the influence of biochar and fertiliser with biofertiliser for yield, quality and soil fertility of maize in Typic Haplustalf of Tamirabharani tracts. The experiment was imposed with randomized block design with fifteen treatments (two levels of biochar and two levels of recommended dose of fertiliser with biofertiliser (Azophos 4 pockets ha⁻¹) and two replications. Application of biochar with inorganic fertilisers and biofertiliser increased the yield components of maize viz., hundred grain weight (38.9g), cob length (23.5cm), cob weight (310g), grain yield (8100 kg ha⁻¹) and stover yield (12,150 kg ha⁻¹) and also quality trait such as crude protein content. Higher yield and quality was obtained from the combination of 5 t ha⁻¹ plus 100 per cent recommended dose of N, P₂O₅ and K₂O plus biofertiliser on maize. The combined application of biochar with 100 per cent recommended dose of fertiliser and biofertiliser increased the yield, quality and soil fertility in maize growing soil.

Keywords
Engineered char, Pyrolysis, Biochar, Carbon sequestration, Soil fertility, Climate change.

Introduction

Greenhouse gases (e.g., CO₂, CH₄) from anthropogenic and biogenic sources are accumulating in the atmosphere. The concentration of atmospheric CO₂ alone is projected to double from pre-industrial levels by the mid to late 21st century. According to general circulation models of climate change, infrared radiation trapped by the additional greenhouse gases in the troposphere could cause the earth’s surface temperature to increase 1.5 to 4.5°C and influence frequency and distribution of regional precipitation. To evaluate a possible means for offsetting part of the increase of atmospheric CO₂, an assessment began in late 1990 to evaluate the potential to enhance C sequestration in global
terrestrial ecosystems through forest and agroforest management. Climate change and fossil fuel shortage is a main concern for using renewable feedstock for energy. For replacing fossil fuel, agricultural wastes, crop residues and woods are subjected to conversion of energy through biological or thermal conversion. Pyrolysis of this biomass which is produces the char, oil and gases. Biochar and char which is produced through pyrolysis technique (thermal conversion). Agricultural waste and wood have the cellulose, hemicelluloses and lignin us a building unit. Through the thermal conversion process, these building units are produced the volatile products. Biochar is a product of thermal decomposition of biomass produced by a process termed pyrolysis. In recent years, application of black, charred carbon (biochar) has been increasingly discussed as a mitigation strategy for sequestering recalcitrant carbon into agricultural soils, which can, at the same time, improve soil fertility (Glaser et al., 2002). Modern pyrolysis techniques, which are currently undergoing a rapid technical development (Laird et al., 2010) allow energy production from syngas (mainly CO, H₂ and CH₄ and other hydrocarbons) and / or liquid - fuel production while simultaneously generating different types of biochar. The resulting biochars can greatly differ in their material properties (CHO-concentrations, aromaticity, cation exchange capacity, pH, nutrient contents, porosity, energy density etc.), depending on feedstock and pyrolysis conditions (Amonette and Joseph, 2009; Downie et al., 2009). Experimental evidence so far shows that biochar is quite stable and hence principally suitable for C sequestration (Major et al., 2010) and addition often promotes plant growth, in particular combined with N-fertilizer addition in poor soils (Blackwell et al., 2009), and followed by it reduces nutrient leaching (Chan et al., 2008). Additionally it could be shown that the cation exchange capacity (CEC) of soils increases with biochar addition (Liang et al., 2006) in particular over time as the functional groups are oxidized (Cheng et al., 2008). Significant improvement in the available N, P, K and DTPA- extractable Zn, Fe, Cu and Mn status at different growth stages of maize was evidenced with the conjoint application of biochar with fertilisers and biofertilisers. The present study was undertaken to study the effect of yield, quality and soil fertility in sandy clay loam as influenced by biochar in Typic Haplustalf.

Materials and Methods

Preparation of Prosopis biochar

Prosopis biochar is made by heating biomass under oxygen-limited conditions- 450°C (e.g. slow pyrolysis).The thermo-chemical conversion drives off the volatile components of the biomass and stabilizes the remaining carbon into a black, highly aromatic solid.

Characterization of Prosopis juliflora L. biochar

The Biochar samples were collected from the pyrolysis stove sieved (< 0.25 mm) and their important characteristics were analyzed (Table 2). The biochar sample was subjected to structural analysis for xylem structure and surface properties by using Scanning Electron Microscope at Tamil Nadu Agricultural University – Nano technology laboratory (Fig. 1). The degree of ashing, mobile or labile matter and resident matter or recalcitrant matter was analyzed and followed by characterizing biochar (Hugh McLaughlin. 2010).

Biochar application

Biochar was applied in different levels viz. 5.0 and 7.5 t ha⁻¹ as soil application with two
levels of NPK fertilization for maize. The biochar was applied uniformly in the respective plots at 5 cm depth of the soil prior to sowing.

**Study site description**

A field experiment was conducted in farmer’s field at Sivasubramaniyapuram village near to the Agricultural College and Research Institute, Killikulam of Thoothukudi district with test crop of maize during 2011-2012 to evaluate the impact of soil applied *Prosopis* biochar on yield and quality of maize in Alfisol.

The experimental site located at 80º 46'N latitude and 77º42' longitude at an elevation of 40 meters above mean sea level. The soil of the experimental site belonged to Sivasubramaniapuram series and according to USDA soil taxonomy it could be classified as Sandy clay loam, fine non arid Kaolinticisomergathemic family of TypicHaplustalfs. The characteristics of the experiment soil, determined by standard methods are presented in Table 1. Crude protein was analyzed by using this formula N (%) content × conversion factor 6.25. The method as suggested by Merrill and Watt (1973).

**Experimental description**

A field experiment for yield, quality and soil fertility of maize hybrid (Pioneer 30R77) was investigated with different levels of biochar, fertilizers and biofertilisers during September 2011 - January 2012. The experimental soil was sandy clay loam in texture with the pH, EC, CEC and organic carbon content of 6.2, 0.45 ds m⁻¹,16 c mol (p+) kg⁻¹ and 0.43 per cent respectively. The soil was low in KMnO₄ - N (223.4 kg ha⁻¹), medium in Olsen - P (11.32 kg ha⁻¹) and low in NH₄OAc - K (270.7 kg ha⁻¹). The recommended dose of nutrients for maize as 135: 62.5: 50 kg N, P₂O₅ and K₂O hectare⁻¹. The treatment combinations comprises two levels of recommended dose of fertilizer and two levels of biochar and biofertiliser in 15 treatments viz., T₁ - (control), T₂ - (5 t ha⁻¹ biochar), T₃- (7.5 t ha⁻¹ biochar), T₄- (75 % RDF), T₅- (100 % RDF), T₆- (75 % RDF + biofertiliser), T₇- (100 % RDF + biofertiliser), T₈ - (5 t ha⁻¹ biochar + 75 % RDF), T₉ - (5 t ha⁻¹ biochar + 100 % RDF), T₁₀ - (7.5 t ha⁻¹ biochar + 75 % RDF), T₁₁ - (7.5 t ha⁻¹ biochar + 100 % RDF), T₁₂ - (5 t ha⁻¹ biochar + 75% RDF + biofertiliser), T₁₃ - (5 t ha⁻¹ biochar + 100 % RDF+ biofertiliser), T₁₄ - (7.5 t ha⁻¹ biochar + 75% RDF+ biofertiliser), T₁₅ - (7.5 t ha⁻¹ biochar + 100 % RDF + biofertiliser) with two replications were statistically analyzed with randomized block design.

**Results and Discussion**

**Properties of *Prosopis* biochar**

*Prosopis* is widely grown in many parts of Tamil Nadu and it is available in large quantities particularly in dry tracts and wastelands. The data obtained from the *Prosopis* biochar was presented in the Table 2. The *Prosopis* biochar had a very little moisture (1.52 %) and 1.4 w w⁻¹ of ash.

Mobile and resident matter of the biochar was 38 g kg⁻¹ and 31 g kg⁻¹ respectively. In respect of pH and EC was obtained at 8.1 and 1.45 dSm⁻¹ of *Prosopis* biochar. The organic carbon content and cation exchange capacity of the biochar was 720 g kg⁻¹ and 17.2 c mol (p+) kg⁻¹. With respect to total nutrient content, *Prosopis* biochar had high amount of carbon and low amount of total nitrogen (1.82 g kg⁻¹). It had low amount of total phosphorus (2.02 g kg⁻¹) and total potassium (25.3 gkg⁻¹) and also contained the exchangeable cations like calcium (12.2 g kg⁻¹) and magnesium (0.47 g kg⁻¹).
Effect of biochar with fertiliser on growth, yield parameters and yield of maize in alfisols

Growth parameters

Combination of biochar and recommended dose of fertilisers had significantly increased the plant height from vegetative to harvest stage. The plant height ranged from 83 to 136 cm and 177 to 245 cm at vegetative and harvest stages respectively. Among the treatment T13 (biochar @ 5 t ha\(^{-1}\) +100 % recommended dose of N, P\(_2\)O\(_5\) and K\(_2\)O + biofertiliser) was significantly superior in improving the plant height by recording 136 cm and 245 cm at vegetative and harvest stages respectively. This might be attributed due to application of biochar could retain soil moisture and nutrients because of their porous xylem structure. These would adsorb the cation and exchange the nutrients because of their net negative charges of biochar and clay component. This was augmented with the findings of Peng et al., (2011) who revealed the increase in growth and biomass by biochar was recorded in maize with rice straw derived biochar amendment could be attributed with dry matter production.

Yield components of maize

Significant influence of biochar with fertilizers on the yield components of maize viz., hundred grain weight, cob length, cob weight was presented (Table 3). The hundred grain weight, cob length and cob weight were ranged from 17.2 to 38.9 g, 15.0 to 23.5 cm and 155 to 310 g respectively. Among treatments, application of biochar @ 5 t ha\(^{-1}\) plus 100 per cent recommended dose of N, P\(_2\)O\(_5\) and K\(_2\)O plus biofertiliser (T13) recorded the highest hundred grain weight (38.9 g), cob length (23.5 cm) and cob weight (310 g) over other treatments and control. While comparing other treatment combinations, it was observed that the treatment received biochar @ 5 t ha\(^{-1}\) plus 75 per cent recommended dose of N, P\(_2\)O\(_5\) and K\(_2\)O biofertiliser (T12) recorded next best levels of hundred grain weight, cob length and cob weight of 35.0 g, 23.0 cm and 306 g respectively. The lowest hundred grain weight, cob length and cob weight of 17.2 g, 15.0 cm and 155 g was recorded in T1 (control). This was ascribed due to application of fertiliser and biochar would increase the availability of assimilates (source) and storage (sink) exert an important regulative function on the complex process of yield formation. The present findings is accordance with Chan et al., (2008) also recorded that the lowest application of biochar @10 t ha\(^{-1}\) increases 42 per cent yield compared with the unamended control in radish.

Grain and stover yield of maize

Application of biochar with NPK fertilisation significantly increased the grain and stover yield (Table 4) of maize which ranged from 2,538 to 8,100 kg ha\(^{-1}\) and 4,061 to 12,150 kg ha\(^{-1}\) respectively. While comparing the biochar treatments, it was evident that application of biochar to maize crop was significantly higher with combination of different levels of fertilisers and biofertiliser. In the treatment combinations, the treatment received biochar @ 5 t ha\(^{-1}\) plus 75 per cent recommended dose of N, P\(_2\)O\(_5\) and K\(_2\)O plus biofertiliser (T13) recorded the highest grain and stover yield of 8100 and 12150 kg ha\(^{-1}\) respectively and followed by T12 (biochar @ 5 t ha\(^{-1}\) + 75 % recommended dose of N, P\(_2\)O\(_5\) and K\(_2\)O + Biofertiliser) recorded higher grain (7700 kg ha\(^{-1}\)) and stover yield (11,550 kg ha\(^{-1}\)). The control (T1) recorded the lowest grain and stover yield of 2538 and 4061 kg ha\(^{-1}\) respectively.

This may be attributed that application of biochar with N would increase nitrogen availability its regulating nitrate reductase by high negative charged biochar particles increased the grain and stover yield of maize. And also the pattern of nutrient release to the environment was slower when compared to control. This was in agreement with the findings of Baronti et al., (2010) reported that application of biochar @ 10 t ha\(^{-1}\) recorded higher grain production in maize, wheat and also in ryegrass.

**Quality**

**Crude protein content**

The crude protein content of maize varied from 5.0 to 9.9 per cent showing the significant influence of biochar and fertilisers (Table 4). Among the treatments, biochar @ 5 t ha\(^{-1}\) plus 100 per cent recommended dose of N, P\(_2\)O\(_5\) and K\(_2\)O plus biofertilisers (T\(_{13}\)) recorded significantly the highest crude protein content (9.9 %) in maize followed by biochar @ 5 t ha\(^{-1}\) plus 75 per cent recommended dose of N, P\(_2\)O\(_5\) and K\(_2\)O + biofertiliser (T\(_{12}\)) recorded higher (9.3 %) crude protein content in maize as compared over to other treatments and control. This might be due to increase the available of nitrogen and its uptake and storage in grain. Potassium uptake by maize has also marked due to biochar with fertiliser application. Rondon et al., (2007) who reported that different types of biochar applied in soil influencing high K uptake by maize. Usherwood (1985) who reported that potassium can play a role in quality development of maize, when supplement K fertilisation was applied to maize, it produced on increase in grain protein content and amino acid content and Yang et al., (2004) also supporting this high protein concept.

It could be concluded that application of biochar along with fertiliser and biofertiliser would increase the maize growth and yield. This may be due biochar had porous medium and the graphite sheet could be adsorbed higher moisture and nutrient. The oxidation of functional groups of biochar would adsorb more cation and exchange with root hairs (H\(^+\)) leads to higher nutrient assimilation by plants.
Also biochar leads to increase the organic carbon in soil by way of less oxidation of organic matter in to CO₂ leads to sequester carbon in soil. These can applicable when soils are contaminated with heavy metals, biochar could act like an organic matter by adsorb the heavy metal through ligand exchange mechanism to less availability of heavy metal into ground water and phyto toxicity. Less CO₂ emissions also leads to reduce the climate change effect on environment.
