Abstract
Flat-band systems are ideal model systems to study strong correlations. In a large class of one or two dimensional bosonic systems with a lowest flat-band it has been shown that at a critical density the ground states are Wigner crystals. Under very special conditions it has been shown that pair formation occurs if one adds another particle to the system. The present paper extends this result to a much larger class of lattices and to a much broader region in the parameter space. Further, a lower bound for the energy gap between these pair states and the rest of the spectrum is established. The pair states are dominated by a subspace spanned by states containing a compactly localised pair. Overall, this strongly suggests localised pair formation in the ground states of the broad class of flat-band systems and rigorously proves it for some of the graphs in it, including the inhomogeneous checkerboard chain as well as two novel examples of regular two dimensional graphs. Physically, this means that the Wigner crystal remains intact if one adds a particle to it.

1 Introduction

1.1 Flat-Band Systems

Flat-bands are convenient to study strong correlation phenomena. Strong correlations occur if the interaction is large compared to the band width. In a flat-band system, the latter vanishes. Therefore, an arbitrary small interaction is already sufficient to produce strong correlation effects. That explains the huge interest in flat-band systems. On the other hand, simple approximation methods which treat the interaction as a perturbation or within a mean field approach may fail in flat-bands due to the high degeneracy in the single particle spectrum.
Therefore, many studies of flat-band systems use mathematically rigorous methods or more sophisticated approaches.

A prototypical class of lattices with a flat-band are line graphs with the kagome lattice as a prominent example [1]. Flat-band models have been studied theoretically for more than 40 years. In strongly correlated systems phenomena like ferrimagnetism [2], ferromagnetism [1,3–5], or macroscopic magnetization jumps [6] occur. Many of these phenomena in flat-band systems are today well understood, see e.g. the book by Tasaki [7] or the review on correlated flat-band systems by Derzhko et al. [8]. Since approximately 10 years, flat-band systems are studied also experimentally, mainly with the help of optical lattices, see e.g. [9]. And recently, flat-bands are also studied in twisted bilayer graphene at some magic angles, see e.g. [10].

Single particle eigenstates in flat band systems are typically localised. In a large class of systems, also on line graphs, there are strictly localised single particle eigenstates, which means that they vanish outside of a finite number of lattice sites. Often, these strictly localised states do not form an orthonormal basis, but even then one can construct a Wannier basis within the flat band. For the bosonic systems we discuss in this paper, the existence of strictly localised single particle eigenstates in the flat band is essential. The parameters are chosen such that these states do not overlap and are therefore orthogonal.

1.2 Bosons in Flat-Band Systems

Due to the recent progress of both theoretical [11–18] and experimental [14,17,19,20] nature, strongly correlated bosons on lattices have been gathering a lot of attention over the past few years. This has led to an improved understanding of several phenomena, including the Bose condensation and more recently the repulsive bosonic pair formation [21–24]. These papers investigate pair formation in very special classes of flat band systems.

Interestingly, the majority of rigorous results in flat band systems stems from fermionic systems or spin systems, whereas for bosonic systems less is known. One rigorous result for bosons in a flat band is the formation of a Wigner crystal at a critical density [25], which is valid for a large class of two-dimensional line graphs. Even below this critical density a full classification of all ground states is possible and one obtains a system with a residual entropy. Although the proof is non-trivial, the physical picture behind it is easy to understand. In a repulsive Hubbard model, where the interaction is purely local, particles in a flat band with strictly localised states can avoid each other if they sit in non-overlapping localised single particle states. Suppose one starts with a system with a single particle in one of the degenerate strictly localised states. Then one can put a next particle in one of the other strictly localised states which does not overlap with the first. Thereby, the interaction energy between the two particles remains zero. One can now add further particles to the system which all avoid each other. This procedure works up to a critical density. At the critical density the particles form a Wigner crystal.

The question is now, what happens if one adds additional particles to the system at the critical density. Various states like the formation of domain walls, charge density waves, or Bose–Einstein condensation have been proposed [26] for weak interactions. For strong repulsion, it has been shown that pair formation may occur [21–24]. These papers on bosonic pair formation in flat bands focus on specific lattices and are to some degree based on numerical analysis or approximations without rigid error bounds. A rigorous analytical proof on the other hand, even in specific systems, has proven to be difficult. One important step towards this goal was achieved by Mielke [18] and published in this journal. He proved
pair formation for hard-core bosons if one adds one particle to the system at the critical density of the Wigner crystal. But even there, the class of lattices is restricted to line graphs of graphs consisting of elementary cycles of length 4 and with an additional condition on the hopping matrix elements. The hopping $t'$ between the elementary cycles of length 4 must be sufficiently smaller than the hopping $t$ on those cycles. We will provide a complete explanation of these hopping terms and of the construction of the lattices below.

Although the proof for pair formation in these systems is non-trivial, the physical idea behind it is not difficult. At the critical density, the ground state is a Wigner crystal. If the interaction strength is large, it may be energetically favourable if an additional particle modifies the state only locally, so that the Wigner crystal remains intact up to a local modification. If the sites occupied by the particles of the Wigner crystal are a subset of all lattice sites, the additional particle may eventually be put on a set of the remaining sites, so called interstitials. But if the Wigner crystal occupies all lattice sites, then the only possibility for a small local perturbation of the Wigner crystal is to put the additional particle on a set of lattices sites which are already occupied by another particle. Under certain conditions, the two particles form an eventually localised pair state.

1.3 Purpose of the Present Paper and Main Results

In Ref. [18] two theorems were proven. The first shows the existence of pair formation in a certain class of lattices. The second shows that the pair states are localised and thus form an effective flat band. The latter result could only be shown for an even more restricted class of one-dimensional lattices like the chequerboard chain.

This paper substantially generalises the class of graphs considered in Ref. [18] to include, among other things, two dimensional graphs with doubly periodic boundary conditions, and fills a gap in Mielke’s proofs by showing that the preconditions of his second theorem, which concerns the overlap of ground states with states containing a localised pair, are actually fulfilled under the conditions of the first theorem, thereby completing a first rigorous proof for the existence of localised pair formation in the ground state of certain systems. In addition to the chequerboard chain, where only the aforementioned gap was missing for such a proof, the systems with completely provable localised pair formation also include some novel two dimensional lattices, of which two are explicitly constructed.

Furthermore, several improvements on a qualitative as well as a quantitative level have been achieved. The proof in Ref. [18] uses a Gerschgorin type argument. By introducing an asymmetrical norm in that argument and a simplified partitioning of the Fock space, we are able to increase the regime in which the theorem can be applied significantly, proved that both the energy of the lowest state and the gap to the next highest states are constant to first order in the secondary hopping parameter $t'$ and were able to derive a concrete lower bound for the overlap of the ground states with those of the uncoupled system (i.e. $t' = 0$). While the complete proofs of localised pair formation make use of a specific local symmetry and some form of a global translational or rotational invariance, the main result of this paper, which already strongly suggests the existence of localised pair formation, does not require any kind of global symmetry in the class of graphs to which it applies.

The actual physical meaning of the formation of localised pairs is that the Wigner crystal remains globally stable if one adds a particle to it. The localised pair replaces one of the particles in the crystal, which remains otherwise unchanged. This strongly suggests that even for a small but finite density of additional particles we only get local changes of the Wigner crystal. This holds for a hard-core repulsion. On the other hand, variational and numerical
studies strongly suggest other phases like charge density waves or Bose condensates for weak interaction [26]. This means that there must be a quantum phase transition at some interaction strength to the Wigner crystal.

Let us remark that the densities we are looking at are much lower than the densities at which for fermionic systems ferromagnetism occurs. In the Wigner crystal the particles avoid each other. Two occupied localised single-particle states do not have a lattice site in common. In contrast, in order to obtain ferromagnetism in a flat band systems, one needs a certain connectivity condition to be fulfilled, see Ref. [3–5]. As a consequence, the occupied single particle states must touch each other and the density must be higher.

The paper is structured as follows: The next section introduces the bosonic Hubbard model on line graphs and thereby specifies also the notation. It also states the main result of Ref. [25], the existence of the Wigner crystal at the critical density. Section 3 starts with some general remarks on the class of lattices considered in the main result. The main result is stated and proved in Sect. 3.3. Section 3.4 introduces a subclass of lattices with a local symmetry and the implications of the main results for lattices with this local symmetry are discussed. Finally, in Sect. 4, we explain some ideas how the results of this paper can eventually be generalised to fermionic systems or to other bosonic systems, but also the limitations of the present approach.

2 Hard-Core Bosons in Flat-Band Systems

2.1 The Hubbard Model

The Hamiltonian of the bosonic Hubbard model is given by

\[ H = \sum_{\{i,j\} \in E} t_{ij} b_i^\dagger b_j + \sum_{i \in V} U_i n_i (n_i - 1). \]  

(1)

Here \( V \) denotes the set of sites or vertices of a graph \( G = (V, E) \) and \( E \) is the set of edges. \( b_i^\dagger (b_i) \) denote the spinless bosonic creation (annihilation) operators on site \( i \), \( t_{ij} \) and \( U_i \) are real parameters while \( n_i = b_i^\dagger b_i \) is the particle number operator on site \( i \).

Often, one takes only nearest neighbour hopping, i.e. \( t_{ij} = t a_{ij} \) where \( A_G = (a_{ij})_{i,j \in V} \) is the adjacency matrix of the graph. It is defined as \( a_{ij} = 1 \) for \( \{i, j\} \in E \), \( a_{ij} = 0 \) otherwise.

Originally the model was independently proposed by Hubbard [27], Kanamori [28] and Gutzwiller [29] for fermionic systems and by Gersch and Knollman for bosonic systems [30]. While it strongly simplifies the interactions in a real solid, by reducing them to a hopping term with hopping strength \( t_{ij} \) and an on-site interaction \( U_i \), it already correctly predicts plenty of effects in real solids including ferromagnetism [1–5] and superconductivity [31] in the fermionic, and superfluid–insulator transition [32] in the bosonic model. In many situations one will choose a translation invariant graph, homogeneous on-site interaction and nearest-neighbour hopping (i.e. \( U_i = U \) for all \( i \in V \), \( t_{ij} = t \) for \( \{i, j\} \in E \) and \( \{i, j\} \in E \) iff \( |i - j| = 1 \)). However, in the class of models under consideration in this paper we will need two different hoppings and will not require any kind of translational invariance as we will see later on. For more general background information we refer to overviews by Lieb [33], Tasaki [34], Mielke [35], and the book by Tasaki [7], since we will focus our intention on a certain subclass of Hubbard models: those on line graphs with a flat band.
2.2 Flat-Band Systems

There are multiple ways of constructing Hubbard models with single particle flat bands. One method is mentioned by Sutherland [36]. Lieb’s famous theorems on the Hubbard model [2] contain flat bands, his construction is a special case of the one in Ref. [36]. As he points out, for any bipartite graph $G$ consisting of the two subgraphs $A$ and $B$ with $|B| > |A|$ the single particle Hamiltonian has at least $|V| - 2|A| = |B| - |A|$ zero eigenvalues. Consequently, in the translational invariant case and for $|B||A| \propto |V|$, there is at least one flat band in the middle of the spectrum. He was able to give the first proof of itinerant ferrimagnetism for these systems in case of a repulsive interaction (i.e. $U_i > 0$ for all $i$). Although here ferromagnetism only occurs in a weaker sense of the spin being an extensive quantity and is in fact not saturated, this example already shows why Hubbard models with flat bands are such interesting objects.

Of particular interest in the last years and focus of this work are Hubbard models with flat bands at the bottom of the spectrum. One class of graphs with such a low lying flat band is formed by decorated lattices, as they are treated for example by Tasaki [4]. A second class are line graphs of bipartite and two-connected graphs [3].

As one can see from these examples, early research into graphs with flat bands focused heavily on fermionic systems. However, recent development has shown that bosons might be just as interesting to study on them, as we will discuss later on.

2.3 Line Graphs

Since line graphs are at the heart of the present work we will go over their construction. Our explanations are based on those presented in Ref. [18]. We generalise it in two ways. First, we also include toroidal graphs (i.e. graphs that can be drawn on a torus without having any edges crossing another one). Second, Mielke treated only line graphs of bipartite graphs. We allow also for line graphs of non-bipartite graphs. We also refer to this work for greater details on some aspects of the construction.

We start with some finite, toroidal and two-connected graph $G = (V(G), E(G))$. It should be noted that the set of graphs that are both finite and planar is a subset of toroidal graphs, therefore this work applies to them as well, while it also includes two dimensional graphs with doubly periodic boundary conditions (DPBC), which are not planar. Once again $V(G)$ and $E(G)$ denote the set of vertices and edges of $G$. The line graph of $G$ is now given by $L(G) = (V(L(G)), E(L(G)))$ with $V(L(G)) = E(G)$ and $E(L(G)) = \{[e, e']|e, e' \in E(G), |e \cap e'| = 1\}$. For a more intuitive understanding, one can imagine the construction of the line graph from the original graph in the following way: We draw a vertex on each edge of the toroidal representation of $G$ and connect two vertices by an edge in $L(G)$ if and only if the edges they are drawn upon have a common vertex in the original graph. An illustration of the process for a simple square lattice can be found in the left two images of Fig. 1. Figure 2 shows a second example for the construction where interstitial sites occur.

2.4 The Subgraph $L(G_1)$

Before we can define the Hamiltonian on the line graph, we first need to introduce some additional terms. The toroidal representation of the original graph $G$ decomposes the plane into faces and since a torus is a bounded object, all surfaces are bounded as well. Most of the faces can be contracted to a point, such faces are called null-homotopic [37]. We call the set
Fig. 1 The left two images show a simple square lattice $G$ and its line graph $L(G)$. The members of $F_1(G)$, $C_1$, $C_2$, $C_3$, and $C_4$ are coloured in green and the right two images show the graph $G_1$ and its line graph $L(G_1)$. Figure taken from [18] (Color figure online)

Fig. 2 The top left figure shows the hexagonal chain $G$, the top right its line graph $L(G)$. The members of $F_1(G)$ are $C_1, C_3$. The bottom left figure shows the graph $G_1$, the bottom right its line graph $L(G_1)$, consisting of the two cycles $C_1$ and $C_3$. Also shown are the four interstitials, they are not part of $L(G_1)$

of all null-homotopic faces $F(G)$ and by $C \in F(G)$ we denote both the surface itself and its boundary. Since $G$ is connected, there is at most one face that can not be contracted to a point. This face is one-homotopic [37]. We call the elements of $F(G)$ elementary cycles (they are indeed cycles since $G$ is toroid). Since the elementary cycles $C$ are subgraphs of $G$, we can define their set of vertices $V(C)$ and their set of edges $E(C)$. We now look at the colouring of the surfaces. We can colour two surfaces $C$ and $C'$ with the same colour if they have no edge in common (i.e. $E(C) \cap E(C') = \emptyset$).

Now let $F_1(G) \subset F(G)$ be the largest set of surfaces that can be coloured with the same colour and that all have even cycle length. If there are multiple of these sets, we just choose one of them. Note that for a bipartite graph the second condition is trivially fulfilled for any subset of $F(G)$ since all cycles in bipartite graphs have even length. By $E_1(G)$ we denote the set of edges, which form the boundaries in $F_1(G)$, $E_1(G) = \bigcup_{C \in F_1(G)} E(C) \subset E(G)$. Every edge in $E(G)$ belongs to a cycle in $F_1(G)$ if all faces that are not in $F_1(G)$, including the potential one-homotopic one, can be coloured by a single colour. Otherwise $E(G) \setminus E_1(G)$ is non-empty and we call its elements interstitials. For the example in Fig. 1 there are no interstitials. The example shown in Fig. 2 has four interstitials.

Additionally we define the graph $G_1$ which consists of all vertices and edges from cycles in $F_1(G)$ where we consider the vertices from different cycles to be distinct, even if they...
correspond to the same vertex in $G$ (see Fig. 1 for an illustration of the process). Note that there is a one-to-one mapping between $E(G_1)$ and $E_1(G)$ since every edge in $E_1(G)$ belongs to exactly one cycle in $F_1(G)$ (otherwise they could not all be coloured by the same colour) and therefore we write $E(G_1) = E_1(G)$ while acknowledging the slight imprecision of the expression.

The same can however not be said about $V(G_1)$ and $V_1(G)$ since one vertex in $V_1(G)$ can be counted for multiple times in $V(G_1)$. Therefore, $V(L(G_1)) = E(G_1) = E_1(G) \subset E(G) = V(L(G))$ and two edges in $E(G_1)$, which are connected to a common vertex are also connected in $E(G)$, hence $E(L(G_1)) \subset E(L(G))$. Furthermore it should be noted that since $G_1$ consists of isolated cycles, it is isomorphic to its line graph, meaning that any cycle $C \in F_1(G)$ corresponds to a cycle of the same length in $L(G)$ and every edge in $C \in F_1(G)$ corresponds to a vertex on the corresponding cycle in the line graph. Consequently we conclude that $L(G_1)$ is a subgraph of $L(G)$ consisting of isolated cycles of even length.

### 2.5 The Hubbard Hamiltonian

We can now define our Hamiltonian on the line graph $L(G)$. The class of graphs we consider are toroidal graphs. In order to have non-trivial graphs only we restrict this class further to connected graphs which have at least one face with an even cycle, so that $F_1(G)$ is not empty.

$$H = \sum_{\{e,e'\} \in E(L(G))} t_{ee'} b_e^\dagger b_{e'} + \sum_{e \in V(L(G))} U_e n_e (n_e - 1),$$

with hopping strengths

$$t_{ee'} = \begin{cases} t & \text{if } \{e, e'\} \in E(L(G_1)) \\ t' & \text{if } \{e, e'\} \in E(L(G)) \setminus E(L(G_1)). \end{cases}$$

This means we allow for hopping strength $t$ between the edges of elementary cycles and $t'$ on all other edges of the line graph (see Fig. 3). Throughout this paper we choose $t > 0$ and $t \geq t' \geq 0$ and we will note additional restrictions whenever they become necessary. Furthermore, we will only consider the hard-core limit $U_e \to \infty$ for all $e$ such that at maximum one particle can be placed on each vertex in $L(G)$. Hence $H$ can be written as

$$H = P_{\leq 1} \sum_{\{e,e'\} \in E(L(G))} t_{ee'} b_e^\dagger b_{e'} P_{\leq 1},$$

where $P_{\leq 1}$ denotes the projector on the subspace of the Fock space with at maximum one particle on each vertex. This allows to rewrite our Hamiltonian to

$$H = t P_{\leq 1} \sum_{C \in F_1(G)} H_C P_{\leq 1} + t' P_{\leq 1} \sum_{\langle C,C' \rangle} H_{C,C'} P_{\leq 1} + t' H_1.$$  

Here $H_C$ describes the hopping on the elementary cycle $C$, $H_{C,C'}$ the hopping between two neighbouring cycles $C$ and $C'$ (i.e. $V(C) \cap V(C') \neq \emptyset$) and $H_1$ the hopping to, from and between any interstitials.
2.6 Example: The Chequerboard Chain

There are many different graphs within this class, but to get a more concrete idea, we will have a closer look into one specific: the chequerboard chain. It is defined as the line graph of a chain of corner sharing squares and consists of cycles of length $|C| = 4$, which are connected by complete graphs. It is depicted in Fig. 3. As it was also explained in Ref. [18], we can construct compactly localised one particle eigenstates $\psi_C$ with eigenvalue $-2t$ independently of $t'$ on any cycle $C$ in the line graph by labeling an arbitrary vertex with the index 1 and then we number them clockwise. Now we choose $\psi_C = \frac{1}{\sqrt{|C|}} \sum_{i=1}^{|C|} (-1)^i b_i^\dagger(C)|0\rangle$, where $b_i^\dagger(C)$ is a bosonic creation operator on site $i$ of cycle $C$; i.e. the absolute value is the same along the cycle while the sign alternates. It is easy to see that they are indeed eigenstates on $C$ with eigenvalue $-2t$ and the alternating signs ensure that the hopping terms to neighbouring cycles vanish. For $t' < t$ these are unique single particle ground states of the system. For $t' = t$ they remain single particle ground states, in case of periodic boundary conditions (PBC) they are no longer unique though. As the eigenstates on different cycles do not overlap, we can construct multi particle ground states from them, simply by putting at maximum one particle in the ground state of each cycle $C$. Again it turns out that these are the only ground states for $t' < t$. This is possible until there are $N = |F_1(G)|$ particles in the system. We call this the critical density.

2.7 Ground States at or Below the Critical Density

In fact this result holds for the general class of graphs we are looking at. Mielke proved this for the class he was treating in Ref. [18] and the proof straightforwardly generalises to the larger class considered here. The precise statements are:

**Proposition 1** Let $G = (V(G), E(G))$ be a finite two-connected toroidal graph. Then for the Hubbard model on its line graph as defined in (5) the following holds: For $t > t' \geq 0$ the ground state eigenvalue of the single particle Hamiltonian is $-2t$ and is $|F_1(G)|$-fold degenerate. For any $C \in F_1(G)$ a single particle ground state is given by

$$\psi_C = \frac{1}{\sqrt{|C|}} \sum_{i=1}^{|C|} (-1)^i b_i^\dagger(C)|0\rangle,$$

and its eigenvalue does not depend on $t'$. These states form a complete set of single particle ground states of (5) if $t > t' > 0$. 

---

Fig. 3 Illustration of the chequerboard chain: hopping on the cycles with hopping strength $t$ is indicated by a continuous red line, hopping between them with hopping strength $t'$ by a dashed red line and for the graph of corner sharing graphs, whose line graph the chequerboard chain is, thin grey lines in the background are used (Color figure online)
The single-particle eigenstates of the Hamiltonian (4) are the eigenstates of the hopping matrix \( T = (\langle e e' \rangle)_{e, e' \in E} \). This matrix can be written as \( T = t' A_{G} + (t - t') A_{G_1} \). As introduced above, \( A_{G} \) denotes the adjacency matrix of the line graph \( L(G) \). To construct the ground states of \( T \), we have once again labeled an arbitrary edge of \( C \) (corresponding to a vertex in the line graph) with 1 and then numbered the others consecutively. \( C \) is a cycle of even length, since all cycles in \( F_1(G) \) have even length. The state \( \psi_C \) is a state which has an alternating sign on the vertices in \( C \) and vanishes all other vertices on \( L(G) \). These states are eigenstates of both, \( A_{G} \) and \( A_{G_1} \), with eigenvalue \(-2\), since any edge in \( G \setminus C \) that is connected to \( C \) is connected to exactly two neighbouring edges in \( C \), so that any hopping to other edges cancels out, see also Refs. [1,3]. They are even ground states since for line graphs, the adjacency matrix is bounded from below by \(-2\). Further, since \( L(G_1) \) is a set of disjoint cycles, these states are the only ground states of \( A_{G_1} \). They are therefore also the only ground states of the hopping matrix \( T \) if \( t - t' > 0 \).

It should be noted that these states remain ground states in the homogeneous case \((t = t')\), although they are no longer unique in general. More precisely, if \( G \) is planar, the ground states remain unique only if \( F(G) \setminus F_1(G) \) contains no cycles of even length and if not, we need to additionally demand that no cycle that is a boundary of the potential one-homotopic face is of even length. Otherwise, additional linearly independent ground states can be placed on the line graphs of the corresponding cycles in the same manner as for the cycles in \( F_1(G) \). This also explains, why for the homogeneous checkerboard chain the ground states remain unique for open boundary conditions, as its underlying graph is planar and \( F(G) \setminus F_1(G) = \emptyset \). On the other hand, for PBC the square chain surrounds another face in \( F \) and vanishes all other vertices on \( L(G) \). This is equivalent to \( E(C) = t N \).

For the multi-particle ground states at or below the critical density the result is given by:

**Proposition 2** For \( t > t' > 0 \) and \( N \leq |F_1(G)| \), the ground states of the Hubbard model on line graphs of finite two-connected toroidal graphs with \( N \) hard-core bosons are the same as the ones for \( t' = 0 \) and the ground state energy is \(-2t N \).

The proof also generalises directly from Mielke’s proof to the broader class in question. Similar to the hopping matrix \( T \) in Proposition 1, the Hamiltonian in (4) can be decomposed into one part \( \propto t' \) and a second part \( \propto (t - t') \). The ground states for \( t' = 0 \) remain the ground states of the full Hamiltonian because they minimize the first part of the Hamiltonian \( \propto t' \) and are the only ground states of the second part \( \propto (t - t') \). Once again in the homogeneous case \( t' = t \) these states remain ground states but are no longer unique in general. For more information on the homogeneous case at or below the critical density, we refer to Ref. [25].

### 3 Hard-Core Bosons Above the Critical Density

#### 3.1 Additional Conditions

As we have seen, we are able to characterize the ground states up to the critical density. The naturally occurring question is what happens if we add an additional particle beyond the critical density. To at least give a partial answer to that question, we need to establish some additional constraints on the class of graphs we are treating. First of all, we demand that there are no interstitials present on the line graph \( L(G) \). This is equivalent to \( \bigcup_{C \in F_1(G)} E(C) = \)}
As we have seen, it can also be expressed as it being possible to colour the faces of $G$ (including the potential one-homotopic face) with just two colours and $F_1(G)$ containing all members of one colour. Additionally, we demand all cycles $C$ in $F_1(G)$ to be of length 4. It should be noted that all other faces in $F(G)$ might have boundaries of arbitrary length.

Intuitively one can imagine the construction of an arbitrary graph in this class as follows: We start with a simple torus, which we colour in one colour, e.g. yellow, and then place a single quadrilateral on it, which we w.l.o.g. colour in blue. Now we continue to place additional blue quadrilaterals on the torus which need to obey the following conditions: they need to be connected to the other quadrilaterals (i.e. if we number the quadrilaterals according to the order in which we place them on the torus and denote them by $C_k$, then for any $k$ there needs to be some $1 \leq i < k$ such that $V(C_k) \cap V(C_i) \neq \emptyset$). It must not share an edge with any of the quadrilaterals (i.e. $E(C_k) \cap E(C_i) = \emptyset$ for $i \neq k$; this allows for quadrilaterals to have the same colour). Last they must not intersect with any of the previously placed quadrilaterals (i.e. leave the toroidal structure of the graph intact). Now one repeats this process arbitrarily often and ends up with a graph that is toroidal, has only two colours and where the blue surfaces make up the elements of $F_1(G)$ and the potential remaining one-homotopic surface is coloured in yellow. Therefore, this graph has no interstitials, is two-connected (since removing any edge from a quadrilateral still allows for another path along the other three edges of the quadrilateral) and toroidal by construction. See Fig. 4 for an example of this construction including the colouring of the faces.

For later purpose we introduce the quantity $c(C)$ for any cycle $C \in F_1(G)$. It denotes the number of cycles in $F_1(G)$ which have a vertex with $C$ in common. $c(G)$ denotes the maximum of all $c(C)$. For the graph depicted in Fig. 4, we have $c(C) = 4$ for all $C$ and therefore $c(G) = 4$. For the chequerboard chain we have $c(C) = 2$ except for the edges and $c(G) = 2$.

Both the one dimensional chequerboard chain and its two dimensional analogue, the chequerboard lattice, are a member of this class for arbitrary boundary conditions. So are all other examples mentioned in Fig. 6 (for the regularly shaped ones once again regardless of boundary conditions) and Fig. 4 features a member of the class, which is not bipartite. Other interesting cases like the kagome lattice are however not, as its cycles have length six and three colours are necessary to colour its underlying graph, the honeycomb lattice. The limitation to cycles of length 4 could be avoided without much theoretical difficulty. However, the results become generally worse with longer cycles, as it is energetically less expensive to put multiple particles into one cycle and mixed cycle lengths would require additional treatment. The reason we are excluding the existence of interstitials is that they allow for additional possibilities for the additional particle to spread to.

### 3.2 Solution for $t' = 0$

For $t' = 0$ our Hamiltonian reduces to

$$H_{F_1(G)} = t \sum_{C \in F_1(G)} H_C P_{\leq 1}. \quad (7)$$

Under conditions stated above our initial question (What would happen if one particle is added to a Wigner crystal formed on the line graph?) has an obvious answer for $H_{F_1(G)}$: The additional particle can simply be put on any cycle $C \in F_1(G)$ to form the two particle ground state (which has energy $-2\sqrt{2}t$, see $\gamma^\dagger_s(C)$ in Table 1 for the precise form of its creation operator). All other single particle states which all together form the Wigner crystall
remain unchanged. There is exactly one particle on each of the remaining cycles. We call these ground states $\psi_k$, $1 \leq k \leq N - 1$ and they span any ground state for $t' = 0$. We denote this subspace by $\Omega_0$ and the projector onto it by $P^{(0)}$. These states are degenerate and separated by a gap from the rest of the spectrum.

Since the graph only consists of isolated cycles of length 4 all eigenstates can be written as products of eigenstates on the isolated cycles. We can therefore write all eigenstates of the $N = |F_1(G)| + 1$ as a product of one cycle eigenstates and can thereby not only state the ground states but solve the system completely. As we will make use of these eigenstates in the proof of the main result we introduce a notation for them here. Since each cycle has 4 vertices and each can either be empty or filled, there are $2^4$ linearly independent one cycle eigenstates. Their creation operators are listed as $\gamma_i^\dagger(C)$ in Table 1 (as in Fig. 3 we label an arbitrary vertex with 1 and number the other vertices clockwise) and we denote the numbers of particles in the $i$th state by $N_i$ and its energy by $\tilde{E}_i$(the tilde is used to distinguish it from the energy of the full system). We denote the eigenstates of $HF_1(G)$ by $\psi_k$ and their energies by $E_k$ and order them such that the energies are nondecreasing, i.e. $E_k \leq E_{k+1}$. If the cycle $C$ is occupied by the $i$th eigenstate in $\psi_k$, we write $\beta_k^\dagger(C) = \gamma_i^\dagger(C)$, $N_k(C) = N_i$ and $E_k(C) = \tilde{E}_i$. For all $k$ we can then write

$$\psi_k = \prod_{C \in F_1(G)} \beta_k^\dagger(C) |0\rangle, \quad (8)$$

$$N = \sum_{C \in F_1(G)} N_k(C), \quad (9)$$

and

$$E_k = \sum_{C \in F_1(G)} E_k(C). \quad (10)$$

As it will also prove handy later on we also introduce $e_i$, the difference between the energy $\tilde{E}_i / T$ of the $i$th one cycle eigenstate (normalised by $t$) and the again normalised energy of distributing all $N_i$ particles in the state in one particle ground states,

$$e_i = \frac{\tilde{E}_i}{t} + 2N_i. \quad (11)$$
Table 1: The creation operators, $\gamma_i^\dagger$, are listed for all single cycle eigenstates, the numbering of the vertices on the cycle are understood to be clockwise increasing staring at an arbitrary vertex.

| $i$ | $\gamma_i^\dagger$ | $s_i$ | $e_i$ | $\mu_i$ | $v_i$ |

The $s_i$ function as weights for the norms of the states and are introduced in Eq. (38) and (42). $\alpha$ and $d$ are defined in Eq. (55). The $e_i$ are introduced in Section 3.2. The $\mu_i$ ($v_i$) represent the $1$-norm of the states after a boson jumps from (to) that state and include the weights.
The values of the $e_i$ are also listed in Table 1. Accordingly we write $e_k(C) = e_i$ if $C$ is occupied by the $i$th eigenstate in $\psi_k$. We can then write the energies as

$$E_k = \left(-2N + \sum_{C \in F_1(G)} e_k(C)\right)t.$$  \hfill (12)

In particular it should be noted that the ground states ($1 \leq k \leq N - 1$) are of the form

$$\psi_k = \gamma_5^\dagger(C_k) \prod_{C \neq C_k} \gamma_1^\dagger(C)|0\rangle,$$  \hfill (13)

and their energy is

$$E_k = -(2N - e_5)t.$$  \hfill (14)

### 3.3 Main Result

The two particle one cycle ground state is no longer an eigenstate for $t' > 0$. But for not too large $t'$ we can show that the lower energy levels of the Hamiltonian are still separated by a gap from the rest of the spectrum and the number of the corresponding eigenstates is the same as for $t' = 0$. In this section we state and prove our main result. Under the conditions set out at the beginning of this section we now show the following rigorous bounds for the lower energy levels of $H$ as well as for the gap to the rest of the spectrum up to a certain $t'_{\text{sup}}$ and show that the lower energy states are dominated by the ground states of the uncoupled system.

**Theorem 1** (Main result) *Let $G$ be a two-connected toroidal graph with $\bigcup_{C \in F_1(G)} E(C) = E(G)$ and $|C| = 4$ for all $C \in F_1(G)$. Let

$$H = t \sum_{C \in F_1(G)} H_C P_{\leq 1} + t' \sum_{C \neq C' \in F_1(G)} H_{C,C'} P_{\leq 1},$$

be the Hamiltonian with $N = |F_1(G)| + 1$ hard-core bosons on $L(G)$, let $E_k$ and $\psi_k$, $1 \leq k \leq \binom{N-1}{N}$, be the energy levels and corresponding eigenstates of $H$ such that the $E_k$ are nondecreasing, i.e. $E_k \leq E_{k+1}$ for all $k$ and such that the $\psi_k$ form an orthonormal basis. Then the following holds for $t' < t'_{\text{sup}}$:

1. For $1 \leq k \leq N - 1$ the energy levels $E_k$ satisfy

$$-(2N - e_5)t - b\sqrt{e(G)}\eta_+(t')t' \leq E_k \leq -(2N - e_5)t.$$  \hfill (16)

2. There is a gap $\Delta = E_N - E_{N-1}$ between these lowest energies and the rest of the spectrum satisfying

$$\Delta \geq e_5 t - \left(a \frac{t'}{t} \frac{e^2(G)}{\sqrt{e(G)}} + b \eta_-(t') \sqrt{e(G)}\right)t',$$  \hfill (17)

uniformly in $N$.

3. For $1 \leq k \leq N - 1$ the eigenstates satisfy

$$\|P^{(0)} \psi_k\|_2 \geq (1 + \eta_2(t'))^{-\frac{1}{2}}.$$  \hfill (18)
Here

\[
\eta\pm(t') = \frac{2b\sqrt{c(G)}}{e_{5} - a\tilde{t}^{2}c^{2}(G)} + \sqrt{(e_{5} - a\tilde{t}^{2}c^{2}(G))^{2} + 4b^{2}\tilde{t}^{2}c(G)}

\]

\[
\tilde{t} = \frac{1}{2} \eta\pm(t')
\]
It is important to note that the vector norms on the $\Omega_i$ can be chosen arbitrarily and independent of each other. Also, since
\[
\left(\| B^{-1}\| \right)^{-1} = \min_{\| x \|=1} \| Bx \|, \quad (24)
\]
for any invertible matrix $B$, it is the natural continuation to define $\left(\| B^{-1}\| \right)^{-1} = 0$ for singular $B$.

Once again let $\Omega_0$ be the space spanned by the ground states of $H_{F_1(G)}$, $\Omega_1$ its orthogonal subspace, $P^{(1)} = 1 - P^{(0)}$ the corresponding projector and $n_i = \dim(\Omega_i)$ for $i = 0, 1$. Then we can write $H$ as
\[
H = \begin{pmatrix} H^{(0)} & H^{(01)} \\ H^{(10)} & H^{(1)} \end{pmatrix} = \begin{pmatrix} P^{(1)} H P^{(0)} & P^{(0)} H P^{(1)} \\ P^{(1)} H P^{(0)} & P^{(1)} H P^{(1)} \end{pmatrix}. \quad (25)
\]

The bases we use are $\{ \psi_k^{(0)} \}_{1 \leq k \leq n_0} = \{ \psi_k \}_{1 \leq k \leq n_0}$ for $\Omega_0$ and $\{ \psi_k^{(1)} \}_{1 \leq k \leq n_1} = \{ \psi_k^{n_0} \}_{1 \leq k \leq n_1}$ for $\Omega_1$. The $\psi_k$ are the eigenstates of $H_{F_1(G)}$ as introduced in Sect. 3.2. Furthermore we choose our norms as $\| \cdot \|_{\Omega_0} = \eta \| \cdot \|_2$ and $\| \cdot \|_{\Omega_1} = \| \cdot \|_2$, where $\| \cdot \|_2$ is the Euclidean norm on $\Omega_i$, $i = 0, 1$ and $\eta$ a positive real number, which we will specify later on.

We also define the two sets
\[
\Lambda_0 = \left\{ \lambda \in \mathbb{R} \mid \left( \| (H^{(0)} - \lambda I^{(0)})^{-1} \| \right)^{-1} \leq \| H^{(01)} \| \right\}, \quad (26)
\]
and
\[
\Lambda_1 = \left\{ \lambda \in \mathbb{R} \mid \left( \| (H^{(1)} - \lambda I^{(1)})^{-1} \| \right)^{-1} \leq \| H^{(10)} \| \right\}, \quad (27)
\]
that contain all energy levels of $H$ by the above theorem. Now our goal is to show that
\[
\sup \Lambda_0 < \inf \Lambda_1, \quad (28)
\]
for all $t' < t'_{\text{sup}}$ and an appropriate choice of $\eta$. Since we know that for $t' = 0$ there are exactly $|F_1(G)|$ eigenvalues of $H$ in $\Lambda_0$ and the eigenvalues vary continuously in $t'$, this number cannot change as long as the two sets are disjoint. Therefore, we will have proven the separation of the lowest eigenvalues from the others and will also be able to establish an upper boundary for their values.

We start by looking at $\Lambda_0$. Since $H^{(0)} = -(2N - e_5) t I^{(0)}$ (the $e_i$ were introduced in Sect. 3.2) we have
\[
\left( \| (H^{(0)} - \lambda I^{(0)})^{-1} \| \right)^{-1} = \frac{1}{-(2N - e_5) t - \lambda}. \quad (29)
\]

Also
\[
\| H^{(01)} \| = \max_{\psi \in \Omega_1, \| \psi \|_{\Omega_1} = 1} \| H^{(01)} \psi \|_{\Omega_0}
= \eta \sqrt{\frac{\rho \left( (H^{(01)})^* H^{(01)} \right)}{\rho \left( H^{(01)} H^{(01)} \right)}}
= \eta \sqrt{\frac{\rho \left( H^{(01)} H^{(10)} \right)}{\rho \left( H^{(01)} H^{(10)} \right)}}. \quad (30)
\]
where $\rho(\cdot)$ is the spectral radius of a matrix. The third equality holds because the non-zero eigenvalues of $(H^{(01)})^\dagger H^{(01)}$ and $H^{(01)}(H^{(01)})^\dagger$ are the same. The last equality holds since $H$ is Hermitian. The spectral radius equals the largest eigenvalue of $H^{(01)}H^{(10)}$ since $H^{(01)}H^{(10)}$ is a positive matrix. The eigenvalues of $H^{(01)}H^{(10)}$ can be explicitly calculated and the corresponding eigenvectors are just the $\psi_k^{(0)}$.

To illustrate the calculation, we perform it explicitly for a system consisting of only two (neighbouring) cycles and then note how it generalises to a system with arbitrary size. Let $L(G_0)$ be this line graph. Its vertices can be seen in Fig. 5.

Let $\psi_1^{(0)}$ be the ground state with two particles on $C_1$ and one particle on $C_2$, i.e. $\psi_1^{(0)} = \gamma_1^\dagger(C_2)\gamma_5^\dagger(C_1)|0\rangle$. Then

$$H^{(10)}\psi_1^{(0)} = t' P_{\leq 1} H_{C_1,C_2} \psi_1^{(0)} = t' P_{\leq 1} \left( b_1^\dagger(C_2) + b_4^\dagger(C_2) \right) \gamma_1^\dagger(C_2) (b_2(C_1) + b_3(C_2)) \gamma_5^\dagger(C_1)|0\rangle$$

$$= t' \left( \left( \frac{1}{2} - \frac{1}{\sqrt{2}} \right) \gamma_4^\dagger(C_1) + \frac{1}{2\sqrt{2}} \left( \gamma_2^\dagger(C_1) - \gamma_3^\dagger(C_1) \right) \right) \frac{1}{\sqrt{2}} \left( \gamma_6^\dagger(C_2) - \gamma_7^\dagger(C_2) \right) |0\rangle.$$ 

(31)

So the additional boson jumps to $C_2$ under $H^{(10)}$. Applying $H^{(01)}$ lets the particle jump back,

$$H^{(01)}H^{(10)}\psi_1^{(0)} = t' P^{(0)} P_{\leq 1} H_{C_1,C_2} \left( H^{(10)} \psi_1^{(0)} \right) = t'^2 \left( 1 - \frac{1}{\sqrt{2}} \right) \gamma_4^\dagger(C_2) \gamma_5^\dagger(C_1)|0\rangle$$

(32)

It should be noted that $P_{\leq 1} H_{C_1,C_2}$ creates several other terms with two particles in $C_1$ and one particle in $C_2$ as well, but as they are all non-ground states, they get suppressed by $P^{(0)}$.

For a general $L(G)$ only little changes compared to this most simple situation. If $C_k$ is the cycle occupied by two particles in $\psi_k^{(0)}$, then $H_{C,C'}$ only produces nonvanishing terms if either $C$ or $C'$ is $C_k$, i.e. only jumps to cycles neighbouring $C_k$ play any role. Because each of the neighboring cycles are equivalent, each of them contributes the same amount with the same sign. The contributions of the different neighboring cycles simply add up. If some neighbouring cycle $C$ of $C_k$ connected to any other cycle, $C'$, $H^{(01)}$ will also create some terms, where the additional particles jumps to $C'$ before $P^{(0)}$ is applied. However, these jumps will leave the states of $H^{(10)}\psi_k^{(0)}$ on $C_k$ invariant and, as illustrated in Eq. (31), there
is no component of the single particle ground state on $C_k$ in $H^{(10)}\psi_k^{(0)}$ and therefore these terms get also suppressed by $P^{(0)}$.

Hence the $\psi_k^{(0)}$ satisfy the eigenvalue equation

$$H^{(01)}H^{(10)}\psi_k^{(0)} = t'^2 c(C_k) \left(1 - \frac{1}{\sqrt{2}}\right) \psi_k^{(0)}.$$  \hspace{1cm} (33)

Since $H^{(01)}H^{(10)}$ is an $n_0 \times n_0$ matrix and there are $n_0$ of the $\psi_k^{(0)}$, they are all eigenvectors and, by definition of $c(G)$, the spectral radius is given by

$$\rho(H^{(01)}H^{(10)}) = t'^2 c(G) \left(1 - \frac{1}{\sqrt{2}}\right).$$  \hspace{1cm} (34)

Defining $b^2 = \left(1 - \frac{1}{\sqrt{2}}\right)$, we can write

$$\|H^{(01)}\| = \eta b\sqrt{c(G)}t'.$$  \hspace{1cm} (35)

Combining (29) and (30) we get

$$\Lambda_0 = \left\{ \lambda \in \mathbb{R} \mid -(2N - e_5)t - \lambda \leq \eta b\sqrt{c(G)}t' \right\},$$  \hspace{1cm} (36)

and subsequently

$$\sup \Lambda_0 = -(2N - e_5)t + \eta b\sqrt{c(G)}t'.$$  \hspace{1cm} (37)

For $\Lambda_1$ the calculation is not as straightforward. $H^{(1)}$ is non-diagonal and therefore we need to look at $\left(\left\| (H^{(1)} - \lambda I^{(1)})^{-1}\right\|\right)^{-1}$ more carefully. We define the vector norms $\|x\|_1 = \sum_{i=1}^n |x_i|$ and $\|x\|_\infty = \max_i |x_i|$. Then their derived matrix norms, $\|A\|_i = \max_{\|x\|_1=1} \|Ax\|_i$, $i = 1, \infty$ satisfy $\|A\|_\infty = \|A^\dagger\|_1$. Let $S$ be a diagonal Matrix with $S_{kk} > 0$ for all $k$. Then $S$ is non-singular and we can apply Proposition 1.1 of [39] to achieve the following lower bound.
\[
\left( \left\| (H^{(1)} - \lambda I^{(1)})^{-1} \right\| \right)^{-1} 
\geq \left( \left\| S \left( (H^{(1)} - \lambda I^{(1)})^{-1} \right) \right\|_{1} \left\| (S^{-1} (H^{(1)} - \lambda I^{(1)}) S)^{-1} \right\|_{\infty} \right)^{-\frac{1}{2}} 
= \left( \left\| S \left( (H^{(1)} - \lambda I^{(1)})^{-1} \right) \right\|_{1} \right)^{-1} 
= \min_{\|\psi\|=1} \left\| S \left( (H^{(1)} - \lambda I^{(1)})^\dagger \right) \psi \right\|_{1} 
= \min_{\|\psi\|=1} \sum_{i=1}^{n_1} \left| (S(H^{(1)} - \lambda I^{(1)})^\dagger)_{ii} \psi_i + \sum_{j \neq i} (SH^{(1)}S^{-1})_{ij} \psi_j \right| 
= \min_{\|\psi\|=1} \sum_{i=1}^{n_1} \left( (H^{(1)}_{ii} - \lambda) \psi_i + \sum_{j \neq i} S_{ii} H^{(1)}_{ij} S_{jj}^{-1} \psi_j \right) 
\geq \min_{\|\psi\|=1} \sum_{i=1}^{n_1} \left( (H^{(1)}_{ii} - \lambda) \psi_i - \sum_{j \neq i} S_{ii} H^{(1)}_{ij} S_{jj}^{-1} \psi_j \right) 
= \min_{\|\psi\|=1} \sum_{i,j=1}^{n_1} |S_{ii} H^{(1)}_{ij} S_{jj}^{-1} - \lambda \delta_{ij} | |\psi_j| (2\delta_{ij} - 1) 
\geq \min_{1 \leq k \leq n_1} \left( H^{(1)}_{kk} - \lambda \right) - \sum_{i \neq k} \left| S_{ii} H^{(1)}_{ik} S_{kk}^{-1} \right| \min_{\|\psi\|=1} \sum_{j=1}^{n_1} |\psi_j| 
= \min_{1 \leq k \leq n_1} \left( H^{(1)}_{kk} - \lambda \right) - \sum_{i \neq k} \left| S_{ii} H^{(1)}_{ik} S_{kk}^{-1} \right). 
\]

We are interested in \( \inf \Lambda_1 \) and \( \lambda = -(2N - 2e_5) t \) fulfils

\[
\min_{1 \leq k \leq n_1} \left( H^{(1)}_{kk} - \lambda \right) - \sum_{i \neq k} \left| S_{ii} H^{(1)}_{ik} S_{kk}^{-1} \right| \leq \left\| H^{(10)} \right\|, 
\]

trivially for all \( t' \), as it is the lowest non ground state eigenvalue of \( H_{F_1(G)} \). Therefore, we now assume \( \lambda \leq -(2N - 2e_5) t \) and note \( \lambda \leq H^{(1)}_{kk} \) for all \( 1 \leq k \leq n_1 \). Consequently we can drop the absolute value in the first term without changing its value. Our next goal is to rewrite the argument of (39) as a constant independent of \( k \) plus a sum over the connections between neighbouring cycles. To achieve this we make use of the \( e_i \) as introduced in Sect. 3.2. Recall that the base states of \( \Omega_1 \) are \( \{\psi_k^{(1)}\}_{1 \leq k \leq n_1} = \{\psi_{k+n_0}\}_{1 \leq k \leq n_1} \), the non ground state eigenstates of \( H_{F_1(G)} \). Accordingly we define \( e_k^{(1)}(C) = e_{k+n_0}(C) \) and \( N_k^{(1)}(C) = N_{k+n_0}(C) \). This allows us to rewrite \( H^{(1)}_{kk} \) as

\[
H^{(1)}_{kk} = \sum_C \left( e_k^{(1)}(C) - 2N_k^{(1)}(C) \right) t = -2Nt + \sum_C e_k^{(1)}(c)t, 
\]

since \( \sum_C N_k^{(1)}(C) = N \) for all \( k \) by definition. The values of all \( e_i \) are given in Table 1.
To be able to evaluate the second term, we first specify our choice of $S$,

$$S_{kk} = \prod_C s_k(C),$$

(42)

where $s_k(C) = s_i$ only depends on the one cycle state $i$ which occupies $C$ in $\psi_k^{(1)}$. Besides the restriction $s_i \neq 0$ for all $i$, the $s_i$ can be chosen freely and our choice is listed in Table 1.

For our next calculation we introduce $p_C^\dagger(C) (p_C(C))$, the creation (annihilation) operator of an additional boson on cycle $C$, as if it jumped from (to) $C'$. We can write the $H_{C,C'}$ in terms of them,

$$H_{C,C'} = p_C^\dagger(C)p_C(C') + p_C^\dagger(C')p_C(C).$$

(43)

For illustrational purpose consider the two-cycle system depicted in Fig. 5. There we have e.g. $p_{C_1}^\dagger(C_2) = b_1^\dagger(C_2) + b_4^\dagger(C_2)$ and $p_{C_2}(C_1) = b_2(C_1) + b_3(C_1)$.

Then

$$\sum_{i \neq k} |S_{ii} H_{ik}^{(1)} S_{kk}^{-1}|$$

$$= \|S \left(H^{(1)} - H_{kk}^{(1)}\right) S^{-1} \psi_k^{(1)}\|_1$$

$$\leq \sum_{\langle C,C' \rangle} t' \|SP^{(1)} H_{C,C'} S^{-1} \psi_k^{(1)}\|_1$$

$$\leq \sum_{\langle C,C' \rangle} t' \|SH_{C,C'} S^{-1} \psi_k^{(1)}\|_1$$

$$= \sum_{\langle C,C' \rangle} t' \left(\|SP_{C'}^\dagger(C)p_C(C') S^{-1} \psi_k^{(1)}\|_1 + \|SP_{C'}^\dagger(C')p_C(C) S^{-1} \psi_k^{(1)}\|_1\right).$$

(44)

Looking at one of these terms specifically,

$$\|SP_{C'}^\dagger(C)p_C(C') S^{-1} \psi_k^{(1)}\|_1$$

$$= \|SP_{C'}^\dagger(C) S^{-1} \beta_k^\dagger(C)0\|_{1;C} \|SP_{C'}^\dagger(C') S^{-1} \beta_k^\dagger(C')0\|_{1;C'}$$

$$=: \nu_k(C) \mu_k(C').$$

(45)

Here $S'$ is the restriction of $S$ on single cycles, $S'_{ij} = s_i \delta_{ij}$ and $\|\cdot\|_{1;C}$ the 1-norm restricted to $C$. The defined $\nu$ does not depend on $C'$ since $C'$ only determines the direction from which the particles are hopping to $C$ but $\nu$ is invariant under discrete rotations (as can be seen in Table 1). As $\nu_k(C)$ only depends on the one cycle state $i$, which occupies $C$ in $\psi_k^{(1)}$, we can once again write $\nu_k(C) = \nu_i$. Accordingly for $C'$ occupied by the $j$th one cycle state we write $\mu_k(C) = \mu_j$. All values of $\mu$ and $\nu$ are listed in Table 1. Equation (44) is then bounded by

$$\sum_{i \neq k} |S_{ii} H_{ik}^{(1)} S_{kk}^{-1}| \leq \sum_{\langle C,C' \rangle} \left(\mu_k(C) \nu_k(C') + \mu_k(C') \nu_k(C)\right) t',$$

(46)
and together with (41)

\[
|H_{kk}^{(1)} - \lambda| - \sum_{i \neq k} |S_{ii} H_{ik}^{(1)} S_{kk}^{-1}| \\
\geq -2Nt - \lambda + \sum_{c} e_k^{(1)}(C)t - \sum_{\langle C, C' \rangle} (\mu_k(C)v_k(C') + \mu_k(C')v_k(C)) t' \\
= -2Nt - \lambda + \sum_{\langle C, C' \rangle} \left( \frac{e_k^{(1)}(C)}{c(C)} + \frac{e_k^{(1)}(C')}{c(C')} \right) t - (\mu_k(C)v_k(C') + \mu_k(C')v_k(C)) t' \\
=: -2Nt - \lambda + \sum_{\langle C, C' \rangle} \Lambda_k (C, C').
\]

(47)

This expression has a great advantage: Let $C(C')$ be occupied by the $i$th($j$th) one cycle state in $\psi_k^{(1)}$, for $t' < \sqrt{\frac{2es}{a c(G)}}$, $a = \frac{1425 + 974\sqrt{2}}{896}$ our free parameters can then be chosen such that

\[
\Lambda_k (C, C') \\
= \left( \frac{1}{c(C)} e_k(C) + \frac{1}{c(C')} e_k(C') \right) t - (\mu_k(C)v_k(C') + \mu_k(C')v_k(C)) t' \\
= \left( \frac{1}{c(C)} e_i + \frac{1}{c(C')} e_j \right) t - (\mu_i v_j + \mu_j v_i) t' \\
\geq \frac{1}{c(G)} (e_i + e_j) t - (\mu_i v_j + \mu_j v_i) t' \\
=: \Lambda_{ij} \\
\geq 0,
\]

for all $i, j$ and $\Lambda_{ij} > 0$ for $i \neq 0, 1$. (We will explicitly calculate one such set of parameters later on). Hence we can drop arbitrary summands and by doing so only decrease the sum. Since $N > |F_1(G)|$ there is at least one non-empty cycle not occupied by the one particle ground state. Let $C_1$ be such a cycle in state $\psi_k^{(1)}$ and $t' < \sqrt{\frac{2es}{a c(G)}}$. First we look at the case where $C_1$ is occupied by a state $i$ with either three or four particles or with two particles, not in their ground state, and let $u(C_1)$ be the set of cycles neighbouring $C_1$. Then, by definition, $u(C_1)$ has $c(C_1)$ elements and we can calculate

\[
\sum_{\langle C, C' \rangle} \Lambda_k (C, C') \\
\geq \sum_{C' \in u(C_1)} \Lambda_k (C_1, C') \\
= e_k^{(1)}(C_1)t + \sum_{C' \in u(C_1)} \frac{1}{c(C')} e_k(C')t - (\mu_k(C_1)v_k(C') + \mu_k(C')v_k(C_1)) t' \\
\geq e_i t + \sum_{C' \in u(C_1)} \min_{j} \left( \frac{1}{c(C')} e_j t - (\mu_i v_j + \mu_j v_i) t' \right) \\
= e_i t + c(C_1) \min_{j} \left( \frac{1}{c(C)} e_j t - (\mu_i v_j + \mu_j v_i) t' \right)
\]
\[ \geq e_i t + c(G) \min_j \left( \frac{1}{c(G)} e_j t - (\mu_i v_j + \mu_j v_i) t' \right) \]
\[ = c(G) \min_j \left( \frac{1}{c(G)} (e_i e_j) t - (\mu_i v_j + \mu_j v_i) t' \right) \]
\[ = c(G) \min_j (A_{ij}) . \tag{49} \]

The lower bound in the last inequality holds since \( c(C_1) \leq c(G) \) and
\[ \min_j \left( \frac{1}{c(G)} e_j t - (\mu_i v_j + \mu_j v_i) t' \right) \leq \left( \frac{1}{c(G)} e_0 t - (\mu_i v_0 + \mu_0 v_i) t' \right) \]
\[ = -\mu_i v_0 t' \]
\[ \leq 0. \tag{50} \]

Now let \( C_1 \) be occupied by a one particle non ground state (still called \( i \)). Then the calculation still applies but in addition there needs to be at least one additional cycle \( C_2 \) with at least two particles since otherwise the state would contain at maximum \( N - 1 \) particles. W.l.o.g. \( C_2 \) can be assumed to be occupied by the two particle ground state (\( l = 5 \)), otherwise the first calculation applies. We need to consider both, the case where \( C_1 \) and \( C_2 \) are neighbouring each other and the one where they are not; we start with the latter and obtain in the same way as in the last calculation
\[ \sum_{(C, C')} A_k (C, C') \geq c(G) \left( \min_j (A_{ij}) + \min_m (A_{lm}) \right) . \tag{51} \]

For \( C_1 \) and \( C_2 \) neighbouring each other we obtain
\[ \sum_{(C, C')} A_k (C, C') \]
\[ \geq \sum_{C_2 \neq C' \in u(C_1)} A_k (C_1, C') + \sum_{C_1 \neq C' \in u(C_2)} A_k (C_1, C') + A_k (C_1, C_2) \tag{52} \]
\[ \geq (c(G) - 1) \left( \min_j (A_{ij}) + \min_m (A_{lm}) \right) + A_{il} . \]

For the remaining case let \( C_1 \) be occupied by the two particle ground state, then there needs to be at least one additional cycle \( C_2 \) not in the one particle ground state or otherwise \( \psi_k^{(1)} \) would be in \( \Omega_0 \). W.l.o.g. \( C_2 \) can be assumed to be occupied by the two particle ground state too, or otherwise one of the other calculations applies. We demand our parameters to be chosen such that \( A_{55} \geq 2 \min_j (A_{5j}) \) (which essentially means \( v_5 \leq \max (v_0, v_1) \)). Then, regardless of the positions of \( C_1 \) and \( C_2 \) we obtain
\[ \sum_{(C, C')} A_k (C, C') \geq 2c(G) \min_j (A_{5j}) . \tag{53} \]

Therefore \( \sum_{(C, C')} A_k (C, C') \) is bounded by either (49), (51), (52) or (53) for all \( k \) and for \( t' = 0 \) the smallest of them is \( 2c(G) A_{50} \). We now choose our free constants such that
\[ \min_{1 \leq k \leq n_1} \left( |H_k^{(1)} - \lambda| - \sum_{i \neq k} |S_{ii} H_k^{(1)} S_{kk}^{-1} - S_{ii} H_k^{(1)} S_{kk}^{-1}| \right) \geq -2Nt - \lambda + 2c(G) A_{50} . \tag{54} \]
also remains satisfied for \( t' > 0 \) while maximizing the lower bound. To simplify the calculations we choose \( \alpha^{-2} \) to be linear in \( t' \) and \( d \) constant. Under these conditions the optimal
solution (i.e. the smallest possible constant in the $\xi$ term) can be found to be

$$
\xi(t') = \frac{1}{a^2(t')} = \frac{a}{3 + \sqrt{2}} \frac{t'}{c(G)}
$$

(55)

$$
d = 4/3.
$$

For $\lambda \leq (-2N + 2\epsilon_5) t$ and $t' \leq \sqrt{\frac{2\epsilon_5}{a}} \frac{t}{c(G)}$, Eq. (39) satisfies

$$
\left( \left\| (H^{(1)} - \lambda I^{(1)})^{-1} \right\| \right)^{-1} \geq -2Nt - \lambda + 2c(G) \Lambda_{50}
$$

(56)

$$
= (-2N + 2\epsilon_5) t - \lambda - \xi(t') \left( 3 + \sqrt{2} \right) c(G) t'
$$

$$
= (-2N + 2\epsilon_5) t - \lambda - \frac{c^2(G) t^2}{t}.
$$

To calculate $\|H^{(10)}\|$ we can once again make use of the Hermitian invariance of the spectral norm and $H$ itself being Hermitian to arrive at

$$
\|H^{(10)}\| = \frac{1}{\eta^2} \|H^{(01)}\|
$$

(57)

$$
= \frac{1}{\eta} b \sqrt{c(G) t'}.
$$

Combining (56) and (57) then leads to

$$
\inf A_1
$$

(58)

$$
\geq \inf \left\{ \lambda \in \mathbb{R} \left| (-2N + 2\epsilon_5) t - \lambda - \frac{c^2(G) t^2}{t} \leq \frac{1}{\eta} b \sqrt{c(G) t'} \right\}
$$

$$
= (-2N + 2\epsilon_5) t - \left( \frac{1}{\eta} b \sqrt{c(G)} + a \frac{t'}{t} c^2(G) \right) t'.
$$

Now we can use (37) and (58) to finally arrive at

$$
\sup A_0
$$

(59)

$$
= (-2N + \epsilon_5) t + \eta b \sqrt{c(G)} t'
$$

$$
< (-2N + 2\epsilon_5) t - \left( \frac{1}{\eta} b \sqrt{c(G)} + a \frac{t'}{t} c^2(G) \right) t'
$$

$$
\leq \inf A_1,
$$

which holds for

$$
\tilde{t} < \frac{\epsilon_5}{a \tilde{c}^2(G) + \left( \frac{1}{\eta} + \frac{1}{\eta b} \right) b \sqrt{c(G)}}.
$$

(60)
We have introduced $\bar{t} = \frac{t}{\bar{t}}$ for reasons of readability. This upper boundary becomes maximal for $\eta = 1$ and its supremum $\bar{t}_{\sup}$ can be found by solving the equality case for $t'$:

$$\bar{t}_{\sup} = \left( \sqrt{\frac{b^2}{a^2c(G)} + \frac{e_5}{a} - \frac{b}{a\sqrt{c(G)}}} \right) \frac{1}{c(G)}$$

$$= 0.6120 \left( \sqrt{0.07993 \frac{c(G)}{c(G)}} + 1 - \frac{0.2827}{\sqrt{c(G)}} \right) \frac{t}{c(G)}.$$

For a given $\bar{t} < \bar{t}_{\sup}$ we call $\eta_-(t')$ the infimum of all $\eta$ such that the upper bound of $\sup A_0$ is smaller than the lower bound of $\inf A_1$. It is given by

$$\eta_-(t') = \frac{2b\sqrt{c(G)}}{(e_5 - a\bar{t}^2c^2(G)) + \sqrt{(e_5 - a\bar{t}^2c^2(G))^2 - 4b^2\bar{t}^2c(G)}} \bar{t}$$

$$= \frac{b\sqrt{c(G)}}{e_5} \bar{t} + O(\bar{t}^3).$$

Since $A_0$ and $A_1$ are separated we can apply Theorem 2 of [18] with our norms. Therefore, we know that for all eigenstates $\psi_k$, $1 \leq k \leq n_0$ of $H$ with eigenvalues in $A_0$ and $\eta_-(t')$

$$\eta \| P_0\psi_k \|_2 = \| P_0\psi_k \|_{\Omega_0} > \| P_1\psi_k \|_{\Omega_1} = \| P_1\psi_k \|_2.$$ (63)

Using $\| \psi \|_2^2 = \| P_0\psi \|_2^2 + \| P_1\psi \|_2^2$ one achieves the third result:

$$\| P_0\psi_k \|_2 \geq \frac{1}{\sqrt{1 + \eta_-(t')}} \| \psi_k \|_2.$$ (64)

Since the lowest energy levels are in $A_0$ for $t' < t_{\sup}$ we also obtained bounds for them. These bounds are however by no means optimal and can be improved with the help of the following arguments.

Since any eigenvalue needs to be a member of either $A_0$ or $A_1$ all eigenvalues satisfy

$$E_k \geq \min \{ \inf A_0, \inf A_1 \}.$$ (65)

This holds true for all $\eta > 0$ regardless of the sets overlapping or not. For a given $t'$ the lower bound found this way becomes maximal for

$$\eta = \eta_+(t') = \frac{2b\sqrt{c(G)}}{(e_5 - a\bar{t}^2c^2(G)) + \sqrt{(e_5 - a\bar{t}^2c^2(G))^2 + 4b^2\bar{t}^2c(G)}} \bar{t}.$$ (66)

Hence a lower bound for all energy eigenvalues is given by

$$E_k \geq -(2N - e_5) t - b\sqrt{c(G)}\eta_+(t') t'.$$ (67)

To find an upper boundary on the energy of the $|F_1(G)|$ lowest states, we first observe that since $H^{(0)}$ is diagonal for any normalised $\psi \in \Omega_0$, the expectation value of $H$ for $\psi$ is given by

$$\langle \psi | H | \psi \rangle = -(2N - e_5) t.$$ (68)
We now choose an orthonormal base \( \{ \varphi_k \} \) of eigenstates of \( H \), such that their energies are monotonously increasing, i.e. \( E_k \leq E_{k+1} \) for all \( k \). Then we rewrite the (normalised) elements of \( \Omega_0 \) in terms of this basis,
\[
\psi = \sum_k a_k \varphi_k,
\]
with \( \sum_k |a_k|^2 = 1 \). Since \( \Omega_0 \) is \( |F_1(G)| \) dimensional, it is possible to find an (again normalised) \( \bar{\psi} \in \Omega_0 \) with coefficients \( \bar{a}_k \) such that its first \( |F_1(G)| - 1 \) ones are all vanishing. Combining this with (68) leads to
\[
-(2N - e_5) t = \langle \bar{\psi} | H | \bar{\psi} \rangle = \sum_{k \geq |F_1(G)|} |\bar{a}_k|^2 E_k \geq E_{|F_1(G)|}.
\]
And as the \( E_k \) are chosen to increase monotonously, the inequality holds true for all \( k \leq |F_1(G)| \). Overall the bound for the energies of the \( |F_1(G)| \) lowest states then reads
\[
-(2N - e_5) t - b\sqrt{c(G)\eta_+(t')} t' \leq E_k \leq -(2N - e_5) t,
\]
hereby having proven the first result. On the other hand, we can also maximise \( \eta \) in the same manner as in (62) to find an optimised lower boundary for the energy of the eigenstates in \( \Lambda_1 \). For a fixed \( t' \) it is given by sup \( \eta = \eta_-(t') \) and we obtain an energy gap between the lowest states and the upper states of at least
\[
\Delta \geq \text{est} - \left( a\tilde{c}^2(G) + b\sqrt{c(G)\eta_-(t')} \right) t' = \text{est} + O(\tilde{t}^2),
\]
which concludes the proof.

### 3.4 Degeneracy of Ground States of Graphs Possessing a Local Reflection Symmetry

In this subsection, we will focus on specific graphs in the larger class of graphs treated in the main result, namely graphs possessing a local reflection symmetry. We will use this reflection symmetry to prove a degeneracy of the ground state which, combined with the main result, allows for a very strong statement on local pair formation.

We look at the chequerboard chain with PBC. Using a symmetry argument, Drescher and Mielke were able to show the following result, which we slightly rephrase to cater towards the needs of this work [24]:

**Proposition 3** (Drescher, Mielke, 2017) If for some \( |F_1(G)| + 1 \) particle ground state \( \varphi_1 \) of \( H \) on the chequerboard chain with PBC, there is an overlap with the ground states of the uncoupled system (i.e. \( \| P_0 \varphi_1 \|_2 \neq 0 \)), then the ground states are at least \( |F_1(G)| \) fold degenerated.

This can be proved using a symmetry property of the chequerboard chain: Its Hamiltonian remains invariant under exchanges of the lower vertices with their upper counterparts (i.e. in Fig. 3 to interchange vertex 1 with 4 and 2 with 3, respectively, or, equivalently, to exchange the upper and lower edges of the square in the original graph) for any cycle \( C \) and we call the operator that performs this operation \( S_C \). Therefore, it is possible to find a common base of
eigenstates of $H$ and all of the $S_C$ (as they also commute with one another). Since the base states of $\Omega_0$, $\psi_k^{(0)}$ with two particles on $C_k$ have eigenvalue $2\delta_{C_k,C_k} - 1$ under $S_C$, there is a unique signature for all base states. Now we look at a ground state $\varphi_1$ of $H$ with $\| P_0\varphi_1 \|_2 \neq 0$ which is also an eigenstate of all $S_C$. Therefore, its signature needs to be identical to one of the base states of $\Omega_0$. Additionally, the Hamiltonian is invariant under shifting the state by one face to the right due to the PBC. Hence, the resulting state $\varphi_2$ must also be a ground state but since its signature differs from the one of $\varphi_1$ they cannot be identical. This argument can be repeated to create $| F_1(G) \rangle$ ground states $\varphi_k$ with unique signatures, which therefore are linearly independent, which proves the proposition. Moreover the $\varphi_k$ only overlap with a single base state of $\Omega_0$, the one they share the signature with. Hence they obey $P_0\varphi_k = r\psi_j^{(0)}$, for some $1 \leq j \leq n_0$ and $0 < |r| \leq 1$, i.e. their projector into $\Omega_0$ has a compactly localised pair.

We now look at the lattice of intertwined rhombi chains (abbreviated LIR (4,1), here 4 stands for the maximum number of rhombi that share a single vertex and 1 for the number of rhombi between two such vertices) with DPBC as depicted in Fig. 6a. Since the rhombi share only corners but not edges, they can indeed be coloured by one colour and they form the set $F_1(G)$. One immediately notices that its line graph does possess the same local reflection symmetry, since for all rhombi the mirroring on the longer diagonal leaves the Hamiltonian of the line graph invariant and we can again find a common base of eigenstates of $H$ and all $S_C$. Any ground state of $H$ in this basis can overlap with at maximum one base state of $\Omega_0$. Now we assume such an overlapping ground state, $\varphi_1$, does indeed exist and $\psi_j^{(0)}$ is the state it overlaps with. Then we can again use the translational invariance due to the DPBC to find additional ground states which overlap with different base states of $\Omega_0$. This is possible for all $\psi_j^{(0)}$ as long as $C_j$ and $C_l$ share the same spatial orientation (i.e. are either both members of a horizontal or both members of a vertical chain.) Now we additionally demand that the lattice has the same length in both directions and call this the symmetric case. The Hamiltonian is then also invariant under a global rotation by $\pi/2$ around an arbitrary vertex of $G$ which connects multiple rhombi. This maps $C_j$ onto a rhombus of different orientation and therefore maps $\varphi_1$ onto a ground state overlapping with a state in $\Omega_0$ with two particles on that rhombus. Repeating the translations we can find a ground state of $H$ which exactly overlaps with $\psi_k^{(0)}$ for every $1 \leq k \leq n_0$.

Similarly one can work out the ground state degeneracy under this condition for the line graph of the thinned out lattice of intertwined rhombi (abbreviated LIR (3,2), use of the numbers in accordance to the (4,1) case). It is depicted in Fig. 6b. Starting from one ground state with a given signature we can use the translational invariance to find linearly independent ground states with signature $+1$ on every rhombus in the lattice, given it has the same position in the “rotor” the graph is build from (marked in blue in Fig. 6b). The rhombi enclose regular hexagons which can be thought of as a honeycomb lattice if we consider the rhombi to be their edges. If all chains of hexagons have the same length, we call this again the symmetric case. In this case the Hamiltonian is invariant under rotations by $\pi/3$ around the centre of any "hexagon" which allows us to find ground states with signature $+1$ on every rhombus of the "basic rotor" and in combination with the translational invariance, we achieve the same result as for the chequerboard chain:

**Proposition 4** If the line graphs of the symmetric LIR (4,1) with DPBC or of the symmetric LIR (3,2) with DPBC possess a $| F_1(G) \rangle + 1$ particle ground state $\varphi_1$ of $H$ that has an overlap with the ground states of the uncoupled system (i.e. $\| P_0\varphi_1 \|_2 \neq 0$), the ground states are at least $| F_1(G) \rangle$ fold degenerated.
Remarks  Several similar regular two dimensional lattices obeying this local symmetry can be found. We decided to present these two specifically because the (4,1) version seems like the most intuitive one, while in the (3,2) case every rhombus only neighbours three others, which is the minimal possible number for a regular two dimensional structure which proves to be beneficial for the main result.

Given a sufficiently small acute angle, one can of course attach arbitrarily many rhombi to a central vertex and we call this the \( n \) rhombi star. Essentially the LIR are build up from such stars for \( n = 4 \) and \( n = 3 \), respectively. For \( n = 12 \) it is depicted in Fig. 6c. Since it obeys the local reflection symmetry and is invariant under global rotations by \( \frac{2\pi}{n} \) around its centre, an analogue proof for the degeneracy of its ground state energy is possible. However, since the number of other next neighbours is proportional to the number of rhombi within the graph, the main result very quickly gets extremely bad even for a moderate number of rhombi (and therefore allowed particles in the systems). Hence, we consider the (isolated) star with an arbitrary \( n \) to be more of an academic curiosity, than a physically relevant system (at least in the context of localised pair formation).

While the energetic degeneracy depends on some form of a global symmetry, the possibility to find ground states that overlap with at maximum one base state of \( \Omega_0 \) only relies on the existence of the local reflection symmetry for all \( C \). Therefore, it also holds for all other graphs in our class obeying this symmetry. Examples of graphs obeying the local symmetry but without any kind of global rotational or translational invariance are treelike structures such as the one described in [18, Sect. 5].

From this proposition we can see that the ground state of the chequerboard chain and the lattice of intertwined rhombi chains with (D)PBC is at least \(|F_1(G)|\) fold degenerated if there is some overlap with the ground states of the decoupled system. The main result states that under certain conditions such an overlap exists and that there are exactly \(|F_1(G)|\) eigenvalues in \( \Lambda_0 \), the set that contains the lowest eigenvalues, which are separated from the rest of the spectrum. Combining these two results, we obtain the following corollary:

**Corollary 1**  For \( t' < t_{\text{sup}}' \) the chequerboard chain with PBC, the line graph of the symmetric LIR (4,1) with DPBC and the line graph of the symmetric LIR (3,2) with DPBC with \( N \)
hard-core bosons on $N - 1$ cycles $C_1, \ldots, C_{N-1}$ have an exactly $N - 1$ fold degenerated ground state energy $E_0$, satisfying

$$((-2(N - 2) - 2\sqrt{2}) t - b\sqrt{c(G)}\eta_+(t') t' \leq E_0 \leq ((-2(N - 2) - 2\sqrt{2}) t). \quad (73)$$

The ground state is spanned by orthonormal states $\varphi_k$, satisfying $P_0 \varphi_k = r(t') \varphi_{C_k}$ with $r(t') \geq 1 + \eta^2(t')$. Here $\varphi_{C_k}$ once again denotes the orthonormal base states of $\Omega_0$ with two particles on cycle $C_k$ and one particle on every other cycle. All other quantities are defined as in the main theorem for $c(G) = 2$, $c(G) = 6$ and $c(G) = 3$, respectively.

**Remarks** We thereby have proven that the ground states of the bosonic chequerboard chain and the line graphs of the LIRs are dominated by localised pairs and that their band is indeed flat. Therefore, we have found both one dimensional and two dimensional regular graphs with rigorously provable localised repulsive bosonic pair formation. To our knowledge this had not been achieved yet for either dimension.

As noted earlier, we can generalise the statement $P_0 \varphi_k = r(t') \varphi_{C_k}$ with $r(t') \geq 1 + \eta^2(t')$ for the $|F_1(G)|$ lowest lying states to all graphs obeying the local symmetry for all cycles. It should be noted that the lower dimension of the ground states is not a contradiction to [25], as their result only applies to the homogeneous case (see also Sect. 2.7).

### 4 Potential Improvements, Generalisations and Open Questions

#### 4.1 General Model

While the results of this paper already cover a broad class of line graphs, extending the results to an even broader class of graphs would be very desirable. Lifting or weakening the restrictions on cycles lengths or interstitials would be one way of accomplishing this. As already noted earlier, the longer cycles should not be a principal problem, while the interstitials could indeed lead to some technical as well as physical problems. One particular achievement would be to solve both of these issues at the same time and include the kagome chain or kagome lattice in the class of applicable graphs. Another way would be to generalise the results to three dimensions. Especially the chequerboard lattice generalises relatively straightforwardly into a three dimensional analogous with cubes with hopping strength $t$ on them as basic units and complete graphs with hopping strength $t'$ between neighbouring faces. This model has compact eigenstates on every cube with eigenvalue $-3t$ or even $-4t$ if one allows for edges on the diagonals of the cube (but not on the diagonals of its surfaces,) while the corresponding two particle ground states on the cube have energies $-4\sqrt{2}t$ and $-12\sqrt{3}t$, respectively. This looks like a very encouraging start to any potential future investigation.

Moving in another direction, one could also discuss additional terms in the Hamiltonian. One interesting extension could be to allow for repulsive next neighbour interactions defined in analogy to the hopping strengths, with $V \geq 0$ being the interaction on the cycles and $V' \geq 0$ the interaction between the cycles. While the $V' = 0$ case seems relatively straightforward as it would only alter the one cycle ground states, the $V' > 0$ case would alter the model a lot more fundamentally, as putting two particles into neighbouring cycles would in general make them interact with each other and would therefore lower the critical density by a varying amount depending on the geometry of the graph in question.
4.2 Fermionic Models

In addition to generalisations to the bosonic models it looks also promising to investigate a potential translation of our result to fermionic models. At first glance it seems most straightforward to look into a spinless model, as its properties in regard to the occupation of single cycles are similar to the bosonic case. However, there are multiple issues with this choice: The two particle ground state on a single cycle is not unique, for \( t' \neq 0 \) there are non-vanishing matrix elements between them and further issues arise. Adding the next neighbour interactions discussed in Sect. 4.1 might be one solution to these issues, but if one wants to consider a similar approach to the one taken in this paper, a model with spin might be more promising. In the hardcore limit the spin \( \frac{1}{2} \) case has, in a certain sense, a lot higher similarity with the bosonic case than the spinless model. Unlike the spinless model, it has a unique singlet two particle one cycle ground state following the same structure as the corresponding ground state in the bosonic case. Therefore, a deeper analysis looks very promising and might also lead to interesting discoveries on the spin behaviour of the whole system. As our approach can in principle be applied to any kind of particle, not allowing for a macroscopic occupation of single cycles, one could even consider fermions with a finite (but still repulsive) on-site interaction. While one of course expects the results to worsen as \( U \) gets smaller, it should still be possible for any given \( U > 0 \) to prove a separation in the energy levels for \( t' \) sufficiently small.

4.3 Hard-Core Bosons

When looking at the details of the main theorem’s proof, the reader might have noticed that there are a few points where this work doesn’t completely maximise out the possibilities of the given approach. First of all, any state with exactly two cycles with the two particle ground state and all other particles in the one particle ground states will have exactly one empty cycle and all remaining cycles will be occupied by one particle ground states. Taking this into account complicates the calculations of lower bounds for \( \sum_{(C,C')} \Lambda_k (C,C') \) but could decrease the value of \( a \) by around \( \frac{1}{3} \frac{c(G)-1}{c(G)} \) and consequently slightly improve all dependent quantities.

A potentially bigger improvement can be achieved by allowing for more free parameters in the definition of the \( s_j \). Ideally, one would want them to be chosen completely independent initially and would allow them to be arbitrary functions in \( t' \). However, it becomes clear immediately that solving for that many free parameters with the given constraints is not achievable analytically, hence a numerical analysis would be very beneficial and might be able to improve the applicability of the theorem well into the area of \( t' \approx \frac{1}{c(G)} t \).

Nonetheless our work also shows some limits which the given approach cannot exceed: Since \( \| H(0) \|, \| H(10) \| \) and \( \| (H(0) - \lambda I(0))^{-1} \|^{-1} \) are all calculated exactly, even for the hypothetical (and unrealistic) assumption that \( \| (H(1) - \lambda I(1))^{-1} \|^{-1} \) does not depend on \( t' \) at all, one would still end up with \( t'_{\text{sup}} = \frac{G}{2b} t \approx \frac{1}{c(G)} t \). This upper limit cannot be breached by using the given norms and partition of \( H \). Also, the Euclidean norm already tends to be a relatively small matrix norm compared to other norms: For example using either the 1-norm or the \( \infty \)-norm with the same asymmetrical ansatz only decreases the result because of \( \| A \| \leq \sqrt{\| A \|_1 \| A \|_\infty} \) and the symmetry of the Hamiltonian, while choosing the 1-norm on \( \Omega_0 \) and the \( \infty \)-norm on \( \Omega_1 \) (or the other way around) completely breaks the result as either \( \| H^{(10)} \| \) or \( \| H^{(01)} \| \) becomes proportional to \( N \). Choosing a more fragmented partition of \( H \)
also tends to worsen the result since having more non-diagonal matrices only leads to terms adding to the bounds of \( \| (H^{(i)} - \lambda I^{(i)})^{-1} \|^{-1} \) and in many cases these bounds can even become dependent on \( N \) and thereby also breaking the result entirely. Hence, we conclude that it seems very unlikely that any kind of Gershgorin-like argument can reach the desired case of \( t_{\text{sup}}' \geq t \) even for \( c(G) = 2 \) and presumably a completely new ansatz will have to be found for results that include systems like the homogeneous chequerboard chain.

Beyond these incremental improvements, one can hope to prove the macroscopic degeneracy of the ground state energy for more members of the class of graphs, in which our main result holds and thereby concluding a rigorous proof for the existence of localised pairs in the ground state. Especially for the two dimensional chequerboard lattice with DPBC such a result is highly suggested by the main result of this paper in combination with its high symmetry; however, the lack of a local symmetry as discussed for some of the graphs in our class makes a formal proof much harder to achieve.
