Interproximal wear versus incisors extraction to solve anterior lower crowding: A systematic review

Natália Valli de Almeida¹, Giordani Santos Silveira¹, Daniele Masterson Tavares Pereira², Claudia Trindade Mattos³, José Nelson Mucha⁴

Objective: To determine by means of a systematic review the best treatment, whether interproximal wear or incisor extraction, to correct anterior lower crowding in Class I patients in permanent dentition. Methods: A literature review was conducted using MEDLINE, Scopus and Web of Science to retrieve studies published between January 1950 and October 2013. In selecting the sample, the following inclusion criteria were applied: studies involving interproximal wear and/or extraction of mandibular incisors, as well as Class I cases with anterior lower crowding in permanent dentition. Results: Out of a total of 943 articles found after excluding duplicates, 925 were excluded after abstract analysis. After full articles were read, 13 were excluded by the eligibility criteria and one due to methodological quality; therefore, only fours articles remained: two retrospective and two randomized prospective studies. Data were collected, analyzed and organized in tables. Conclusion: Both interproximal wear and mandibular incisor extraction are effective in treating Class I malocclusion in permanent dentition with moderate anterior lower crowding and pleasant facial profile. There is scant evidence to determine the best treatment option for each case. Clinical decision should be made on an individual basis by taking into account dental characteristics, crowding, dental and oral health, patient’s expectations and the use of set-up models.

Keywords: Incisor. Angle Class I malocclusion. Tooth extraction.

Objetivo: determinar, por meio de uma revisão sistemática, o melhor tratamento entre desgastes interproximais e extração de incisivos para a correção de apinhamento anteroinferior em pacientes Classe I com dentição permanente. Métodos: foram feitas buscas nas bases de dados eletrônicas MEDLINE, Scopus e Web of Science por artigos publicados de janeiro de 1950 até outubro de 2013. Os critérios de inclusão foram estudos que abordassem tratamentos com desgastes interproximais e/ou extração de incisivos inferiores, de casos Classe I com apinhamento anteroinferior na dentição permanente. Resultados: dos 943 artigos encontrados após a remoção dos duplicados, 925 foram excluídos após a leitura dos resumos. Após leitura dos artigos completos, 13 foram excluídos pelos critérios de elegibilidade e um pela qualidade metodológica, restando quatro artigos, sendo dois retrospectivos e dois prospectivos randomizados. Os dados foram coletados, analisados e organizados em tabelas. Conclusões: tanto o desgaste interproximal quanto a extração de incisivo inferior são tratamentos eficazes em Classe I na dentição permanente, com apinhamento anteroinferior moderado e perfil facial agradável. Há fracas evidências para determinar a escolha do melhor tratamento para cada caso. A decisão clínica deve ser tomada em bases individuais, considerando as características anatômicas dentárias, da severidade do apinhamento, condições de saúde dentária e bucal, expectativas dos pacientes e ensaio em modelos (set-up).

Palavras-chave: Incisivo. Má oclusão de Angle Classe I. Extração dentária.

INTRODUCTION

A pleasant smile and proper alignment of anterior teeth are the main motivation for patients seeking orthodontic treatment. In permanent dentition, the mandibular anterior region is most susceptible to patient’s dissatisfaction. It is the most common complaint, particularly among older adult patients due to greater exposure of mandibular teeth at smiling.

Orthodontic planning for this type of deficiency may involve permanent teeth extraction or other approaches that do not involve extractions, such as interproximal wear, dental expansion, distraction osteogenesis of the mandibular symphysis, and as well as a combination of different techniques.

The treatment of choice should be based on a number of features, such as type of malocclusion, negative discrepancy, facial profile, Bolton’s ratio, dental and periodontal conditions, and patient’s chief complaint. For a better prognosis, diagnostic or virtual set-ups are indicated.

The aim of this study was to determine — in cases in which there is doubt as to the most appropriate procedure — the best treatment option between interproximal wear and incisor extraction to correct anterior lower crowding in Class I patients in permanent dentition and to achieve good facial esthetics.

MATERIAL AND METHODS

The guidelines and directives set by the Preferred Reporting Items for Systematic Reviews and Meta-Analysis, the PRISMA Statement, were adopted for this review.

The search, as well as the inclusion/exclusion criteria, were based on PICO format (Table 1).

For sample selection, the following inclusion criteria were applied: studies involving interproximal wear and/or extraction of mandibular incisors in cases of anterior lower crowding and Class I malocclusion in permanent dentition. The exclusion criteria were: case reports; case series; laboratory studies; epidemiological studies; narrative reviews; opinion articles; studies involving orthognathic surgery, distraction osteogenesis, extraction of premolars, syndromic and/or cleft patients, supernumerary teeth and/or abnormal shape of teeth, transverse deficiencies, anterior crossbite, use of auxiliary devices; primary or mixed dentition and/or Class II or III malocclusion.

The literature review was conducted using MEDLINE (via PubMed), Scopus and Web of Science to retrieve studies that met the eligibility criteria and had been published from January 1950 to October 2013, without language restrictions. The combinations of words or terms used are described in Table 2.

Duplicate articles were eliminated from the final search results. Titles and abstracts were read independently by two reviewers who analyzed the articles in light of the inclusion and exclusion criteria. All articles found to be compatible and somehow related to the question (Table 1) were reviewed. Disagreements between reviewers were settled in a consensus meeting held with a third investigator. The articles selected were fully read. The references of the articles included in the research were also analyzed in search of potential relevant articles that might not have been found in the selected databases.

The articles selected were assessed for methodological quality according to a list based on CONSORT, whenever applicable, and modified by the reviewers (Table 3). Disagreements were solved in consensus meetings, and articles were classified into high (≥13), moderate (<13 and ≥9) and low (<9) methodological quality.

Data were extracted from the articles by two reviewers.
RESULTS

The search in the literature identified 1,094 studies, 706 from MEDLINE, 240 from Scopus and 148 from Web of Science, which are all presented in a “Prism Flow Diagram” (Fig 1). After excluding 151 repeated articles, all titles and abstracts were read and those found to be unrelated to the review were eliminated. Eighteen preselected articles were read in full and the inclusion and exclusion criteria were applied. Five articles remained and were classified according to the methodological quality assessment.

One article was assigned as presenting low methodological quality and was, therefore, not included in this study. Four articles showed moderate quality, and none presented high quality (Table 4). Most articles offered insufficient sample description, both demographically and in terms of sample size calculation.

Of the four studies included, two were randomized prospective and two were retrospective studies. Only one article presented sample size calculation. In the study by Ileri et al., only the sample data for incisor extraction (IE) were considered, given that no wear was mentioned in the non extraction (NE) group, and although the authors were contacted by e-mail, no response was given. Only the data from groups of interest were extracted from the articles.

All information regarding the author, year, study type, sample, type of treatment, statistical analysis, data evaluated and total treatment time, was gleaned from the included articles and described in Table 5.
Table 3 - Methodological quality assessment - based on CONSORT.\textsuperscript{25}

| Methodological quality features assessed in the included studies | Score |
|---------------------------------------------------------------|-------|
| A Description of study objectives                             | 1     |

| H Sample description (demographic - age, sex and ethnicity)    | 1     |
| I Sample description (overjet, overbite, perimeter discrepancy, Bolton, tooth form, oral health, profile) (0.5 point/item. More than 6 items = 3 points) | 3     |
| J Description of treatment duration and follow-up (1 point each) | 2     |
| K Description of limitations, biases and inaccuracies of the study | 1     |
| L Operator calibration                                         | 1     |

Data analyzed in each study varied widely. Ileri et al.\textsuperscript{25} assessed changes in the PAR index and Bolton ratio, and treatment included mandibular incisor extraction. Dacre\textsuperscript{26} correlated cephalometric measurements, overjet, overbite and initial intercanine width also involving mandibular incisor extraction. Germec\textsuperscript{23} et al. analyzed the effect of interproximal wear on cephalometric measurements, overbite and overjet. Germec-Cakan et al.\textsuperscript{24} compared intercanine and intermolar widths, as well as pre and post-treatment arch perimeter after interproximal wear. Only one study\textsuperscript{26} described sample follow-up. Three studies\textsuperscript{24,25,26} mentioned treatment time.

Given that studies included different data, it was impossible to compare them directly and/or perform meta-analysis.

**DISCUSSION**

By the end of this research, only one systematic review\textsuperscript{37} with indications, contraindications and effects of extracting a mandibular incisor in patients with different malocclusions, was found. Our review, however, had a different goal: to determine the advantages and disadvantages as well as the indications and contraindications of interproximal wear versus incisor extraction for correction of anterior
lower crowding in patients in permanent dentition and Class I malocclusion.

Several clinical cases\(^{12,5,9,12-15,17-21,30,31,38}\) reported interproximal wear or mandibular incisor extraction as potential therapies for mild or moderate anterior lower crowding in patients in permanent dentition, with Class I malocclusion and a pleasant facial profile. Nevertheless, there are yet few clinical trials or randomized controlled trials addressing this issue.

Of the 943 articles found after duplicates removal, only eighteen were selected for full reading. The articles excluded after title and abstract reading included case reports or epidemiological research. Either that or the sample had undergone treatment for crossbite, distal movement of molars, surgical treatment and extraction of other permanent teeth. Some articles addressed mixed and primary dentition, or only Class II or Class III malocclusion.

Of the eighteen\(^{16,22-26,37,39-49}\) articles included for full reading, only five\(^{22-26}\) were selected for methodological quality assessment. The reasons for exclusion were: no description of treatment used when referring to nonextraction; lack of clear information on whether or not interproximal wear had been performed; treatment including dental arch expansion or incisor protrusion;\(^{39,40,42-49}\) use of auxiliary appliances;\(^{40}\) systematic review performed using some other approach;\(^{37}\) description of clinical cases;\(^{16}\) and whenever data from Class I, II and III groups were presented together, which precluded the use of data from Class I patients, only.\(^{41}\)

Only one\(^{22}\) out of the five articles selected for methodological assessment was excluded due to low methodological quality and also because it failed to report the final results. Two out of the four articles included after qualifying addressed treatment with incisor extraction\(^{25,26}\) while two reported using interproximal wear.\(^{23,24}\)

Mandibular wear performed in the study by Germeç et al\(^{23}\) measured 5.1 ± 0.9 mm, with 2.0 ± 0.5 mm in anterior lower teeth, only. To solve crowding of 4 mm to 8 mm, Sheridan\(^{50}\) advocates interproximal reduction carried out mostly, but not exclusively, in the anterior segment. Wear should be limited to about 0.5 mm on each side of anterior teeth, and 0.8 mm on posterior teeth.\(^{9,28}\) It should not exceed

50% of total enamel thickness. The areas of mandibular teeth where enamel thickness is greater are the distal surfaces of lateral incisors and the mesial and distal surfaces of canines.

Germec-Cakan et al. observed that cases in which interproximal wear was carried out had a decrease in intermolar width whereas intercanine width and arch perimeter remained unchanged. This treatment allows the creation of a contact area between teeth, which favors stability. When performed carefully, interproximal wear yields a healthy dentition, which is not susceptible to periodontal disease and tooth decay. There is a certain degree of concern, however, that a thin interdental alveolar septum might accelerate gingival attachment loss and the spread of periodontal disease.

According to Ileri et al., a PAR index comparison showed that malocclusions were corrected by extracting mandibular incisors, which was indicated in cases with mandibular anterior Bolton discrepancy whereby the anterior ratio equals to 81.7 ± 4.5, thereby corroborating other articles. This seems to suggest that in cases in which mandibular dental volume excess is smaller, the best alternative may be interproximal wear. The other groups compared by Ileri et al. (premolar extraction and treatment without extraction) were assigned better scores after treatment, perhaps due to difficult intercuspatation and/or overjet remaining in cases involving mandibular incisor extraction. Thus, in these cases, interproximal wear is indicated on maxillary anterior teeth to correct remaining overjet. Priority should be given to extracting incisors in patients with decreased overjet and overbite.

Dacre showed in a follow-up of 16 patients, after mandibular incisor extraction and retainer removal, that only five cases preserved good alignment, while seven had mild crowding relapse, one had moderate relapse, and three showed space opening. Intercanine width was slightly reduced, since extraction caused canines to move closer to the region where the dental arch is narrower.

Selection of the incisor to be extracted is usually based on malposition, periodontal involvement, color change, decay and/or fracture, factors which are less likely to induce changes in profile, and arch length. Loss of interdental papilla or formation of

Interproximal wear versus incisors extraction to solve anterior lower crowding: A systematic review

original article

Interproximal wear is given priority when aiming at conservative treatment with minor changes in a pleasant profile, in Class I cases, cases without mandibular dental excess (Bolton &lt; 3 mm), mild to moderate mandibular crowding, normal overjet and overbite, low incidence of caries, proper oral hygiene, teeth with a triangular shape, potential for maxillary wear, and treatment confirmed by set-up model tests.

Several case reports addressing the issue were not included, given their low evidence and inference that these cases were successful. Lack of high-methodological-quality articles is a limitation of the present study. Nevertheless, no studies have been found with good methodological quality comparing the two treatments in patients with Class I malocclusion, moderate crowding and pleasant facial profile. However, there is credible evidence showing that treatment involving interproximal wear and incisor extraction do help to improve malocclusion.

CONCLUSIONS

Both mandibular incisor extraction and interproximal wear are effective to treat patients with Class I malocclusion with moderate anterior lower crowding, in permanent dentition and with a pleasant facial profile. There is, however, scant evidence to determine the best treatment approach.

Decreased overjet, overbite and Bolton’s tooth-size discrepancy were the most decisive parameters used to indicate mandibular incisor extraction.

Clinical decision should be made on an individual basis by taking into account patient’s dental anatomical characteristics, crowding, dental and oral health conditions, expectations and the use of set-up models.
