In this study, we generated transgenic Arabidopsis (Arabidopsis thaliana) plants overexpressing the Rieske FeS protein (PetC), a component of the cytochrome b6f (cyt b6f) complex. Increasing the levels of this protein resulted in concomitant increases in the levels of cyt f (PetA) and cyt b6 (PetB), core proteins of the cyt b6f complex. Interestingly, an increase in the levels of proteins in both the photosystem I (PSI) and PSII complexes also was seen in the Rieske FeS overexpression plants. Although the mechanisms leading to these changes remain to be identified, the transgenic plants presented here provide novel tools to explore this. Importantly, overexpression of the Rieske FeS protein resulted in substantial and significant impacts on the quantum efficiency of PSI and PSII, electron transport, biomass, and seed yield in Arabidopsis plants. These results demonstrate the potential for manipulating electron transport processes to increase crop productivity.

Increasing food and fuel demands by the growing world population has led to the need to develop higher yielding crop varieties (Fischer and Edmeades, 2010; Ray et al., 2012). Transgenic studies, modeling approaches, and theoretical considerations provide evidence that increasing photosynthetic capacity is a viable route to increase the yield of crop plants (Zhu et al., 2010; Raines, 2011; Long et al., 2015; von Caemmerer and Furbank, 2016). There is now a growing body of experimental evidence showing that increasing the levels of photosynthetic enzymes in carbon metabolism results in increased photosynthesis and plant biomass (Miyagawa et al., 2001; Lefebvre et al., 2005; Raines, 2006, 2011; Rosenthal et al., 2011; Uematsu et al., 2012; Simkin et al., 2015, 2017; Driever et al., 2017). In addition, the manipulation of photosynthetic electron transport by the introduction of the algal cytochrome \textit{c}$_{1}$ protein has been shown to improve the efficiency of photosynthesis and to stimulate plant growth in low light (Chida et al., 2007).

One endogenous target identified for manipulation is the cytochrome b6f (cyt b6f) complex, which is located in the thylakoid membrane and functions in both linear and cyclic electron transport, providing ATP and NADPH for photosynthetic carbon fixation. Initially, cyt b6f inhibitors (Kirchhoff et al., 2000), and later, transgenic antisense studies suppressing the accumulation of the Rieske FeS protein (PetC), a component of the cyt b6f complex, demonstrated that the activity of the cyt b6f complex is a key determinant of the rate of electron transport (Price et al., 1995, 1998; Anderson et al., 1997; Price et al., 1999, 1998; Anderson, 1992; Knight et al., 2002; Cramer and Schöttler, 2006; Crater et al., 2001, 2002, 2003, 2004, 2005; Schwenkert et al., 2007; Hojka et al., 2014). Essential roles directly in the monomer-monomer interaction and stability of the complex and the petD gene product functioning as a scaffold (Hager et al., 1999; Cramer et al., 2006; Schwenkert et al., 2007; Hojka et al., 2014). Essential roles in the assembly and stability of the cyt b6f complex also have been shown for the PetG, PetN, and PetM subunits, and a minor role in stability was assigned to the PetL gene product (Bruce and Malkin, 1991; Kuris and Wollman, 1994; Hager et al., 1999; Monde et al., 2000; Schöttler et al., 2007; Schwenkert et al., 2007; Hojka et al., 2014).

\]
Notwithstanding both the genetic and structural complexity of the cyt b6f complex, it has been shown previously that it is possible to manipulate the levels of the cyt b6f complex by down-regulation of the expression of the Rieske FeS protein (Price et al., 1998; Yamori et al., 2011b). It also has been shown that the Rieske FeS protein is one of the subunits required for the successful assembly of the cyt b6f complex (Miles, 1982; Metz et al., 1983; Barkan et al., 1986; Anderson et al., 1997). Based on these results, we reasoned that overexpression of the Rieske FeS protein could be a feasible approach to take in order to increase the electron flow through the cyt b6f complex. In this article, we report on the production of Arabidopsis (Arabidopsis thaliana) with increased levels of the tobacco (Nicotiana tabacum) Rieske FeS protein, and we show that this manipulation resulted in increases in photosynthetic electron transport, CO2 assimilation, and yield. This work provides evidence that the process of electron transport is a potential route for the improvement of plant productivity.

RESULTS

Production and Selection of Rieske FeS Overexpression Transformants

The full-length tobacco Rieske FeS coding sequence (X64353) from the cyt b6f complex was used to generate an overexpression construct B2-NtRi (Supplemental Fig. S1). Following floral dipping, transgenic Arabidopsis plants were selected on both kanamycin- and hygromycin-containing medium (Nakagawa et al., 2007), and plants expressing the integrated transgenes were identified using reverse transcriptase-PCR (data not shown). Proteins were extracted from leaves of the T1 progeny, allowing the identification of three lines with increased levels of the Rieske FeS protein (PetC; Supplemental Fig. S2A). Immunoblot analysis of T3 progeny of lines 9, 10, and 11 showed them to have higher levels of the Rieske FeS protein when compared with the wild type (Fig. 1; Supplemental Fig. S2B). The overexpression of the Rieske FeS protein (hereafter referred to as Rieske FeS ox) resulted in a concomitant
increase in both cyt f (PetA) and cyt b₆ (PetB; Fig. 1A). An increase in the level of the PSI type I chlorophyll a/b-binding protein (LhcaI) and an increase in the core protein of PSI (PsaA) also were observed. Furthermore, the D1 (PsbA) and D2 (PsbD) proteins, which form the reaction center of PSI, also were shown to be elevated in Rieske FeS ox lines. Finally, an increase in the ATP synthase δ-subunit (AtpD) also was observed in Rieske FeS ox lines (Fig. 1A). In contrast, no notable differences in protein levels for the chloroplastic FBP aldolase (FBPA), the mitochondrial Gly decarboxylase-H protein (GDC-H), or the Rubisco large subunit were observed (Fig. 1A). A quantitative estimate of the changes in protein levels was determined from the immunoblots of leaf extracts isolated from two to three independent plants per line. An example is shown in Figure 1B. These results showed a 2- to 2.5-fold increase in the Rieske FeS protein relative to wild-type plants, and a similar increase also was observed for cyt f, cyt b₆, Lhca1, D2, and PsaA (Fig. 1C). No increase in the stromal FBPA protein was evident.

Chlorophyll Fluorescence Imaging Reveals Increased Photosynthetic Efficiency in Young Rieske FeS ox Seedlings

In order to explore the impact of increased levels of the Rieske FeS protein on photosynthesis, the quantum efficiency of PSII ($F_{q}/F_{m}'$) was analyzed using chlorophyll a fluorescence imaging (Baker, 2008; Murchie and Lawson, 2013). A small increase in $F_{q}/F_{m}'$ was found in the Rieske FeS ox plants at irradiances of 310 and 600 µmol m⁻² s⁻¹ (Fig. 2). Leaf area, generated from these images, was significantly larger in all Rieske FeS ox lines compared with the wild type (Fig. 2C), but no significant difference in leaf thickness was observed between the leaves of Rieske FeS lines 9 and 11 and the wild-type plants (Supplemental Table S1).

Photosynthetic CO₂ Assimilation and Electron Transport Rates Are Increased in the Rieske FeS ox Plants

The impact of overexpression of the Rieske FeS protein on the rate of photosynthesis in mature plants was investigated using combined gas-exchange and chlorophyll fluorescence analyses. Both the light-saturated rate of CO₂ fixation and the relative light-saturated rate of electron transport (ETRIP) were increased in the Rieske FeS ox lines compared with the wild type when measured at 2% [O₂] (Fig. 3, A and B; Table I). Additionally, the light-saturated rate of CO₂ assimilation at ambient [CO₂] also was increased when measured at 21% [O₂] (Supplemental Fig. S3). No significant difference in leaf absorbance between the Rieske FeS ox and wild-type plants was found (Supplemental Table S1).

In plants grown at a light level of 130 µmol m⁻² s⁻¹, no difference in the light- or CO₂-saturated rate of CO₂ assimilation ($A_{\text{max}}$) was found. In contrast, in a second group of plants grown at 280 µmol m⁻² s⁻¹, $A_{\text{max}}$ was greater in the Rieske FeS ox lines 9 and 11 relative to the wild type (Fig. 3C; Table I). Further analysis of the $A/C_i$ curves revealed that maximum electron transport rate was significantly greater in the Rieske FeS ox plants when compared with the wild type (Table II), but no significant difference in the maximum rate of Rubisco (data not shown) was observed.

The Quantum Efficiency of PSII and PSI Was Increased in the Rieske FeS ox Plants

To further explore the influence of increases in the Rieske FeS protein on PSII and PSI photochemistry, dark-light
induction responses were determined in the wild type and Rieske FeS ox (lines 11 and 10) using simultaneous measurements of P700 oxidation state and PSII efficiency. These results showed that the quantum yields of both PSI and PSII were increased in the Rieske FeS ox plants compared with the wild type and that the fraction of PSII centers that were open ($q_L$) also was increased, while the level of Qa reduction ($1 - q_p$) was lower in leaves of 27-d-old plants from line 11 (Fig. 4). Non-photochemical quenching (NPQ) levels also were shown to be lower in the Rieske FeS ox plants, together with a reduction in stress-induced limitation of NPQ ($q_N$) when compared with wild-type plants (Fig. 4). Similar results were obtained for both lines 10 and 11 when plants were analyzed later in development (34 DAP; Supplemental Fig. S4). The increase in the quantum yields of PSI and PSII observed here were accompanied by corresponding increases in electron transport rates (ETRI and ETRII; Supplemental Fig. S5, A and D); however, a bigger increase in ETRII relative to ETRI was observed, demonstrated by the wild type having a higher ETRI-ETRII ratio (Supplemental Fig. S5, C and D).

**Growth, Vegetative Biomass, and Seed Yield Are Increased in the Rieske FeS ox Plants**

The leaf area of the Rieske FeS ox lines was significantly greater than that of the wild type as early as 10 DAP in soil, and by 18 d it was 40% to 114% larger (Fig. 5). Destructive harvest at day 25 showed that this increase in leaf area translated to an increase in shoot biomass of between 29% and 72% determined as dry weight (Fig. 5C). To determine the impact of increased Rieske FeS protein on seed yield and final shoot biomass, a second group of plants was grown in the same conditions as described in Figure 6. Interestingly, at 38 DAP, 40% of the Rieske FeS ox plants had flowered, in contrast to 22% in the wild-type plants (Fig. 6A). Following seed set (52 DAP), both vegetative biomass (Fig. 6B) and seed yield (Fig. 6C) were determined, and although a significant increase in biomass was observed in all of the Rieske FeS ox plants, a statistically significant increase in seed yield was evident only in line 11.

**Pigment Content Was Altered in the Rieske FeS ox Plants**

The pigment composition of the leaves of the Rieske FeS ox lines and wild-type plants was determined. Increases in the levels of chlorophyll $a$ and $b$ (14%–29%) were observed in the Rieske FeS ox compared with wild-type

plants (Fig. 7). Plants with increased Rieske FeS protein also were found to have a small increase in the chlorophyll \( a/b \) ratio, from 2.96 to 3.12. These increases were accompanied by increases in the carotenoids, neoxanthin (+38%), violaxanthin (+59%), lutein (+75%), and \( \beta \)-carotene (+169%). No detectable change in the level of zeaxanthin was evident in the Rieske FeS ox plants. The increases in both total chlorophyll and total carotenoids also led to a significant decrease in the chlorophyll-to-carotenoid ratio, from 3.6 to 2.4 (Fig. 7).

**DISCUSSION**

In recent years, increasing the rate of photosynthetic carbon assimilation has been identified as a target for improvement to increase yield. Evidence to support this has come from the theory and modeling of the photosynthetic process, growth of plants in elevated \( \text{CO}_2 \), and transgenic manipulation (Zhu et al., 2010). It was shown previously in antisense studies that reducing the levels of the Rieske FeS protein resulted in a reduction in levels of the cyt \( b/f \) complex, a decrease in photosynthetic electron transport, and, in rice (Oryza sativa), a decrease in both biomass and seed yield (Price et al., 1998; Yamori et al., 2011b). However, the impact of overexpression of the Rieske FeS protein was clearly not restricted to increasing the activity of the cyt \( b/f \) complex but resulted in changes in PSI, PSII, and the ATPase complex, which led to an increase in electron flow through the entire electron transport chain. Analysis of the ratio of PSI to PSII electron transport showed that, relative to wild-type plants, the Rieske ox lines have higher rates of PSI ETR relative to PSI, which may be related to cyclic electron flow, differences in energy distribution, and/or the PSI-PSII ratio (Kono et al., 2014).

In addition to increased rates of photosynthesis, a substantial and significant increase in the growth of the

roseate area was observed in the Rieske FeS ox plants in the early vegetative phase, which resulted in an approximately 30% to 70% increase in biomass yield in the different lines. Importantly, seed yields in line 11, which showed the biggest increases in shoot biomass, also were shown to be increased relative to the wild type. Given that increases in leaf area are evident in the Rieske ox plants from early in development, the improvements in biomass are likely due to a combination of increased light capture and photosynthesis due to the greater leaf area.

**Figure 4.** Determination of the efficiency of electron transport in leaves of young Rieske FeS ox plants. Wild-type (WT) and Rieske FeS ox plants were grown in controlled-environment conditions with a light intensity of 130 mmol m\(^{-2}\) s\(^{-1}\) and an 8-h-light/16-h-dark cycle, and the redox state was determined (27 DAP) using a Dual-PAM instrument at a light intensity of 220 \(\mu\)mol m\(^{-2}\) s\(^{-1}\). The data were obtained using four individual plants from Rieske FeS ox line 11 compared with the wild type (five plants). Significant differences are indicated (*, \(P < 0.05\)). Rieske FeS ox Plants Have Increased Levels of Proteins in the cyt $b_6f$, PSI, and PSII Complexes

In keeping with our analysis of the electron transport processes in the Rieske FeS ox plants, increases in the levels of cyt $b_6$ and cyt $f$, core proteins of the cyt $b_6f$ complex, were evident. Furthermore, increases in the levels of proteins in both PSII and PSI and the $\delta$-subunit of the ATPase complex also were observed. This result was unexpected, given that no changes in the components of PSII or PSI were observed in the Rieske FeS antisense plants. In contrast, in keeping with this study, the hcf mutant, in which the biogenesis of the cyt $b_6f$ complex was inhibited, also had a reduced accumulation of components of both PSI and PSII (Lennartz et al., 2001). In addition, a recent study reported increases in cyt $b_6f$ protein levels in Arabidopsis plants grown under square-wave light compared with plants grown under fluctuating light, and these were accompanied by increased levels of PSII, PSI, and the $\delta$-subunit of the ATPase proteins (Vialet-Chabrand et al., 2017). Taken together, these results provide further demonstration of the ability of the thylakoid membrane to respond to changes in the external and internal environments (Foyer et al., 2012). Although there are many examples of coordination of the accumulation of photosynthetic complexes in the thylakoid membrane, the underlying regulation of the synthesis and assembly of components of the thylakoid membrane, the factors determining the accumulation of these complexes, is still poorly understood (Schöttler et al., 2015). Recently, a nucleus-encoded chloroplast RNA-binding protein, photosystem biogenesis regulator1 (PBR1), was identified and shown to be involved in the coordination of the biogenesis of the PSI, cyt $b_6f$, and NDH complexes (Yang et al., 2016). It will be interesting to explore the role of PBR1 in the plants produced in this study, as these are likely useful tools to investigate fundamental questions on factors controlling both the biogenesis and activities of the photosynthetic complexes in the electron transport chain.

A recent study has shown that, for rice plants growing in elevated CO$_2$, a small decrease in Rubisco protein levels resulted in an increase in the electron transport components and an increase in biomass (Kanno et al., 2017). Given the increase in thylakoid protein composition of the Rieske ox plants, it might be expected that there would be some tradeoff, and a reduction in other proteins may occur to compensate. Although no comprehensive analysis of proteins has been undertaken in these plants, we found no evidence of changes in the levels of Rubisco, which is a major N sink or FBPA and GDC. What is not yet clear is the impact of this manipulation on nitrogen use efficiency (NUE), and a full analysis of the performance of these plants under different N regimes will be needed to explore this question.

Overexpression of Rieske FeS Significantly Modifies the Pigment Content of Leaves

In parallel with the increase in components of the thylakoid membranes, plants with increased Rieske FeS protein were found to have increases in the levels of both chlorophyll $a$ and $b$ and a small increase in the chlorophyll $a/b$ ratio, from 2.96 to 3.12. The increases in chlorophyll $a$ and $b$ suggest a greater investment in both light capture and PSII reaction centers and would fit with the increase in photosynthetic electron transport
capacity in the Rieske FeS ox plants. In previous work, plants with reduced levels of the Rieske FeS protein had a lower chlorophyll $a/b$ ratio (Hurry et al., 1996; Price et al., 1998), which is the opposite of what was observed in the Rieske FeS ox plants. In addition to increases in chlorophyll, significant increases in the carotenoid pigments also were seen with $\beta$-carotene (+169%), violaxanthin (+59%), lutein (+75%), and neoxanthin (+37%). $\beta$-Carotene is a component of both the reaction centers (RC) and light-harvesting complex (Kamiya and Shen, 2003; Ferreira et al., 2004; Loll et al., 2005; Litvin et al., 2008; Janik et al., 2016), and the increase in these pigments observed in the Rieske FeS ox plants is in agreement with the investment in both light harvesting and increasing RC efficiency. We also observed a significant decrease in the chlorophyll-to-carotenoid ratio in Rieske FeS ox plants, which would suggest that there is a greater investment in photoprotection relative to the increased chlorophyll for light harvesting. This increase in carotenoids relative to chlorophyll may contribute to the lower NPQ observed in Rieske FeS ox plants (Kaňka et al., 2016).

Lutein, neoxanthin, and violaxanthin are the main xanthophyll pigment constituents of the largest light-harvesting pigment-protein complex of photosystem II.

**Figure 7.** Pigment content in wild-type (WT) and Rieske FeS ox plants. Plants were grown at 130 $\mu$mol m$^{-2}$ s$^{-1}$ light intensity in short days (8 h of light/16 h of dark). Two leaf discs, collected from two different leaves, were immersed in $N,N$-dimethylformamide (DMF) at 4°C for 48 h and separated by ultra-performance liquid chromatography. Results are represented as $\mu$g g$^{-1}$ fresh weight (FW). Statistical differences are shown by asterisks (*, $P < 0.1$; **, $P < 0.05$; and ***, $P < 0.001$). Error bars represent SE.
(Thayer and Björkman, 1992; Ruban et al., 1994, 1996, 1999; Ruban, 2012; Janik et al., 2016). Acidification of the thylakoid lumen as a result of electron transport (and driven in particular by the activities of the cyt b/f complex) is accompanied by the deepoxidation of viola-xanthin and an accumulation of zeaxanthin (Björkman and Demmig-Adams, 1994; Müller et al., 2001; Ruban, 2012) as well as protonation of carboxylic acid residues of the PsbS protein associated with PSII antennae (Li et al., 2000, 2004). Protonation of PsbS and binding of zeaxan-thin increase NPQ and the thermal dissipation of excitation energy (Baker, 2008; Jahns and Holzwarth, 2012). However, we found that the increase in the level of the Rieske FeS protein led to small but significantly lower steady-state levels of NPQ. The absence of an increase in NPQ in the presence of significant increases in electron transport rates suggests that the Rieske FeS ox plants also have increased rates of ATP synthesis. Although we provide no direct support for this, we did observe an increase in the level of the ATP synthase δ-subunit protein in the Rieske FeS ox plants. Further support for this suggestion comes from earlier work on Rieske FeS antisense plants, which showed that the level of ATP synthase and the thynthylakin pH gradient were both reduced (Price et al., 1995, 1998; Ruuska et al., 2000).

CONCLUSION

A number of studies have shown that increasing photosynthesis through the manipulation of CO₂ assimilation can improve growth (Miyagawa et al., 2001; Lefebvre et al., 2005; Rosenthal et al., 2011; Uematsu et al., 2012; Simkin et al., 2015, 2017). This work, together with a study in which cytchrome c₃ from the red alga Porphyra was expressed in Arabidopsis (Chida et al., 2007), provides direct evidence that there is also an opportunity to improve the efficiency of the electron transfer chain. Here, we have shown not only that overexpression of the Rieske FeS protein resulted in increases in cyt f and cyt b₅ proteins of the cyt b/f complex but that components of PSI, PSII, and the ATPase also were increased. Under the conditions of growth used in this study, these changes led to improvements in photosynthesis and biomass obtained from the Rieske ox plants relative to the wild type.

MATERIALS AND METHODS

Rieske FeS Protein of cyt b/f

The full-length coding sequence of the Rieske FeS protein of the cyt b(f) (X64353) complex was amplified by reverse transcription-PCR using primers NiRieskeFeSF (5’-caAGCCTTCTTCTCTCTC-3’) and NiRieske-FeSR (5’-TCAGCCCAAGCAGTTCATCC-3’). The resulting amplified product was cloned into pENTR/D (Invitrogen) to make pENTR-NiRieskeFeS. The sequence was verified and found to be identical. The full-length cDNA was introduced into the pGW2 Gateway vector (Nakagawa et al., 2007; AR289765) by recombination from the pENTR/D vector to make pGW-NiRieske (B2-Niri). cDNAs are under transcriptional control of the 35S tobacco mosaic virus promoter, which directs constitutive high-level transcription of the transgene, followed by the nos 3’ terminator. Full details of the B2-Niri construct assembly can be seen in Supplemental Figure S1.

Generation of Transgenic Plants

The recombinant plasmid B2-Niri was introduced into wild-type Arabidopsis (Arabidopsis thaliana) by floral dipping (Clough and Bent, 1998) using Agrobacterium rhizogenes GV3101. Positive transformants were regenerated on Murashige and Skoog medium containing kanamycin (50 mg L⁻¹) and hygromycin (20 mg L⁻¹). Kanamycin/hygromycin-resistant primary transformants (T1 generation) with established root systems were transferred to soil and allowed to self-fertilize.

Plant Growth Conditions

Wild-type T2 Arabidopsis plants resulting from self-fertilization of transgenic plants were germinated in sterile agar medium containing Murashige and Skoog salts, selected on kanamycin, and grown to seed in soil (Levington F2; Fisons), and lines of interest were identified by western blot and quantitative PCR. For experimental study, T3 progeny seeds from selected lines were germinated on soil in controlled-environment chambers at an irradiance of 130 μmol m⁻² s⁻¹ in an 8-h/16-h square-wave photoperiod with an air temperature of 22°C and a relative humidity of 60%. Plant position was randomized, and the position of the trays was rotated daily under the light. Leaf areas were calculated from photographic images using ImageJ software (imagj.nih.gov/ij). Wild-type plants used in this study were a combined group of the wild type and null segregants from the transgenic lines, verified by PCR for nonintegration of the transgene, as no significant differences in growth parameters were seen between them (Supplemental Fig. S2).

Protein Extraction and Immunoblotting

Four leaf discs (0.6 cm diameter) from two individual leaves were taken, immediately plunged into liquid N₂, and subsequently stored at −80°C. Samples were ground in liquid nitrogen, and protein quantification was performed (Harrison et al., 1998). Samples were loaded on an equal protein basis, separated using 12% (w/v) SDS-PAGE, transferred to a polyvinylidene difluoride membrane, and probed using antibodies raised against the cyt b/f proteins cyt f j (PetA; AS08306), cyt b₅ (PetB; AS03034), Rieske FeS (PetC; AS08330), the PSI Lhc1 (AS01105) and PsA (AS06172) proteins, the PSII PsbA/D1 (AS01016) and PsbD/D2 (AS06146) proteins, the ATP synthase δ-sub-unit (AS01391), and the Gly decarboxylase H-subunit (AS60507), all purchased from Agrisera (via Newmarket Scientific). FBPA antibodies were raised against a peptide from a conserved region of the protein [C]-ASKLENTEANQRAY-amide (Cambridge Research Biochemicals; Simkin et al., 2015). Proteins were detected using horseradish peroxidase conjugated to the secondary antibody and ECL chemiluminescence detection reagent (Amersham). Proteins were quantified using a Fusion FX Vilber Lourmat imager (Peqlab), as described previously (Viallet-Chabrand et al., 2017).

Chlorophyll Fluorescence Imaging

Chlorophyll fluorescence measurements were performed on 10-d-old Arabidopsis seedlings that had been grown in a controlled-environment chamber at a photosynthetic photon flux density (PPFD) of 130 μmol m⁻² s⁻¹ with ambient CO₂ at 22°C. Images of the operating efficiency of PSII photochemistry (F₉/₅) were taken at PPFDs of 310 and 600 μmol m⁻² s⁻¹ using a chlorophyll fluorescence imaging system (Technologica; Barbagallo et al., 2003; Baker and Rosenqvist, 2004). F₉/₅ was calculated from measurements of steady-state fluorescence in the light (F₉) and maximum fluorescence in the light (F₉₅) was obtained after a saturating 800-ms pulse of 6.200 μmol m⁻² s⁻¹ PPFD using the following equation: F₉/₅ = (F₉₅ − F₉)/F₉₅ (Oxborough and Baker 1997a; Baker et al., 2001).

A/Cₚ Response Curves

The response of A to Cₚ was measured using a portable gas-exchange system (CIRAS-1; PP Systems). Leaves were illuminated using a red-blue light source attached to the gas-exchange system, and light levels were maintained at saturating PPFD of 1,000 μmol m⁻² s⁻¹ with an integral light-emitting diode light.
source (PP Systems) for the duration of the A/Ci response curve. Measurements of A were made at ambient CO₂ concentration (Cᵢ) of 400 µmol mol⁻¹, before Cᵢ was decreased in a stepwise manner to 300, 200, 150, 100, and 50 µmol mol⁻¹ before returning to the initial value and increased to 500, 600, 700, 800, 900, 1,000, 1,100, and 1,200 µmol mol⁻¹. Leaf temperature and vapor pressure deficit were maintained at 22°C and 1 ± 0.2 kPa, respectively. The maximum rate of Rubisco and the maximum rate of electron transport for ribulose 1,5-bisphosphate regeneration were determined and standardized to a leaf temperature of 25°C based on equations from Bernacchi et al. (2001) and McMurtrie and Wang (1993), respectively.

Photosynthetic Capacity

Photosynthesis as a function of PPFD ([A]/[Q] response curves) was measured using the 6400XT portable gas-exchange system (Li-Cor). Covette conditions were maintained at a leaf temperature of 22°C, relative humidity of 50% to 60%, and ambient growth CO₂ concentration of 400 µmol mol⁻¹ for plants grown in ambient conditions. Leaves were initially stabilized at saturating irradiance of 1,000 µmol m⁻² s⁻¹, after which A and stomatal conductance were measured at the following PPFD levels: 0, 50, 100, 150, 200, 250, 300, 350, 400, 500, 600, 800, and 1,000 µmol m⁻² s⁻¹. Measurements were recorded after A reached a new steady state (1–3 min) and before stomatal conductance changed to the new light levels. [A]/[Q] analyses were performed at 21% and 2% [O₂].

PSI and PSII Quantum Efficiency

The photochemical quantum efficiency of PSI and PSII in transgenic and wild-type plants was measured following a dark-light induction transition using a Dual-PAM-100 instrument (Walz) with a DUAL-DR measuring head. Plants were dark adapted for 20 min before placing in the instrument. Following a dark-adapted measurement, plants were illuminated with 220 µmol m⁻² s⁻¹ PPFD. The maximum quantum yield of PSII was measured following a saturating pulse of light for 600 ms at an intensity of 6,200 µmol m⁻² s⁻¹. PSI operating efficiency was determined as described by the routines above. PSI quantum efficiency was measured as an absorption change of P700 before and after a saturating pulse of 6,200 µmol m⁻² s⁻¹ for 300 ms (which fully oxidizes P700) in the presence of far-red light with a far-red preillumination of 10 s. Both measurements were recorded every 1 min for 5 min. ƞₚ or ƞₛ/ƞₚ was calculated from measurements of steady-state fluorescence in the light (Fᵢ) and maximum fluorescence in the light (Fₘ), while minimal fluorescence in the light (Fₛ) was calculated following the equation of Oxboborough and Barker (1997b). The fraction of open PSII centers (ƞₛ) was calculated from ƞₛ × Fₘ/Fₛ (Baker, 2008).

Pigment Extraction and HPLC Analysis

Chlorophylls and carotenoids were extracted using DMF as described previously (Inskipp and Bloom, 1985), which was shown subsequently to suppress chlorophyllide formation in Arabidopsis leaves (Hu et al., 2013). Briefly, two leaf discs collected from two different leaves were immersed in DMF at 4°C for 48 h and separated by ultra-performance liquid chromatography as described by Zapata et al. (2000).

Leaf Thickness

Leaves of equivalent developmental stage were collected from plants after 28 d of growth. Strips were cut from the center of the leaf, avoiding the midvein, preserved in 5% glutaraldehyde, stored at 4°C for 24 h, followed by dehydration in sequential ethanol solutions of 20%, 40%, 80%, and 100% (v/v). The samples were placed in LR White acrylic resin (Sigma-Aldrich), refrigerated for 24 h, embedded in capsules, and placed at 60°C for 24 h. Sections (0.5 µm) were cut using a Reichert-Jung Ultracut microtome (Ametek), fixed, stained, and viewed with a light microscope (López-Juez et al., 1998). Leaf thickness was determined by measuring leaves from two to three plants from lines 9 and 11 compared with leaves from four wild-type plants.

Statistical Analysis

All statistical analyses were done by comparing ANOVA using Systat (University of Essex). The differences between means were tested using the post hoc Tukey’s test (SPPS).

Accession Numbers

Sequence data from this article can be found in the GenBank/EMBL data libraries under accession number X64353.

Supplemental Data

The following supplemental materials are available.

Supplemental Figure S1. Schematic representation of the Rieske Fe₆S ox expression vector pGWRi used to transform Arabidopsis.

Supplemental Figure S2. Determination of photosynthetic efficiency and leaf area of the wild type versus azygous segregating controls using chlorophyll fluorescence imaging.

Supplemental Figure S3. Immunoblot analysis of wild-type and Rieske Fe₆S ox proteins.

Supplemental Figure S4. Light response curves of the Rieske Fe₆S plants at 21% [O₂].

Supplemental Figure S5. Determination of the efficiency of electron transport in leaves of mature Rieske Fe₆S ox plants.

Supplemental Figure S6. Determination of the efficiency of electron transport in leaves of young and mature Rieske Fe₆S ox plants.

Supplemental Table S1. Physiological parameters of Rieske Fe₆S ox plants compared with the wild type.

ACKNOWLEDGMENTS

We thank James E. Fox and Philip A. Davey for help with pigment analysis, Silvere Vailet-Chabrand for help in drafting revisions of the article, and Elena A. Pelech for help with Dual-PAM measurements.
