Abstract. Recently, Harko et al. (2014) derived an approximate metric of the galactic halo in the Eddington inspired Born-Infeld (EiBI) gravity. In this metric, we show that there is an upper limit $\rho_{0}^{\text{upper}}$ on the central density $\rho_{0}$ of dark matter such that stable circular orbits are possible only when the constraint $\rho_{0} \leq \rho_{0}^{\text{upper}}$ is satisfied in each galactic sample. To quantify different $\rho_{0}^{\text{upper}}$ for different samples, we follow the novel approach of Edery & Paranjape (1998), where we use as input the geometric halo radius $R_{\text{WR}}$ from Weyl gravity and equate it with the dark matter radius $R_{\text{DM}}$ from EiBI gravity for the same halo boundary. This input then shows that the known fitted values of $\rho_{0}$ obey the constraint $\rho_{0} \leq \rho_{0}^{\text{upper}} \propto (R_{\text{WR}})^{-2}$. Using the mass-to-light ratios giving $\alpha$, we shall also evaluate $\rho_{0}^{\text{lower}} \propto (\alpha - 1) M_{\text{lum}} R_{\text{WR}}^{-3}$ and the average dark matter density $\langle \rho \rangle^{\text{lower}}$. Quantitatively, it turns out that the interval $\rho_{0}^{\text{lower}} \leq \rho_{0} \leq \rho_{0}^{\text{upper}}$ verifies reasonably well against many dark matter dominated low surface brightness (LSB) galaxies for which values of $\rho_{0}$ are independently known. The interval holds also in the case of Milky Way galaxy. Qualitatively, the existence of a stability induced upper limit $\rho_{0}^{\text{upper}}$ is a remarkable prediction of the EiBI theory.

Keywords: dark matter theory, rotation curves of galaxies, modified gravity

ArXiv ePrint: 1412.7897
1 Introduction

Early observations [1–3] on rotational data of spiral galaxies, now reconfirmed by observations extending well beyond the optical disc [4–18], indicate that they do not conform to Newtonian gravity predictions. Hence the hypothesis is that there could be large amounts of non-luminous matter hidden in the galactic haloes. The rationale is this: Doppler emissions from stable circular orbits of neutral hydrogen clouds in the halo allow measurement of tangential velocity $v_{tg}$ of the clouds treated as probe particles. Contrary to Newton’s laws, where $v_{tg}^2$ should decay with radius $r$, observations indicate that it approximately levels off with $r$ in the galactic halo region, which in turn calls for the presence of additional non-luminous mass, the so called dark matter. Since dark matter has not yet been directly observed, the dark matter hypothesis is often variably referred to as the missing mass problem.

Several well known theoretical models for dark matter exist in the literature but it is impossible to list all of them here (only some are mentioned in [19–34]). In its usual formulation, dark matter is a parametrization of the observed velocity discrepancies and is not a prediction of the formulation. Some simulations require fine tuning of halo parameters to luminous parameters galaxy by galaxy — a procedure that only enlarges the number of parameters rather than reducing them (See [35], pp. 32–33; see also footnote 13). There exist yet another variety of halo models, which treat the missing mass problem as a failure of the Newtonian theory on galactic distance scales rather than as a prediction for dark matter. Such models actually do not require dark matter at all for the interpretation of observed rotation data. This class of theories include, e.g., Modified Newtonian Dynamics (MOND) developed by Milgrom [36–42], Scalar-Tensor-Vector Gravity theory developed by Moffat [43–45], Weyl conformal gravity\footnote{Weyl conformal gravity has been debated for and against in the literature. For instance, Flanagan [46] argues that if the source has associated with it a macroscopic long range scalar field, breaking conformal symmetry, the theory does not reproduce attractive gravity in the solar system. However, subsequently, Mannheim [47] has counter-argued that Schwarzschild tests of solar gravity could still be recovered even in the presence of such macroscopic fields.} implemented by Mannheim and O’Brien [48]. For brevity, we call the last the MO model and we shall use this ingredient in the sequel. A remarkable speciality of the MO model is that, using the best available galactic optical and radio data, and a
standardized, non-biased, treatment for selecting appropriate galactic parameters, the model is able to provide a good fit to the rotation curves without the need for any dark matter whatsoever.

There are various other (non-)dark matter models that are capable of accounting, for example, for observations of galaxy clusters and gravitational lensing or structure formation. A leading example is the cold dark matter (CDM) model, which is a part of the current standard model \( \Lambda \)CDM of cosmology. These models are based on different phenomenologies such as inflation and nucleosynthesis [49–66]. They can successfully explain observations of galaxy clusters [49–54], gravitational lensing [55, 56] or structure formation [57], to name the most important ones. These models postulate that galactic cores may consist of axions [58], massive gravitons [59], BEC [60] or other collisionless particles. The post-recombination fluctuation spectrum nicely explains the formation of galaxies and clusters [49–54]. The CDM is a successful paradigm accounting for the small density inhomogeneities that seed structure formations \( 10^{-34} \text{ sec} \) after the bang and as such provides a bold probe into the Early Universe [57]. Some other and recent works on CDM models are mentioned here though the list by no means is exhaustive [61–66].

Recently, another alternative candidate for dark matter is also being speculated. This is based on the evidence of soft positron spectrum in the AMS-02 [67, 68] cosmic ray data. Despite this alternative, the observed flat rotation curves are still considered as a robust proof that dark matter essentially is of gravitational origin described by general relativity [69–71]. But in general relativity, matter-gravity coupling is linear, while some authors argue (for non-minimal coupling of modified gravity with matter or other insights into the paradigm, see [72–77]) that there is no obvious reason as to why the coupling should be linear. Following this thought, an interesting modification of matter-gravity coupling leading to the Eddington-inspired Born-Infeld (EiBI) theory has been recently developed by Bañados and Ferreira [78, 79], which we shall use as another ingredient. Only in vacuum, the EiBI theory is equivalent to standard general relativity. This new, and more general, theory has led to interesting observable predictions in the context of solar interior dynamics, big bang nucleosynthesis, neutron stars, the structure of other compact stars [80–83] including the possibility of nonsingular cosmological models and alternative to inflation [84].

To get a more complete view of the two ingredients of the present work, the EiBI and the Weyl gravity, it is necessary to mention that several important predictions follow from the two theories. For instance, recent investigation by Du et al. [85] on large scale structure formation in the EiBI gravity shows a deviation in the matter power spectrum between the EiBI gravity and the \( \Lambda \)CDM model, which is a testable prediction. Stability and localization of gravitational fluctuations in the EiBI brane system have been studied in refs. [86, 87]. Further, as shown by Wei et al. [88], strong gravitational lensing observables in EiBI are controlled by the coupling parameter \( \kappa \), which is a new prediction that lends itself to future testing. Similarly, in Weyl gravity, the first order light deflection angle \( \theta_W \) by a galaxy, first obtained by Edery and Paranjape [89], contains the galactic halo parameter \( \gamma \) appearing in the MO model. Bhattacharyya et al. [90, 91] calculated higher order deflection terms. Strong field lensing in the Weyl gravity has been studied recently in [92], and the predictions can be verified by actual observations in the future. A remarkable feature of Weyl gravity is that its solution, the MO model, already contains the successes of the well tested Schwarzschild gravity as a special case. All the above exemplify the current status of the capabilities of the two theories in question.

The possibility of perfect fluid dark matter within the framework of general relativity has already been explored in the literature [93, 94]. A similar possibility has been recently
investigated within the framework of the EiBI theory by Harko et al. [95, 96] and this is the model we are going to analyze further in this paper. Using a tangential velocity profile [97, 98] giving Universal Rotation Curves (URC) and setting the cosmological constant to zero, they obtained, in the Newtonian approximation, a new galactic metric and theoretically explored its gravitational properties. However, the numerical values of the crucial parameter $\kappa$ (denoted by $\kappa = 2R_{DM}^2/\pi^2$) or equivalently the dark matter radius $R_{DM}$, cannot be determined from the theory alone — it has to be obtained either from the observed data or from some other model.\(^2\) It is also expected that the values of $R_{DM}$ would differ from galaxy to galaxy. On the other hand, to our knowledge, apart from the observed last scattering radii $R_{\text{last}}$, the astrophysical literature still seems to lack concrete observed data on $R_{DM}$ for individual galaxies. Therefore, an appropriate numerical input for $R_{DM}$ is needed, which we take from Weyl gravity, if we want to make quantitative predictions.

At this point, we recall a novel idea of Edery & Paranjape [89], where they bridged two different metric theories by equating the same Einstein angle $\theta_E$ (caused by the luminous + dark matter) with the Weyl angle $\theta_W$ (caused by the luminous matter alone), and drew useful and testable conclusions using the identity $\theta_E = \theta_W$. Motivated exactly by this idea, we equate the same EiBI radius of dark matter $R_{DM}$ (caused by dark matter source) with the geometric Weyl radius of the galactic halo $R_{WR}$ (caused by the luminous matter alone). With the numerical input $R_{DM} = R_{WR}$, we shall quantify the relevant central densities in the EiBI theory (see footnote 8). We wish to clarify that we are not talking here of merging or mapping the two theories into one another per se but concentrating only on a particular common prediction. The theories are of course different from each other — one with dark matter source and the other without, not to mention differences elsewhere. But both are metric theories capable of predicting for any given galactic sample a dark matter/halo boundary arising out of the same stability condition $V'' < 0$ (as used, e.g., in the braneworld dark matter [99]). Therefore, without any bias to either theories, we shall investigate if this input leads to limits on dark matter central density $\rho_0$ consistent with those estimated from fits to different known profiles. We shall see that it does.

The radius $R_{WR}$ is to be understood as the geometric halo radius with its interior being filled with Weyl vacuum.\(^3\) We stress that Weyl vacuum is not a vacuum in the ordinary sense but an arena of interplay of several potential energies, predominantly the global quadratic potential due to cosmic inhomogeneities [48]. Thus, our input physically means that the total potential energy contained within the halo radius $R_{WR}$ of Weyl gravity equals the total invisible dark matter energy contained within $R_{DM}$ of EiBI gravity. The radius $R_{DM}$ is defined by the absence of dark matter density at the halo boundary [95, 96], while $R_{WR}$ is defined by the absence of stable circular orbits at the halo boundary [100]. Since stability is an essential physical criterion because Doppler emissions from the halo emanate from stable circular orbits of hydrogen gas [101], we think that $R_{WR}$ should be regarded as the only testable upper limit on the radius of a galactic halo. Fortunately, observed last scattering data $R_{\text{last}}$ so far have not surpassed the predicted limiting value $R_{WR}$ for all the galaxies studied to date, thereby lending excellent observational support to the MO model prediction of $R_{WR}$.

\(^2\)We wish to clarify that the EiBI parameter $\kappa$ is not a universal constant — it’s more like a parameter of the theory that assumes different values depending on the physical situation. For instance, the structure of compact general relativistic star requires a value $\kappa \simeq 10^{12} \text{cm}^2$ [82], which differs from the value $\kappa \simeq 10^{14} \text{cm}^2$ inferred from dark matter density profiles.

\(^3\)Note that we are using here the terminology $R_{WR}$ in lieu of $R_{\text{stable}}^{\text{max}}$ of ref. [100] only to bring it in line with the notation of the present analysis.
The purpose of the present paper is as follows: we shall concentrate on the low surface brightness (LSB) galaxies that are mostly dominated by dark matter. We show that there is an upper limit on the dark matter central density $\rho_0$ specific to each individual galaxy, which we call here $\rho_0^{\text{upper}}$, such that stable circular orbits in the EiBI are possible only when the constraint $\rho_0 \leq \rho_0^{\text{upper}} \propto (R_{\text{WR}})^{-2}$ is satisfied in that galaxy. Using the Weyl gravity input $R_{\text{DM}} = R_{\text{WR}}$, we shall then quantify $\rho_0^{\text{upper}}$, and show that the central density $\rho_0$ predicted from the fit to various simulations including the NFW and Burkert density profiles does obey the constraint. Taking into account the range of the rather uncertain but possible mass-to-light ratios (denoted, say, by $\alpha$), we shall calculate also the lower central density $\rho_0^{\text{lower}} \propto (\alpha - 1)M_{\text{dim}}R_{\text{WR}}^{-3}$ and find that $\rho_0^{\text{lower}} \leq \rho_0 \leq \rho_0^{\text{upper}}$ holds for some known LSB samples for which $\rho_0$ is known from independent fits. Some illustrative galactic samples including the Milky Way are tabulated. The values fall within the predicted interval for each individual galaxy and we conjecture that at least the upper limit might be generally true.

The contents are organized as follows: since both the models under consideration are relatively new, hence possibly unfamiliar, we provide in section 2, a brief outline of the algorithms underlying the EiBI and MO metric models of the galactic halo. In section 3, we shall graphically explore $\rho_0^{\text{upper}}$ for stability of circular orbits in EiBI. In section 4, using the input under consideration, we shall quantify upper and lower central densities for some samples to see if the estimated central densities $\rho_0$ truly fall within the proposed interval, that is, if $\rho_0^{\text{lower}} \leq \rho_0 \leq \rho_0^{\text{upper}}$. In section 5, we discuss the dark matter density profiles in the context of Milky Way. The results are summarized in section 6. We shall take units such that $8\pi G = 1, c = 1$, unless restored.

2 The models

2.1 EiBI model

For easy reference, we outline only the salient features of the EiBI dark matter model developed in [95, 96]. The EiBI action is [78, 79, 85, 102, 103]

$$S_{\text{EiBI}} = \frac{2}{\kappa} \int d^4x \left[ \sqrt{-g}g_{\mu\nu} + \kappa R_{\mu\nu}(\Gamma) \right] - \lambda \sqrt{-|g_{\mu\nu}|} + S_{\text{matter}}, \quad (2.1)$$

where $\lambda$ is a dimensionless parameter, $g_{\mu\nu}$ is the physical metric, $R_{\mu\nu}(\Gamma)$ is the symmetric part of the Ricci tensor built solely from the connection $\Gamma_{\beta\gamma}^\alpha \equiv \frac{1}{2}q^{\alpha\sigma}[\partial_\mu q_{\sigma\beta} + \partial_\beta q_{\sigma\gamma} - \partial_\gamma q_{\sigma\beta}]$ derived from an auxiliary metric denoted by $q_{\mu\nu}$. The meaning of the auxiliary metric $q_{\mu\nu}$ is that it partially satisfies Eddington field equations so that $2\kappa \sqrt{|\Gamma|}R_{\mu\nu} = \sqrt{|q|}q^{\mu\nu}$, which can be rewritten as Einstein field equations if we equate $q_{\mu\nu}$ with $g_{\mu\nu}$ and $\kappa$ with $\Lambda^{-1}$. For small values of $\kappa R$, the action (2.1) reproduces the Einstein-Hilbert action with $\Lambda = \kappa \Lambda + 1$, where $\Lambda$ is the cosmological constant, while for large values of $\kappa R$, the action approximates to that of Eddington, viz., $S_{\text{Edd}} = 2\kappa \int d^4x \sqrt{|\Gamma|}$. For more details, see [78, 79].

Harko et al. [95, 96] deals with dark matter modeling assuming certain restrictive conditions such as spherical symmetry and asymptotic flaness, the latter requiring that $\Lambda = 0 \iff \lambda = 1$. These assumptions of course limit the applicability of EiBI theory but makes the problem at hand much simpler to handle. One spin-off is that the description of the physical behavior of various cosmological and stellar scenarios was assumed to be controlled by the only remaining parameter $\kappa$. The galactic halo is assumed to be filled with perfect fluid dark matter with energy-momentum tensor $T^{\mu\nu} = pg^{\mu\nu} + (p + \rho)U^\mu U^\nu$, where...
\[ g_{\mu\nu} U^\mu U^\nu = -1 \] and the tangential velocity profile provided by the Universal Rotation Curve (URC) \cite{97, 98}

\[ v^2_{\perp} = \frac{v^2_{\infty}}{(r/r_{\text{opt}})^2 + r_0^2}, \]

(2.2)

where \( r_{\text{opt}} \) is the optical radius containing 83\% of the galactic luminosity, \( r_0 \) is the halo core radius in units of \( r_{\text{opt}} \), the asymptotic velocity \( v^2_{\infty} = v^2_{\text{opt}} (1 - \beta_*) (1 + r_0^2) \), \( v_{\text{opt}} = v_{\perp}(r_{\text{opt}}) \), \( \beta_* = 0.72 + 0.44 \log_{10}(L/L_*) \), \( L_* = 10^{10.4} L_c \). For spiral galaxies, \( r_0 = 1.5 (L/L_*)^{1/5} \). Under the Newtonian approximations that the pressure \( p \approx 0 \), \( 8\pi G \rho \ll 1 \), and \( (r/r_{\text{opt}})^2 \gg r_0^2 \), the EiBI field equations yield the Lane-Emden equation with polytropic index \( n = 1 \), which has an exact nonsingular solution for dark matter density distribution as \cite{95, 96}^4

\[ \rho^{(0)}(r) = \rho_0 \left[ \frac{\sin \left( \frac{r}{r_{\text{opt}}} \right)}{r_{\text{opt}}^{\frac{1}{2}}} \right], \]

(2.3)

where \( \rho^{(0)}(0) = \rho_0 \) is the constant central density. Assuming that the halo has a sharp boundary \( R_{\text{DM}} \), where the density vanishes such that \( \rho^{(0)}(R_{\text{DM}}) = 0 \), one has

\[ R_{\text{DM}} = \pi \sqrt{\frac{\kappa}{2}}. \]

(2.4)

The density profile (2.3) exhibits an unphysical behavior of becoming negative for \( R_{\text{DM}} < R < 2R_{\text{DM}} \), which is why one has to require a sharp halo boundary \( \rho^{(0)}(R \geq R_{\text{DM}}) = 0 \).^5

This quite specific behavior of the density profile differs from those of Navarro-Frenk-White (NFW) or Burkert density profiles (that decay to zero only as \( r \to \infty \)).^6

The mass profile of the dark matter is

\[ M(r) = 4\pi \int_0^r \rho^{(0)}(r)r^2 dr = \frac{4R^3_{\text{DM}}}{\pi^2} \rho_0 [\sin(\tau) - \tau \cos(\tau)], \]

(2.5)

where the dimensionless quantity \( \tau = \pi r/R_{\text{DM}} \). The total mass of the dark matter \( M_{\text{DM}} \) and the mean density \( \langle \rho \rangle \) in EiBI theory are given respectively by

\[ M_{\text{DM}} = M(R_{\text{DM}}) = \frac{4}{\pi} \rho_0 R^3_{\text{DM}}, \quad \langle \rho \rangle = \frac{3\rho_0}{\pi^2}. \]

(2.6)

^4The solution (2.3) to the Lane-Emden equation and its connection to dark matter was first pointed out in \cite{96}.

^5We thank an anonymous referee for pointing this out.

^6The observational situation is that the mass density profiles on the logarithmic scale clearly indicate that the density is decaying at a finite radius \cite{104}. While NFW or Burkert density profiles might lead to different physical metrics of interest, the key point of the present investigation is that the dark matter has a finite radius following from stability considerations \cite{100}. See also footnote 11.
The approximate physical metric has been derived in [95, 96] as
\[ d\tau^2 = -B(\tau) dt^2 + A(\tau) dr^2 + r^2 C(\tau) (d\theta^2 + \sin^2 \theta d\phi^2), \] (2.7)

\[ B(\tau) = e^{\nu_0} \left( \frac{R_{\text{DM}}}{\pi r_{\text{opt}}} \right)^2 \frac{1}{\tau^2 + r_0^2} \nu_0^2, \] (2.8)

\[ A(\tau) = \left( \frac{R_{\text{DM}}}{\pi} \right)^2 \left[ 1 - \frac{\rho_0}{\tau} \sin(\tau) + \frac{\rho_0}{\tau} \cos(\tau) \right] \left[ 1 - \frac{\rho_0}{\tau} \sin(\tau) \right], \] (2.9)

\[ C(\tau) = \left( \frac{R_{\text{DM}}}{\pi} \right)^2 \left[ 1 - \frac{\rho_0}{\tau} \sin(\tau) \right], \] (2.10)

where \( e^{\nu_0} \) is an arbitrary constant of integration (which we set to unity) and the dimensionless quantity \( \rho_0 = \frac{8 \rho_0 R_{\text{DM}}^2}{\pi}. \)

Note that the surface area of a sphere at the boundary of dark matter halo defined by \( \tau = \pi \), has the value \( S = 4\pi r^2 C(\tau) = 4\pi r^2 \left( \frac{R_{\text{DM}}}{\pi} \right)^2 = 4\pi R_{\text{DM}}^2 \), which is just the spherical surface area in "standard coordinates". Thus the dark matter radius \( R_{\text{DM}} \) can be identified with standard coordinate halo radius \( R_{\text{HR}} \) derived below. We shall need some of the above equations in the sequel.

### 2.2 Mannheim-O’Brien model

The unique Weyl action is
\[ S_{\text{Weyl}} = -\alpha_g \int d^4 x \sqrt{-g} \left[ C_{\lambda\mu\nu\sigma} C^{\lambda\mu\nu\sigma} \right] = -2\alpha_g \int d^4 x \sqrt{-g} \left[ R_{\mu\sigma} R^{\mu\sigma} - \frac{1}{3} (R^\alpha_\alpha)^2 \right], \] (2.11)

where \( C^{\lambda\mu\nu\sigma} \) is the Weyl tensor and \( \alpha_g \) is the dimensionless gravitational constant. The resulting field equations are fourth order and trace free, rather long and complicated, so we omit them here. The exact solution of vacuum Weyl gravity for the metric ansatz
\[ d\tau^2 = -B(r) dt^2 + \frac{1}{B(r)} dr^2 + r^2 (d\theta^2 + \sin^2 \theta d\phi^2) \] (2.12)

was derived by Mannheim & Kazanas [106] that describes the metric outside of a localized static, spherically symmetric source of radius \( r_0 \) embedded in a region with \( T_{\mu\nu}(r > r_0) = 0 \) as follows (after suitably redefining the constants):
\[ B(r) = (1 - 6M\gamma)^{1/2} - \frac{2M}{r} + \gamma r - kr^2, \] (2.13)

where \( M, \gamma, k \) are constants of integration. Schwarzschild solution is recovered at \( \gamma = 0, k = 0 \) as a special case of Weyl gravity.

---

\(^7\)The role of the URC profile (2.2) is that it determines the metric function \( B(\tau) \equiv e^{\nu(\tau)} \). Following Chandrasekhar [105], we know that the tangential velocity is given by \( v_{\tau}^2 = \frac{\pi}{x} (e')_r \). See the details in ref. [93]. Using the URC for \( v_{\tau}^2 \), defining \( r/r_{\text{opt}} = x \), and integrating, we obtain \( e^{\nu(\tau)} = (x^2 + r_0^2)^{1/2} \). Restoring the original variable \( r/r_{\text{opt}} \), and defining \( \tau = \pi r/R_{\text{DM}} \), we immediately obtain the metric function \( B(\tau) \) of eq. (2.8).
On the other hand, in refs. [48, 107], the arguments and calculations instead proceed from the considerations of potential. In Weyl gravity, a given local gravitational source generates a gravitational potential per unit solar mass as follows (eq. (8) of ref. [107]):

$$ V^* = -\frac{\beta^* c^2}{r} + \frac{\gamma^* c^2 r}{2}, $$

where $\beta^*$ and $\gamma^*$ are constants. Then, on integrating $V^*$ over the local luminous matter distribution, one obtains the local contribution to tangential velocity at $r = R > 4R_0$ [107]:

$$ \frac{v_{\text{loc}}^2}{R} \sim \frac{N^* \beta^* c^2}{R^2} \left(1 - \frac{9R_0^2}{2R^2}\right) + \frac{N^* \gamma^* c^2}{2} \left(1 - \frac{3R_0^2}{2R^2} - \frac{45R_0^4}{8R^4}\right). $$

(2.14)

The meanings and values of the symbols above are as follows: $R_0$ is the scale length such that most of the surface brightness is contained in $R \leq 4R_0$ of the optical disk region, $N^*$ is total number of solar mass units in the luminous galaxy obtained via the mass-to-light ratio: $(M/L)L = M_{\text{lum}} = N^* M_\odot$. Thereafter, detailed arguments (See refs. [48, 107]) are used to introduce two additional potentials of cosmological origin, viz., $\frac{GM_\odot R}{2}$ and $-kc^2 R^2$, that contribute to velocity such that

$$ \frac{v_{\text{tg}}^2}{R} = \frac{v_{\text{loc}}^2}{R} + \frac{\gamma_0 c^2}{2} - kc^2 R. $$

(2.15)

The numerical values of the constants giving best fits to rotation curves of all the 111 galaxy samples in [107] are:

$$ \beta^* = \frac{GM_\odot}{c^2} = 1.48 \times 10^5 \text{ cm}, \quad \gamma^* = 5.42 \times 10^{-41} \text{ cm}^{-1}, $n

$$ \gamma_0 = 3.06 \times 10^{-30} \text{ cm}^{-1}, \quad k = 9.54 \times 10^{-54} \text{ cm}^{-2}. $$

(2.16)

It is evident from eq. (2.15) that, in making the fits, the only parameter that can vary from one galaxy to the other is the mass-to-light ratio $(M/L)$ leading to a galaxy dependent $N^*$. The mass of HI gas is known and included in the fit. With everything else being universal, no hypothetical dark matter is needed — potential effects of cosmological origin plus the local potential caused by the luminous mass of a galaxy are enough to account for the observed rotation data.

For each galaxy with specific value of $N^*$ and other fixed constants as in (2.16), $v_{\text{tg}}^2$ of eq. (2.15) gives a finite value of $R$ at the terminating velocity $v_{\text{tg}}^2(R_{\text{term}}) = 0$, where the potentials balance. To illustrate various results derived here, we need to consider samples and so in the following we choose the LSB galactic sample ESO 1200211. The reason for this choice is that it is one of the samples, whose central dark matter density has been recently fitted to various known density profiles by Robles & Matos [108] and thus it lends itself to easy comparison with the results of the present paper. The plot in figure 1 shows that the rotation curve $v_{\text{tg}}^2$ decays to zero at a radial distance $R_{\text{term}} = 52.04\text{kpc}$, but this is still not the halo radius! The actual halo radius $R_{\text{WR}}$, defined by the stability inequality (2.21) below, will always be less than the value of $R_{\text{term}}$ for reasons of stability, as will soon be worked out.\(^8\)

\(^8\)Note that there are two specific profiles used in the paper: one is the URC velocity profile in eq. (2.2) that is never zero at any radius, $v_{\text{tg}}^2|_{\text{URC}} \neq 0$, while the other is the MO velocity profile, eq. (2.15), that can become zero at a finite radius $r = R_{\text{term}}$ such that $v_{\text{tg}}^2|_{\text{MO}}(R_{\text{term}}) = 0$. Such different behavior might call into question the validity of the identification $R_{\text{DM}} = R_{\text{WR}}$ used as an input in this paper.
Figure 1. Plot of $v_{tg}^2$ vs $R$ (cm) using eq. (2.15) for ESO 1200211. The luminous mass is $M_{\text{lum}} = 5.6 \times 10^7 M_\odot$ so that $N^* = 5.6 \times 10^7$. The other constants are in (2.16) and $R_0 = 2$ kpc [107]. One finds the velocity terminating radius $R_{\text{term}} = 52.04$ kpc.

The MO prescription for $v_{tg}^2$ in eq. (2.15) leads to the Mannheim-Kazanas metric (2.13) of Weyl gravity in the limit of large distances away from the galactic core in which we are interested. It can be seen as follows. The geodesic for a single test particle yields the tangential velocity of material circular orbits at the arbitrary radius $r$ as [107] $v_{tg}^2 = \left( Rc^2 / 2 \right) B'$, where prime denotes derivative with respect to $R$. Integrating, we obtain

$$B(R) = 1 - \frac{2 N^* \beta^*}{R} + \left( N^* \gamma^* + \gamma_0 \right) R - k R^2 + \frac{3 R_0^2 N^* \gamma^*}{2 R} + \frac{15 R_0^4 N^* \gamma^* - 24 R_0^2 N^* \beta^*}{8 R^3}. \quad (2.17)$$

Fit of $v_{tg}^2$ of eq. (2.15) with the observed rotational data [107] reveals that the constant $\gamma$ ($\equiv N^* \gamma^* + \gamma_0$) is of the order of $10^{-30} \text{cm}^{-1}$ since $N^* \approx 10^{11}$ (roughly, the number of stellar

The physical meaning of this input is explained on p. 4. Here we point out some additional grounds justifying the input. Note that it is quite logical that two different theories can predict the same measurable quantity, say, light deflection. Similarly, despite differences in the behavior, the profiles still provide fitted values of the same quantity $\rho_0$. Ideally, the values should exactly be the same, which is not the case, but they are comparable at least by order of magnitudes. In the present case, it is the assumed equality of the radii $R_{DM}$ and $R_{WR}$ provided by the two profiles that is in question. We have equated them on the ground that, observationally, there has to be only one dark matter radius for each sample, no matter how it is defined. So the equality in a way suggests itself. The other ground is that we have been motivated by the approach originally proposed by Edery & Paranjape [89], where they equated the Einstein and Weyl angles. Actually, such identifications are justified only a posteriori, when they are found to yield results that are independently known to be true. For instance, using the input $\theta_E = \theta_W$ for the deflection of light by galaxies, Edery & Paranjape [89] obtained the value of $\gamma$ in the metric (2.18) that is reasonably close to that obtained independently in [48, 107] by rotational data fits to samples. On the other hand, we also know that Weyl and Einstein theories, giving respectively $\theta_W$ and $\theta_E$, are very different from each other — the former involves fourth order equations and is conformally invariant, while the latter shares none of these. For this reason, at the very outset in our paper, we clarified that we were not talking of merging or mapping the two theories entirely into one another (p. 4) but concentrating only on a particular common prediction.

Similarly, despite differences in the EBI theory and the MO model, our identification $R_{DM} = R_{WR}$ leads to constraints on $\rho_0$ that are found to be remarkably compatible with the independent NFW or Burkert data fits — that is, the fitted central density values do fall within the stability induced limits. This is the a posteriori justification for using the identity $R_{DM} = R_{WR}$.
units in a galactic luminous mass). Also, the estimates covering all samples in [107] reveal that the luminous masses lie approximately in the range \( M = N^\star \beta^* \approx 10^{14} - 10^{16} \) cm and from the fitted value of \( \gamma^* = 5.42 \times 10^{-41} \) cm\(^{-1}\). It follows that \( N^\star \gamma^* \approx 10^{-30} \) cm\(^{-1}\). Thus at halo distances \( (R > 4R_0) \), we can ignore the last two terms in (2.18) by order of magnitudes. In the same manner, we see that \( M \gamma \ll 1 \) and it may be easily ignored in (2.13) so that \((1 - 6M \gamma)^{1/2} \approx 1\). Thus the theoretical metric (2.13) and the fitted metric (2.18) coincide at the form
\[
B(r) \approx 1 - \frac{2M}{r} + \gamma r - kr^2
\]
(2.18)
at halo distances \( R > 4R_0 \). This is also the form of the Weyl solution used in refs. [48, 89]. Rephrasing, we can say that \( v_{\text{tg}}^2 \) can be arrived at by differentiating the metric (2.17), which in turn approximates to the Weyl solution (2.18). That’s the relevance of the Weyl solution in the fitting program.

In the asymptotic limit, eq. (2.15) gives
\[
\frac{v_{\text{tg}}^2}{R} \rightarrow \frac{N^\star \beta^* c^2}{R^2} + \frac{N^\star \gamma^* c^2}{2} + \gamma_0 c^2 - kc^2 R,
\]
in which one recognizes the Schwarzschild-like potential \( V_{\beta^*} = N^\star \beta^* c^2 / R \), two linear potential terms, viz., a local \( V_{\gamma^*} = N^\star \gamma^* c^2 R / 2 \) associated with the matter distribution within a galaxy and a global \( V_{\gamma_0} = \gamma_0 c^2 R / 2 \) associated with the cosmological background, while the universal de Sitter-like quadratic potential term \( V_k = -kc^2 R^2 \) is induced by inhomogeneities in the cosmic background. Note that the last three potentials are new inputs into the MO model [48] designed to interpret the rotation curve data.

The radial geodesic in the metric (2.12) is given by
\[
\left( \frac{dr}{dt} \right)^2 = B^2(r) - a \frac{B^3(r)}{r^2} - bB^3(r),
\]
(2.20)
where \( a \) and \( b \) are constants of motion. The right hand side of the above equation is the “effective potential” \( V \), and \( V_{\text{MO}}'' \equiv f(R) \) involves the derivatives of \( B(R) \) that, in turn, contains the so called quadratic potential \( V_k (= -kc^2 R^2) \) introduced in ref. [48]. [The subscript “MO” is used here to distinguish it from the potential \( V_{\text{EIH}} \) to be defined in eq. (3.1)]. This potential \( V_k \) is responsible for providing a finite radius \( R_{\text{WR}} \).

The main reason is the negative sign in \( V_k \) needed for the data fit by MO. Because of this, it is quite evident from the plot of \( V_{\text{MO}}'' \) [figure 2] that the sample ESO 1200211 has a maximally allowed finite halo radius \( \sim 39.033 \) kpc (see also [100] for similar plots). On the other hand, if \( V_k \) has a positive sign (in which case no fit to data) or is altogether removed from \( B(R) \), hence from \( V_{\text{MO}}'' \), it can be graphically verified that there will be no finite stable radius \( R_{\text{WR}} \) for the halo. This shows the crucial role of \( V_k \). Thus, it is the requirement of fitting to data that indirectly limits the halo size to \( R_{\text{WR}} \). As to the physical reason, we see that the repulsive potential \( V_k \) balances the remaining attractive potentials at \( r = R_{\text{term}} \) [see eq. (2.15)] but stability further demands that \( R_{\text{WR}} < R_{\text{term}} \), as is evident from figures 1 & 2. Therefore, we can say that, at \( r = R_{\text{WR}} \), attractive potentials prevail over the repulsive potential \( V_k \) constraining the gas on the circular orbit, as it should.

The right hand side of eq. (2.20) and its first derivative with respect to \( r \), both must vanish at the circular radius \( r = R \) giving
\[
a = \frac{R^3 B'(R)}{2B^2(R)}, \quad b = \frac{2B(R) - RB'(R)}{2B^2(R)}.
\]
The condition for stability is that the second derivative of the “effective potential” $V$ with respect to $r$ must be negative at the circular radius $r = R$. The resultant expression with values of $a, b$ plugged in leads to the generic stability criterion for the MO model:

$$V''_{MO} = 2B'^2(R) - B(R)B''(R) - 3B(R)B'(R)/R < 0.$$  \hspace{1cm} (2.21)

This inequality graphically predicts a finite, stable, maximum halo radius that we call $R_{WR}$ caused solely by the quadratic potential $V_k(R) = -kc^2R^2$. Interestingly, the predicted $R_{WR}$ lends itself to observational testing in the near future as its value does not often much exceed the $R_{last}$ for many samples.

We shall apply the above algorithm to many samples but for illustration, we display $V''_{MO}$ vs. $R$ for the same sample ESO 1200211 in figure 2. The value of $N^*$ can be found from $N^* = M_{lum}/\beta^*$, where $M_{lum} = [(M/L)_{stars} \times L_B + M_{HI}] \times 10^{10}M_\odot$. All necessary components can be read off from the entries in the table 4 in [107]. The value of $N^* (= 5.60 \times 10^7)$ together with other constants in (2.15), when plugged into the inequality (2.21), immediately graphically yields $R = R_{WR} = 39.03\, \text{kpc}$, which is less than $R_{term}$ calculated above.

### 3 Upper limit density for stability

To analyze the stability of circular orbits, one needs to analyze the second order derivative of the concerned potential, which we wish to do here. To find the potential $V$, note that the four velocity $U^\alpha = \frac{dx^\alpha}{d\tau}$ of a test particle of rest mass $m_0$ moving in the halo (restricting ourselves to $\theta = \pi/2$) follows the equation $g_{\mu\nu}U^\mu U^\nu = -m_0^2$ that can be cast into a Newtonian form in the dimensionless radial variable $\tau (= \pi r/R_{DM})$ as

$$\left(\frac{d\tau}{d\tau}\right)^2 = E^2 + V_{\text{EIH}}(\tau)$$  \hspace{1cm} (3.1)
which gives, for the metric eqs. (2.7)–(2.10) of section 2.1, the EiBI potential

$$V_{\text{EiBI}}(\tau) = \left[ \frac{E^2}{A} - 1 \right] - \frac{L^2}{AC^2} - \frac{1}{A}$$

$$E = \frac{U_0}{m_0}, \quad L = \frac{U_3}{m_0},$$

where the constants $E$ and $L$, respectively, are the conserved relativistic energy and angular momentum per unit mass of the test particle. Circular orbits at any arbitrary radius are defined by $\tau = R$ = constant, so that $\frac{d\tau}{d\sigma}|_{\tau=R}=0$ and, additionally, $\frac{dV}{d\sigma}|_{\tau=R}=0$. From these two conditions follow the conserved quantities as under:

$$L^2 = \frac{X}{Z}$$

and using it in $V_{\text{EiBI}}(R) = -E^2$, we get

$$E^2 = \frac{Y}{Z},$$

where

$$X \equiv -\kappa^2 R^3 v_\infty^2 (R - \bar{p}_0 \sin R)^2$$

$$Y \equiv \left( \kappa R^2 + 2r_0^2 \rho_{\text{opt}}^2 \right) \left( \rho_0^2 + \frac{\kappa R^2}{2r_{\text{opt}}^2} \right) \left( \bar{p}_0 R \cos R + \bar{p}_0 \sin R - 2R \right)$$

$$Z \equiv \left\{ \kappa R^2 (1 - 2v_\infty^2) + 2r_0^2 \rho_{\text{opt}}^2 \right\} \bar{p}_0 \sin R + \left( \kappa R^2 + 2r_0^2 \rho_{\text{opt}}^2 \right) \bar{p}_0 R \cos R$$

$$- 4r_0^2 \rho_0 \rho_{\text{opt}}^2 - 2\kappa R^3 (1 - v_\infty^2).$$

Putting the expressions for $L^2$ and $E^2$ in eq. (3.2), we find the complete expression for $V_{\text{EiBI}}$. The orbits will be stable if $V_{\text{EiBI}}'' \equiv \frac{d^2V}{d\tau^2}|_{\tau=R}<0$ and unstable if $V_{\text{EiBI}}'' > 0$. The expression for $V_{\text{EiBI}}''$ is

$$V_{\text{EiBI}}''(R; \kappa, \bar{p}_0, r_0, \rho_{\text{opt}}, v_\infty) = \left[ \frac{2v_\infty^2 (R + \bar{p}_0 R \cos R - \bar{p}_0 \sin R)}{R^2 (\kappa R^2 + 2r_0^2 \rho_{\text{opt}}^2)} \right]$$

$$\times \left[ 32R^2 r_0^2 \rho_{\text{opt}}^2 + 8\kappa R^4 (1 - v_\infty^2) + 6\bar{p}_0 \rho_0 \rho_{\text{opt}}^2 \left( 1 + R^2 \right)$$

$$+ \kappa \bar{p}_0^2 R^2 \left( 1 - 2v_\infty^2 + 3R^2 \right)$$

$$- 2R^2 \left\{ 14r_0^2 \rho_{\text{opt}}^2 + \kappa R^2 \left( 5 - 2v_\infty^2 \right) \right\} \bar{p}_0 \cos R$$

$$+ \left\{ 2 \left( R^2 - 3 \right) r_0^2 \rho_{\text{opt}}^2 - \kappa R^2 \left( 1 - 2v_\infty^2 - R^2 \right) \right\} \bar{p}_0^2 \cos (2R)$$

$$- \left\{ 36r_0^2 \rho_{\text{opt}}^2 + 4R^2 r_0^2 \rho_{\text{opt}}^2 + 6\kappa R^2 + 2\kappa R^4 - 12\kappa R^2 v_\infty^2 \right\} \bar{p}_0 R \sin R$$

$$+ \left\{ 6r_0^2 \rho_{\text{opt}}^2 + \kappa R^2 - 2\kappa R^2 v_\infty^2 \right\} \bar{p}_0 R \sin \left( 2R \right) \right].$$

(3.9)
From the above expression, it is absurd to straightforwardly draw any conclusion about stability or otherwise of the circular orbits. Clearly, much will depend on the parameter ranges chosen on the basis of physical considerations. While other parameters can be reasonably assigned, the as yet unknown parameters are the dark matter radius \( \kappa \) (= \( 2R_{\text{DM}}^2/\pi^2 \)) and the dimensionless central density \( \rho_0 \) (= \( 8\rho_0 R_{\text{DM}}^2/\pi \)), again depending only on \( \kappa \). In the first order approximation, the density distribution in the dark matter has been assumed in \([95, 96]\) to be low such that \( 8\pi G\kappa \rho^{(0)}/c^4 \ll 1 \), but the central density \( \rho_0 \) could still be large since \( |\sin(x)/x| \leq 1 \) [see eq. (2.3)]. The question therefore is how large or small could it be, or turning it around, could there be any upper limit on \( \rho_0 \) imposed by the stability criterion?

The answer is in the affirmative and can be found graphically. We find that \( V'' \) is indeed very sensitive to changes in \( \rho_0 \) leading to different upper limits \( \rho^{\text{upper}}_0 \) for different galactic samples such that stable circular orbits are possible only when \( \rho_0 \leq \rho^{\text{upper}}_0 \). The reason is that \( R_{\text{DM}} \) changes from sample to sample, as it should, and thereby leads to different (though not too different) values for \( \kappa \) and \( \rho^{\text{upper}}_0 \). Let us again consider the previous sample ESO 1200211, a low surface brightness galaxy with a halo/dark matter radius \( R_{\text{WR}} \equiv R_{\text{DM}} \approx 39.03 \text{ kpc} \) that corresponds to \( \kappa = 308.74 \text{ kpc}^2 \). With \( \kappa \) thus fixed, we fix other parameters respecting the Newtonian approximation,\(^9\) e.g., \( r_0 = 0.61, \, v_{\infty}^2 = 0.000001, \, r_{\text{opt}} = 8 \text{ kpc} \), with the dimensionless radius \( \overline{R} = \pi R/R_{\text{DM}} \) chosen in the range \( \overline{R} \in [0.5\pi, \pi] \) corresponding to coordinate radii \( R \in [19.52 \text{ kpc}, 39.03 \text{ kpc}] \), the dimensionless density parameter chosen in the range \( \overline{\rho}_0 \in [0.25\pi, 0.8\pi] \) and plot \( V''_{\text{EBI}} \) vs. \( \overline{R} \) using the expression (3.9).

Graphical analysis shows that, while \( V''_{\text{EBI}} \) is not much sensitive to the variation of the other parameters within the Newtonian approximation, it is greatly sensitive to the variation of the remaining parameter \( \rho_0 \). Figures 3 and 4 respectively show that, for values of \( \overline{\rho}_0 > 0.94 \), there is instability in the entire or partial range of the halo radii \( \overline{R} \), while figure 5 tells us that there is an upper limit occurring at \( \overline{\rho}_0^{\text{upper}} = 0.94 = \lambda^{\text{upper}}\pi \), where \( \lambda^{\text{upper}} = 0.299 \), such

\(^9\)The range of \( r \) and \( r_{\text{opt}} \) is chosen so as to ensure the Newtonian approximation \( r/r_{\text{opt}} \gg r_0 \), while the approximate value of \( v_{\infty}^2 \) is an observed fact. The formula for \( r_0 \) for spiral galaxies is \( r_0 = 1.5 \times (L_B/10^{10.4}L_\odot)^{1/5} \), which evaluates to \( r_0 = 0.61 \) for the sample ESO 1200211, where \( r_{\text{opt}} \approx 4R_0, \, L_B = 0.028 \times 10^{10}L_\odot, \, R_0 = 2 \text{ kpc} \). Data taken from \([107]\).
that for \( \rho_0 \leq \rho_0^{\text{upper}} \), all circular orbits in the entire chosen radial range for \( \overline{R} \) are stable. It can be verified that this value of \( \lambda^{\text{upper}} \) surprisingly remains the same for values for \( \kappa \) across the entire range of 111 samples (some tabulated here), so \( \rho_0^{\text{upper}} \) is quite a reliable limit.

Rewriting in terms of \( \rho_0 \), we have

\[
\rho_0^{\text{upper}} = \frac{\rho_0^{\text{upper}} \pi}{8R_{\text{DM}}^2} = \frac{\lambda^{\text{upper}}}{4\kappa}. \tag{3.10}
\]

This by itself is an interesting prediction of EiBI theory. However, if we want to quantify \( \rho_0^{\text{upper}} \) for a given galaxy, we need to use the value of \( R_{\text{DM}} \) but since concrete observed values are yet unavailable, we choose to use the input \( R_{\text{DM}} = R_{\text{WR}} \). It turns out that this choice, though not mandatory, works well giving definitive values for \( \rho_0^{\text{upper}} \) for all samples. Plugging in the values of \( \lambda^{\text{upper}} \) and \( \kappa \), we find that the constraint \( \rho_0 \leq \rho_0^{\text{upper}} \) immediately translates into a generic constraint such that for

\[
\rho_0 \leq \rho_0^{\text{upper}}, \tag{3.11}
\]

all circular orbits in the chosen range for \( R \) are stable. Thus, using the value of \( \kappa \) as above in eq. (3.10), the sample ESO 1200211 quantitatively yields \( \rho_0^{\text{upper}} = 5.04 \times 10^{12} M_\odot \text{kpc}^{-3} \). In general, as long as \( \rho_0 \) of any galaxy obeys the stability induced constraint (3.11), the circular material orbits in the halo region will be stable up to a maximum radius \( R = R_{\text{WR}} \).

4 Central and mean dark matter density

So far, the algorithm has been as follows: take any galactic sample, find \( R_{\text{WR}} \) for that sample using the method of section 2.2. Then, from the identity \( R_{\text{DM}} = R_{\text{WR}} \), find \( R_{\text{DM}} \) (hence \( \kappa \)) and using eq. (3.10), find \( \rho_0^{\text{upper}} \). However, we still do not know the values of \( \rho_0 \) for all the samples observed to date and cannot ascertain whether or not they satisfy the stability induced constraint \( \rho_0 \leq \rho_0^{\text{upper}} \). On the other hand, some notable dark matter simulations and profiles for several samples show values for \( \rho_0 \) that do respect this constraint (table 2). This success then prompts us to ask if there is any lower limit on \( \rho_0 \) such that \( \rho_0^{\text{lower}} \leq \rho_0 \leq \rho_0^{\text{upper}} \) holds.
Figure 5. Plot of $V''$ vs $\bar{R} \in [0.5\pi, \pi]$ using eq. (3.9) for ESO 1200211. The chosen parameters are: $r_0 = 0.61$, $v_x^2 = 0.000001$, $r_{\text{opt}} = 8$ kpc. Here central density is further lowered to $\rho_0 = 5.04 \times 10^{12} M_\odot \text{kpc}^{-3}$, which corresponds to $\rho_{\text{upper}}^0 = 0.94 = \beta_{\text{upper}} \pi$, where $\beta_{\text{upper}} = 0.299$. The orbit is stable in the entire chosen range for $\bar{R}$. The corresponding $\rho_0$ is the upper limit on central density $\rho_{0}^{\text{upper}}$ specific to the sample.

Fortunately, there is a way to find the values of $\rho_{0}^{\text{lower}}$, once we are able to estimate the total mass of dark matter $M_{\text{DM}}$ using the observed mass-to-light ratios. Fitted data are available for the luminous mass-to-light ratios ($M_{\text{lum}}/L_B$) in solar units $\Upsilon_\odot$ ($\equiv M_\odot/L_\odot$):

$$
\frac{M_{\text{lum}}}{L_B} = \gamma \Upsilon_\odot.
$$

The luminous mass ($M_{\text{lum}}$) of a galaxy is contributed mostly by stars and gases excluding dark matter. The stellar mass-to-light ratios $\gamma$ for 111 samples in [107] are seen to lie between 0.2 and 8 (with just a couple of exceptions), which is consistent with the upper bound of $10 \Upsilon_\odot$ suggested by the population synthesis models [109]. On the other hand, there is no detectable dark matter associated with the galactic disk, most of the dark matter is distributed in the halo [110–114]. So we can write

$$
M_{\text{tot}} = M_{\text{lum}} + M_{\text{DM}},
$$

then

$$
\frac{M_{\text{tot}}}{L_B} = \beta \Upsilon_\odot
$$

where $\beta$ must be larger than $\gamma$, if there is dark matter (observed mass-to-light ratios are still uncertain). We can thus write, following Edery & Paranjape [89]:

$$
\frac{M_{\text{lum}}}{M_{\text{tot}}} = \frac{1}{\alpha},
$$

which gives $\beta = \alpha \gamma$ and $\alpha$ should be so chosen as to make $\beta > \gamma$. In general, one takes $\alpha > 1$ such that $M_{\text{tot}} > M_{\text{lum}}$ thereby accommodating the presence of dark matter.

Assuming that the halos must be substantially larger than the last measured point $R_{\text{last}}$, the dark to luminous mass within $R_{\text{last}}$ then gives an upper limit through $f_b < \frac{M_{\text{lum}}}{M_{\text{tot}}}$ and therefore $f_b < \left(1 + \frac{M_{\text{DM}}}{M_{\text{lum}}}\right)^{-1}$. For some galaxies, $f_b < 0.08$, as reported in de Blok and McGaugh [115]. Thus, using (4.2), we have $f_b < \frac{1}{\alpha}$ and $f_b < 0.08$. Certainly, these
inequalities do not constrain $\alpha$ in any way. One of the infinity of options to ensure that both hold simultaneously is to assume that $\frac{1}{\alpha} = 0.08 \Rightarrow \alpha = 12.5$. While $\alpha$ can be varied at will unless it is definitively fixed by independent concrete observed data, we shall for the moment choose the value $\alpha = 12.5$ only to have an idea of the order of magnitudes of the estimated densities, but we shall change $\alpha$ later. The current choice would imply $\beta \in [2.5, 100]$ corresponding to $\gamma \in [0.2, 8]$. The values of $\beta \sim 100$ is enough to account for the large dark matter content of LSB galaxies (i.e., large mass-to-light ratios $\frac{M_{\text{DM}}}{L_{\text{B}}}$) such as DDO154. Currently favored Burkert density profile can provide an excellent mass model for the dark halos around disk systems up to 100 times more massive than small dwarf galaxies for which the profile was initially intended [116, 117].

The ratio $M_{\text{lum}}/M_{\text{tot}}$ then gives the connection between $M_{\text{DM}}$ of EiBI theory and the luminous mass $M_{\text{lum}}$ of galaxies via eq. (4.1):

$$M_{\text{DM}} = (\alpha - 1)M_{\text{lum}}.$$  

(4.3)

Using $R_{\text{WR}} \equiv R_{\text{DM}}$, eq. (2.6) can be rewritten as

$$\rho_0^{\text{lower}} = \frac{\pi(\alpha - 1)M_{\text{lum}}}{4R_{\text{WR}}^3}, \quad \langle \rho \rangle^{\text{lower}} = \frac{3\rho_0^{\text{lower}}}{\pi^2}.$$  

(4.4)

The superscript “lower” indicates that it is the lower limit of the dark matter central density $\rho_0$ because $R_{\text{WR}}$ is the maximum allowed halo radius (see figure 2), where $V'' < 0$ gives stable radii $R \leq R_{\text{WR}}$. Evidently, $\rho_0^{\text{lower}}$ is proportional to the as yet unknown parameter $\alpha$. We are free to raise the value of $\alpha$ arbitrarily, but then the consequent larger values of $\beta$ would lead to too large an amount of dark matter comparable to that existing in galactic clusters.\footnote{At much larger scales of galactic clusters, the value of $\beta$ could be $\geq 120$ [118, 119] so that $\frac{M_{\text{DM}}}{L_{\text{B}}} \geq 120$ in solar units. We are not contemplating galactic clusters here.}

To illustrate the order of magnitudes involved for $\rho_0^{\text{lower}}$, hence for $\langle \rho \rangle^{\text{lower}}$, we again consider the low mass LSB sample ESO 1200211 for which $M_{\text{lum}} = 5.60 \times 10^7 M_\odot, \gamma = 0.2$ and our method in section 2.2 yields $R_{\text{WR}} = 39.03 \text{kpc}, \kappa = 308.74 \text{kpc}^2, R_{\text{term}} = 52.04 \text{kpc}$. Using eqs. (4.4), and allowing for a fairly large amount of dark matter over luminous matter corresponding to $\alpha = 12.5$, we find $\rho_0^{\text{lower}} = 8.49 \times 10^4 M_\odot \text{kpc}^{-3}$ and $\langle \rho \rangle^{\text{lower}} = 2.58 \times 10^4 M_\odot \text{kpc}^{-3}$. To compare these values of density, we consider several dark matter density profiles: (i) the Bose-Einstein [108] condensate ($\rho_0^{\text{BEC}}$), (ii) Pseudo-Isothermal [120] profile ($\rho_0^{\text{PI}}$), (iii) the NFW [121, 122] profile ($\rho_0^{\text{NFW}}$), (iv) Burkert [116] profile ($\rho_0^{\text{BP}}$), (see section 5 below for the exact forms). They yield values as follows: (i) $\rho_0^{\text{BEC}} = 1.38 \times 10^7 M_\odot \text{kpc}^{-3}$, (ii) $\rho_0^{\text{PI}} = 4.64 \times 10^7 M_\odot \text{kpc}^{-3}$ and (iii) $\rho_0^{\text{NFW}} = 2.45 \times 10^6 M_\odot \text{kpc}^{-3}$ for ESO 1200211 (see the entries in table 1 of [108]). In section 3, we already found for the present sample the value $\rho_0^{\text{upper}} = 5.04 \times 10^{12} M_\odot \text{kpc}^{-3}$. We hence see that the central densities from different profiles fall within the stability induced limits, that is, $\rho_0^{\text{lower}} < \rho_0^{\text{BEC, PI or NFW}} < \rho_0^{\text{upper}}$ holds.\footnote{Once again, a question of compatibility might be phrased as follows: the EiBI density profile has $\rho(r_{\text{DM}}) = 0$ and remains zero beyond $r > R_{\text{DM}}$, while, in contrast, the NFW and Burkert profiles have $\rho(r \to \infty) = 0$. Since the asymptotic behavior of latter density distributions are different from that of EiBI, determining whether the data obtained by fitting to NFW or Burkert profiles fall within the stability induced limits from EiBI theory calls into question the issue of compatibility of the EiBI with those profiles.}

We wish to clarify that it is the central density $\rho_0$, a parameter distinctly appearing in all density distributions, that is under present investigation. No matter what the profile is, the target is always the same: to find information about $\rho_0$ for any given galactic sample. We know that NFW profile is cuspy ($\rho_{\text{NFW}} \propto r^{-1}$), while
we take $\alpha < 12.5$, which should also be quite acceptable for many samples, the values of $\rho_{\text{lower}}^0$ will only be further lowered and of course the interval will be well supported.

If we increase $\alpha$ to an (unlikely) mammoth value, say $\alpha = 300$ so that $M_{\text{tot}} = 300M_{\text{lum}}$ implying $\beta = 60$ so that $\frac{M_{\text{tot}}}{\rho r_{\text{vir}}^3} = 60Y_\odot$ in the considered sample, then $\rho_{\text{lower}}^0 \sim 2.2 \times 10^6 M_\odot \text{kpc}^{-3}$, and we notice that the proposed limits are still not violated! If we exclude NFW profile, then the values $\alpha$ can be increased even further. This testifies to the validity of eq. (4.4) as well as the limits.

5 Milky Way

As for our Milky Way galaxy, the latest reported estimates are the following: using the gas terminal velocity curve, Sgr A* proper motion, an oblate bulge + Miyamoto-Nagai disc and NFW halo, Kafle et al. [123] estimated the luminous (disc + bulge) mass to be $M_{\text{lum}} \sim 1.04 \times 10^{11}M_\odot$, so that $N^* = 1.04 \times 10^{11}$ and the virial mass inclusive of dark matter $M_{\text{vir}} = M_{\text{tot}} \sim 0.80 \times 10^{12} M_\odot$ so that $\alpha = M_{\text{tot}}/M_{\text{lum}} = 7.68$. (We have not considered the data/fit uncertainties). For alternative but not too different values of $M_{\text{tot}}$, see [124–131].

Using the scale length $R_0 = 4.9\text{kpc}$ [123] and the above $N^*$ in the inequality (2.21), we find that $R_{\text{WR}} = R_{\text{DM}} = 111.90\text{kpc}$. With this value of $R_{\text{WR}}$, eq. (3.10) then yields a value $\alpha_{\text{upper}}M_{\odot} = 6.14 \times 10^{11} M_\odot \text{kpc}^{-3}$ characteristic of the Milky way, which does not exceed the maximum density $\sim 10^{12} M_\odot \text{kpc}^{-3}$ proposed in this paper.

The density profiles considered here are of the forms:

\begin{equation}
\rho^{\text{BP}}(r) = \frac{\rho_{0}^{\text{BP}} r_{0}^3}{(r + r_{0})(r^2 + r_{0}^2)} = \rho_{0}^{\text{BP}} \left(1 - \frac{r}{r_{0}} + \frac{r^4}{r_{0}^4} + \ldots\right) \tag{5.1}
\end{equation}

\begin{equation}
\rho^{\text{NFW}}(r) = \frac{\rho_{0}^{\text{NFW}}}{(r/r_S)[1 + (r/r_S)^2]} = \rho_{0}^{\text{NFW}} \left(\frac{r_S}{r} r - \frac{r^3}{r_S^3} + \frac{r^3}{r_S^3} + \ldots\right) \tag{5.2}
\end{equation}

\begin{equation}
\rho^{\text{PI}}(r) = \frac{\rho_{0}^{\text{PI}}}{1 + (r/r_{c})^2} = \rho_{0}^{\text{PI}} \left(1 - \frac{r^2}{r_{c}^2} + \frac{r^4}{r_{c}^4} + \ldots\right) \tag{5.3}
\end{equation}

\begin{equation}
\rho^{\text{BEC}}(r) = \rho_{0}^{\text{BEC}} \left[\frac{\sin (\xi r)}{\xi r}\right] = \rho_{0}^{\text{BEC}} \left(1 - \frac{\xi^2 r^2}{6} + \frac{\xi^4 r^4}{120} + \ldots\right), \tag{5.4}
\end{equation}

others such as that of Burkert are cored ($\rho^{\text{BP}} \propto r^0$). Despite this radical difference in behavior at the origin, both profiles are quite well accepted though per se they are different. One could rephrase this difference as incompatibility. The main thing however is that the fitted values of central density from the two profiles should approximately be the same, at least by order of magnitude, which actually is the case [108, 132]. (A brief account of comparisons as to which profile fits the data better is given at the very last paragraph of our paper). In the same vein, despite differences in the asymptotic behavior of EiBI profile and other density profiles, the information about the common parameter $\rho_0$ should approximately be the same. It would be fair to say that the derived bound for the central density $\rho_0$ is indeed in agreement with the astrophysical data but that it is yet to be determined if the EiBI density profile is compatible with future N-body simulation featuring higher accuracy allowing for testing the outskirts of dark matter halos.

Also, it is very unlikely that the attractive dark matter is spread all the way to infinity, where repulsive dark energy takes over. The finite extent of dark matter is supported by the observed rapid decline of velocity dispersion after a certain radius [143]. It could indeed be interesting to take this fact as an empirical input for $R_{\text{DM}}$ only if we knew the exact radius at which the decline ended. Pending this knowledge, we used theoretical inputs $R_{\text{WR}}$ for $R_{\text{DM}}$, which yielded the interval for $\rho_{0}$ confirmed by data fits so far.

\footnote{In [124], it is reported that $M_{\text{tot}} = (1.4 \pm 0.3) \times 10^{12} M_\odot$ from tidal effects on globular clusters and $M_{\text{tot}} = (1.4 \pm 0.8) \times 10^{12} M_\odot$ from globular cluster radial velocities. The remarkable similarity between these completely independent determinations of mass may be taken as a strong empirical signature for the existence of dark matter around the Milky Way. In [125], the reported estimate is $M_{\text{tot}} = (1.0-1.5) \times 10^{12} M_\odot$, again not too different.}
where \( \rho_0 \) is the galactocentric density, \( \rho_0^{\text{NFW}} \) is related to the density of the universe at the moment the halo collapsed and \( r_0, r_S, r_e \) are core, scale, characteristic radii respectively, while \( \xi = \sqrt{Gm^2/a} \) in which \( m \) is the mass of the dark matter particle and \( a \) is the scattering length [108]. The fitted latest data on Milky Way dark matter central density are \( \rho_0^{\text{BP}} = 4.13 \times 10^7 \, M_\odot \text{kpc}^{-3} \) (Berkert profile) and \( \rho_0^{\text{NFW}} = 1.40 \times 10^7 \, M_\odot \text{kpc}^{-3} \) (NFW profile) [132]. In both cases, we see that these fitted values are four orders of magnitude less than \( \rho_{0,\text{MW}} \), as desired. From eq. (4.4), for \( \alpha \sim 7.68 \), we get \( \rho_{0,\text{MW}} \sim 2.09 \times 10^9 \, M_\odot \text{kpc}^{-3} \) and \( \rho_{0,\text{MW}}^{\text{lower}} \sim 6.37 \times 10^2 \, M_\odot \text{kpc}^{-3} \). Once again, we see that the densities satisfy \( \rho_{0,\text{MW}}^{\text{lower}} < \rho_0^{\text{BP, NFW}} < \rho_{0,\text{MW}}^{\text{upper}} \). A larger value of \( \alpha \) does not disallow the inequalities at either end.

Apart from the galactocentric density \( \rho_0 \), the local (at \( R_0 = 8.5 \text{kpc} \)) dark matter density \( \rho_\odot \) provides a strong basis for the experimental endeavors for indirect detection of the dark matter. Though there is broad consensus, different groups have come up with somewhat different conclusions regarding the local density of dark matter. For example, Kuijken and Gilmore [111–114] find a volume density near Earth \( \rho_\odot \equiv 0.01 \text{GeV/cm}^3 = 2.64 \times 10^5 \, M_\odot \text{kpc}^{-3} \). Other reported values are the following. Bahcall et al. [133] find a best-fit value of \( \rho_\odot = 0.34 \text{GeV/cm}^3 = 8.96 \times 10^6 \, M_\odot \text{kpc}^{-3} \), Caldwell and Ostriker [134] find \( \rho_\odot = 0.23 \text{GeV/cm}^3 = 6.07 \times 10^6 \, M_\odot \text{kpc}^{-3} \), while Turner [135] calculates \( \rho_\odot = 0.3–0.6 \text{GeV/cm}^3 = 7.92 \times 10^6 – 1.58 \times 10^7 \, M_\odot \) kpc\(^{-3} \). For a more comprehensive discussion on the distribution of dark matter, see [136]. The local dark matter energy density, consistent with standard estimates, is \( \rho_\odot = (0.3 \pm 0.1) \text{GeV/cm}^3 = 7.92 \times 10^6 \, M_\odot \) kpc\(^{-3} \) [137]. Bergstrom, Ullio and Buckley [138] find local dark matter densities acceptable in a somewhat broad range 0.2–0.8 GeV/cm\(^3\). The fitting with Burkert profile yields \( \rho_\odot^{\text{BP}} = 0.487 \text{GeV/cm}^3 = 1.28 \times 10^7 \, M_\odot \) kpc\(^{-3} \) and fitting with NFW profile yields \( \rho_\odot^{\text{NFW}} = 0.471 \text{GeV/cm}^3 = 1.24 \times 10^7 \, M_\odot \) kpc\(^{-3} \) [132]. About systematic uncertainties in the determination of local density of dark matter, see [139]. Overall, one could fairly say that \( \rho_\odot \propto 10^{6–7} \, M_\odot \) kpc\(^{-3} \).

We use the above local values as a constraint to estimate the central density \( \rho_0^{\text{BEC}} \) given in eq. (5.4) that approaches a constant value \( \rho_0^{\text{BEC}} \) as \( r \to 0 \) (so does the EiBI profile \( \rho_0^{(0)}(r) \) in eq. (2.3) as the two are essentially of the same form). This behavior is consistent with the currently favored core behavior at the galactic center, as opposed to the NFW cusp. To estimate the values of \( \rho_0^{\text{BEC}} \) for the Milky Way, we constrain the BEC profile such that it coincides with the local value \( \rho_\odot = 1.28 \times 10^7 \, M_\odot \) kpc\(^{-3} \) at \( R_\odot = 8.5 \text{kpc} \) (boundary condition). This then yields a central density \( \rho_0^{\text{BEC}} = 1.29 \times 10^7 \, M_\odot \) kpc\(^{-3} \). This is quite an acceptable central density value for the Milky Way. (We could as well use the same boundary condition using \( \rho_0^{\text{NFW}} \), but it does not lead to a much different value for \( \rho_0^{\text{BEC}} \)). Having determined the value of \( \rho_0^{\text{BEC}} \), we compare it with the corresponding values from NFW and Burkert profiles using data from [132] and observe the following: (i) \( \rho_0^{\text{BEC}} \) is quite comparable with \( \rho_0^{\text{BP}} \) and \( \rho_0^{\text{NFW}} \), (ii) the NFW cusp and the PI, Burkert core behavior are evident from figure 6. (iii) Identifying the BEC constant \( \xi \equiv \rho_0^{\text{BEC}}/\rho_{\text{DM}} \), we see that the \( \rho_0^{\text{BEC}} \) profile shows a much slower monotonic decline from its central value \( \rho_0^{\text{BEC}} \), coasting along almost flat all the way up to a finite \( R_{\text{DM}} (= 111.90 \text{kpc}, \text{in the present case}) \), where it vanishes, (iv) adopted values from the Burkert profile has allowed us to predict \( \rho_0^{\text{BEC}} \), which is seen also to be included in the limiting interval, \( \rho_0^{\text{lower}} < \rho_0^{\text{BEC,BP,NFW}} < \rho_0^{\text{upper}} \) for the Milky Way.

Returning to the profiles (5.3) and (5.4), it is remarkable that the PI and BEC profiles have the same behavior up to second order in \( r \) provided we identify \( r_c = \ell \pi/\xi \) but they begin
to differ in the higher order coefficients thereafter. Also, it is known that the large majority of the high-resolution rotation curves prefer the PI core-dominated halo model, which provide a better description of the data than the cuspy ($\rho_{\text{NFW}} \propto r^{-1}$) NFW profile [140]. In this sense, the EiBI model could be a competing candidate to PI model. It would be our future task to investigate where these two models agree and where they disagree.

6 Conclusions

The present paper, based on a pivotal input from Weyl gravity, viz., $R_{\text{DM}} = R_{\text{WR}}$ (motivated by [89]), offers a new alternative analytical window, different from the standard data-fit approaches, to look at the physical galactic parameters. While the latter approaches are technically more elaborate, and the current EiBI analytic approach is not, the value of the paper lies in the fact that it can still make quantitative predictions about the limits on central dark matter density $\rho_0$. Many samples for which the values of $\rho_0$ are available are shown to satisfy the inequality $\rho_0 \leq \rho_{0\text{upper}} \propto R_{\text{WR}}^{-2} \sim 10^{12} M_\odot \text{kpc}^{-3}$. Only some samples are tabulated here. Table 1 shows the halo/dark matter radius, the velocity terminating radius $R_{\text{term}}$ and the corresponding coupling parameter $\kappa$.

Going a step further, we also calculated $\rho_0^{\text{lower}} \propto (\alpha - 1)M_{\text{lum}}R_{\text{WR}}^{-3}$ that depends on a certain parameter $\alpha$ equal to the the ratio of luminous to total (dark matter included) mass of a galaxy. Definitive estimates of such ratios are yet unavailable. Nevertheless, it is shown that (table 2), for reasonably wider values of $\alpha \geq 12.5$ accounting for huge quantities of dark matter in individual samples, profile dependent values of $\rho_0$ still fall inside the EiBI predicted interval $\rho_0^{\text{lower}} \leq \rho_0 \leq \rho_0^{\text{upper}}$. These limits cover a large class of galaxies and indicate an interesting facet of the EiBI theory. We especially point out that the maximal value $\rho_0^{\text{upper}} \propto R_{\text{WR}}^{-2} \sim 10^{12} M_\odot \text{kpc}^{-3}$ is purely a stability induced constraint on all galaxies with dark matter, while $(\alpha - 1)M_{\text{lum}}R_{\text{WR}}^{-3} \propto \rho_0^{\text{lower}} \leq \rho_0$ is not, due to uncertainties in $\alpha$. Thus, we would particularly advocate a practical verification of $\rho_0^{\text{upper}}$ ($\propto 1/\kappa$) rather than $\rho_0^{\text{lower}}$. If verified, it would also mean that we have a clearcut theoretical algorithm, applicable...
there is an argument $M_{\text{DM}}$ the above limits are those of the fitted luminous part of the Milky Way mass $M_{\text{tot}}$. Note that a small change in $M_{\text{DM}}$ would lead to a large change in $R_{\text{WR}}$. For instance, there is an argument [117, 141] for an upper mass limit indicated by the sudden decline of the visible baryonic mass function of disk galaxies at $M_{\text{disc}}^{\text{max}} = 2 \times 10^{11} M_\odot$. Tentatively assuming that the luminous part of the Milky Way mass $M_{\text{lum}}$ is $2 \times 10^{11} M_\odot$ instead of $1.04 \times 10^{11} M_\odot$.

Table 2. Central densities of dark matter and upper bounds [eq. (3.10)]. All densities are in units of $M_\odot \text{kpc}^{-3}$, $\alpha = 12.5$. to all galactic samples, that provides a definitive, falsifiable information on the radius $R_{\text{DM}}$ of dark matter/halo — something that seems rather scarce in the astrophysical literature.
then the resultant $R_{WR}$ would jump to 177.94 kpc from 111.90 kpc. Similarly, $R_{term}$ would jump to 238 kpc from 150.17 kpc. Thus, for reliable values of $R_{WR}$, the luminous mass data $M_{lum}$ should be as accurate as possible.

We have verified that quantitative upper limit $\rho_{0}^{\text{upper}} \sim 10^{12} M_{\odot} \text{kpc}^{-3}$ is respected by all the samples collected in [107], some of which are given in table 2. The reason for such consistency is not accidental — it stemmed from the fact that the Weyl radius $R_{WR}$ has a solid foundation: the rotation curve is a prediction of Weyl gravity MO solution containing constants ($\gamma_{0}$, $\gamma^{*}$, $k$) that are universally applicable to all the galaxies. LSB or HSB, and that the $R_{WR}$ is a straightforward result from $V'' < 0$. In fact, the reported data on $R_{last}$ for individual samples have so far been found to obey $R_{last} < R_{WR}$. So we conjectured that this radius $R_{WR}$ just might be the dark matter radius $R_{DM}$ specific to individual galaxies.

As we saw, the constraint $\rho_{0} \leq \rho_{0}^{\text{upper}} \sim 10^{12} M_{\odot} \text{kpc}^{-3}$ is a necessary condition for stability of circular orbits. Whether it is also a sufficient condition, that is, whether there are no stable orbits in the halo if this constraint is violated, is a matter of independent practical verification. If sufficiency turns out to be true, then we might expect to observe galaxies with no information on dark matter due to lack of stable circular orbits. It may be noted that our $\rho_{0}^{\text{upper}} \sim 6.14 \times 10^{11} M_{\odot} \text{kpc}^{-3}$ for Milky Way is remarkably consistent with the local upper limit on the dark matter density in the solar system, $\rho_{0}^{\text{upper}} \sim 2.94 \times 10^{12} M_{\odot} \text{kpc}^{-3}$, found by completely different methods and ideas [142].

There are limitations with almost all well known density profiles in the sense that they fit the data so well in one sector, but fail in the other. For instance, it has been argued [143] that the NFW profile does not always follow from the gas rotation curves of large samples. For a constant velocity anisotropy, the PI profile is ruled out, while a truncated flat (TF) model [144] and NFW model are consistent with the data. Incidentally, it might be noted that the TF model expands up to $r^{2}$ like both in the PI and BEC profiles, and further, like the MO model, TF is described solely by two parameters, mass and the scale length. Nesti and Salucci [132] argue that NFW and/or PI halos are not supported by present day observations in external galaxies due to recent improvement of simulation techniques. URC profile for velocity distribution seems to fit the data incredibly well up to $\sim 30$ kpc [97]. The present model based on EiBI eq. (2.3), which is akin to the quantum BEC model, is probably no better or worse than the others. Nevertheless, the foregoing study hopefully provides some new definitive information in an analytic way using a metric solution (2.7) of EiBI theory.

---

13The claim is grounded to the fact that a single set of universal constants ($\gamma_{0}$, $\gamma^{*}$, $k$) and the ($M/L$) ratio of individual samples, all a priori known, are enough to nicely predict all the rotation data — no adjustable free parameters are needed. In contradistinction, NFW, Burkert, PI or other profiles only give the generic shapes of halos, and leave the values for $\rho_{0}$ and $r_{0}$ as free parameters to be finely tuned to data galaxy by galaxy. This procedure then quickly generates large numbers of such values as more and more galactic rotation curves are considered (For details of such “fine tuning”, see [35], pp. 32,33).
