Truffles Regulate Plant Root Morphogenesis via the Production of Auxin and Ethylene

Department of Crop Sciences, Molecular Phytopathology and Mycotoxin Research (R.S., P.K.), Forest Botany and Tree Physiology, Buesgen-Institute (U.F.), and Department of Plant Biochemistry, Albrecht-von-Haller-Institute for Plant Sciences (C.G., I.F.), Georg-August University, D–37077 Goettingen, Germany

Truffles are symbiotic fungi that form ectomycorrhizas with plant roots. Here we present evidence that at an early stage of the interaction, i.e. prior to physical contact, mycelia of the white truffle Tuber borchii and the black truffle Tuber melanosporum induce alterations in root morphology of the host Cistus incanus and the nonhost Arabidopsis (Arabidopsis thaliana; i.e. primary root shortening, lateral root formation, root hair stimulation). This was most likely due to the production of indole-3-acetic acid (IAA) and ethylene by the mycelium. Application of a mixture of the ethylene precursor 1-aminocyclopropane-1-carboxylic acid and IAA fully mimicked the root morphology induced by the mycelium for both host and nonhost plants. Application of the single hormones only partially mimicked it. Furthermore, primary root growth was not inhibited in the Arabidopsis auxin transport mutant aux1-7 by truffle metabolites while root branching was less effected in the ethylene-insensitive mutant ein2-LH. The double mutant aux1-7;ein2-LH displayed reduced sensitivity to fungus-induced primary root shortening and branching. In agreement with the signaling nature of truffle metabolites, increased expression of the auxin response reporter DR5:GFP in Arabidopsis root meristems subjected to the mycelium could be observed, confirming that truffles modify the endogenous hormonal balance of plants. Last, we demonstrate that truffles synthesize ethylene from l-methionine probably through the α-keto-γ-(methylthio)butyric acid pathway. Taken together, these results establish the central role of IAA and ethylene as signal molecules in truffle/plant interactions.

Ectomycorrhizal symbioses are mutualistic interactions between filamentous fungi and plant roots. Truffles, which are ascomycete fungi renowned for their aromatic fruiting bodies, form ectomycorrhizas (ECM) in temperate climates predominantly with trees (i.e. hazel [Corylus avellana], oaks [Quercus spp.]). In soil, microorganisms communicate with plants by exchanging chemical signals throughout the rhizosphere. Depending on the nature of the interaction, these molecules can be either volatiles or solutes (dissolved solids). For example, rhizobacteria induce growth promotion in Arabidopsis (Arabidopsis thaliana) through the action of the volatile compound 2,3-butanediol (Ryu et al., 2003). The sesquiterpene volatile (E)-β-caryophyllene is produced by maize (Zea mays) roots fed upon by arthropods, and serves as attractant to natural enemies of the insects (Rasmann et al., 2005). Nonvolatile signal molecules can also dissolve in water and diffuse in the soil. Indeed the nitrogen-fixing bacteria Rhizobium secrete a nodulation factor that induces changes in root morphology of legumes (Denarié and Cullimore, 1993; Heidstra and Bisseling, 1996). Mycelium branching is induced in the mycorrhizal fungus Gigaspora margarita by 5-deoxystrigol, a strigolactone exuded from the roots of the legume host Lotus japonicus (Akiyama et al., 2005).

Also ectomycorrhizal fungi engage in a molecular dialogue with plants and produce chemical signals that modulate plant root/ECM morphogenesis. The indole alkaloid hypaphorine produced by ectomycorrhizal fungus Pisolithus tinctorius inhibits root hair elongation in the host Eucalyptus globules and the nonhost Arabidopsis (Béguiristain et al., 1995; Reboutier et al., 2002). Hormones, mainly indole-3-acetic acid (IAA), have also been often implicated in symbiotic interactions (Barker and Tagu, 2000; Martin et al., 2001; Sirrenberg et al., 2007; Contreras-Cornejo et al., 2009). Most studies involving hormones have focused at a late stage of interaction, when ECMs were developing or already formed (for review, see Barker and Tagu, 2000). Indeed IAA-overproducing mutants of the ectomycorrhizal fungus Hebeloma cylindrosporum form significantly more mycorrhizas with the host Pinus pinaster than the wild type (Gay et al., 1994). Similarly applying exogenous IAA to the ectomycorrhizal system Piloderma croceum/Quercus robur also

Truffles form ECM with a variety of hosts such as oaks, hazels, but also some shrubs (i.e. Cistus). Under laboratory conditions, the establishment of the symbiotic phase takes 2 to 3 months (Sisti et al., 1998; Miozzi et al., 2005). Strains of the same truffle species vary in their capacity to colonize a single host (Giomaro et al., 2000). Volatile organic compounds have been implicated in the signaling between truffle and plants. Splivallo et al. (2007) discussed the phytotoxic activity of fruiting body volatiles and Menotta et al. (2004) highlighted their potential role as mycorrhization signals. Fruiting bodies volatiles shortened primary roots of plants (Splivallo et al., 2007) while the effect of mycelial metabolites has not been addressed.

Our aim here was to investigate how truffle mycelia modify plant root architecture. We focus our effort on an early stage of interaction (10 d) to explain changes in root morphology prior to ECM formation and highlight the action of diffusible signals on the host plant Cistus incanus and the nonhost Arabidopsis. Using Arabidopsis mutants, we did not aim to investigate the mechanism behind the IAA/ethylene cross talk but rather to show that the fungal metabolites are perceived in planta through both auxin and ethylene signaling pathways. We illustrate how truffle metabolites modify the auxin response of the root meristem using the auxin reporter line DR5::GFP. We further demonstrate that both hormones are produced by truffles at concentrations that fully explain the root phenotypic responses of the host and nonhost plants. Last, we elucidate ethylene biosynthesis in truffles.

RESULTS

Truffles Modify Root Morphology and Architecture of Both Host and Nonhost Plants

The effect of signals released by truffle mycelia on root architecture of the host C. incanus or the nonhost Arabidopsis was investigated. Petri dishes used to cocultivate plants and fungi (Fig. 1) were inoculated with either mycelium of two strains of Tuber melanosporum, two strains of Tuber borchii, or mock inoculated with an agar plug for the control. Root morphology (root length, branching, and root hair length) was recorded every 5 d up to 15 d (Fig. 2). During the period of cocultivation plant roots and mycelium did not enter in direct contact (Supplemental Fig. S1). Changes in root morphology can consequently be attributed to diffusible fungal signals.

The presence of the two strains of T. borchii inhibited primary root growth of Arabidopsis while T. melanosporum inhibited primary root growth only transiently at 5 d postinoculation and resumed normal growth afterward. For the host plant C. incanus all strains of T. borchii and T. melanosporum significantly inhibited primary root growth (Fig. 2, A, B, and F). Root branching was stimulated with all truffle strains for Arabidopsis, but only with the two strains of T. borchii for C. incanus (Fig. 2, C, D, and F). Root hair length of Arabidopsis was also increased by all the truffle strains/species tested here (Fig. 2, E and F)—C. incanus did not develop any root hair (Fig. 2F). In summary, we observed that the presence of truffle mycelia induces profound changes in root morphology and architecture. These changes are partly dependent on the truffle species involved but can occur in a host as well as in a nonhost plant.

Truffles Release IAA in the Culture Medium

The morphological changes observed upon coculturing Arabidopsis seedlings with fungal mycelia (Fig. 2) are reminiscent of plants treated with the phytohormones auxin (IAA) or ethylene. Since both IAA and ethylene can be produced by ectomycorrhizal fungi (Graham and Linderman, 1980; Strzelczyk et al., 1994; Barker and Tagu, 2000), we investigated whether truffles produced IAA and ethylene under the conditions of the bioassay described in Figure 1. IAA exuded by truffles was quantified in petri dishes without plants to assert that the IAA was indeed of fungal origin (Supplemental Fig. S2). Quantification was done by HPLC-electrospray ionization (ESI)-tandem mass
spectrometry (MS/MS) from the Murashige and Skoog agar portion of the petri dishes (Supplemental Fig. S2) after 10 d of mycelial growth (which corresponds to the time when the seeds of the test plants were added to the petri dishes in Fig. 1) and after 10 additional days in the growth chamber (corresponding to 10-d-old seedlings in Fig. 1). After 10 d in the dark, IAA was present in the Murashige and Skoog portion of the control petri dishes (probably due to diffusion of the IAA contained in malt extract; see Dix and Van Staden, 1982) but its concentration was significantly higher in the petri dishes that contained mycelia of T. borchii or T. melanosporum (Fig. 3). After 10 d in the growth chamber (day/night cycles), IAA concentrations had dropped compared to the earlier time point, nevertheless remaining significantly higher than in the control for the strains of T. borchii (Fig. 3). We conclude that T. borchii and T. melanosporum release IAA into the culture medium. IAA accumulates in the medium in the dark, and is partially degraded by light (Dunlap and Robacker, 1988) under the growth chamber conditions (16-h photoperiods).

Truffles Produce Ethylene from L-Met Probably via the α-Keto-γ-(Methylthio)Butyric Acid Pathway

Ethylene production by truffle mycelium was measured by gas chromatography (GC)-flame ionization
Figure 3. IAA concentrations in agar resulting from the exudation of truffle mycelia. After 10 d of growth in the dark, strains of *T. borchii* and *T. melanosporum* increased the IAA concentration from 3 to 10 times compared to the control petri dish containing no mycelium. IAA concentration after 10 more days in the growth chamber had dropped in all samples due to degradation by light (*n* = 3 or 4 petri dish/treatment, bars indicate SD; circles [○ for day 10 and ● for day 10 + 10] indicate statistical differences compared to the respective controls, *P* < 0.05, Mann-Whitney).

Ethylene Released by Truffles Increases Root Hair Length

To confirm that ethylene produced by truffles was responsible for the alteration of root morphology in *Arabidopsis* seedlings, we modified the bioassay setup depicted in Figure 1 as follows (compartmented bioassy): Fungal mycelium was grown inside a small petri dish, itself contained in a larger one with plants (Supplemental Fig. S3). In this manner, nonvolatile metabolites produced by mycelium such as IAA could not reach the seedlings. Since both IAA and ethylene are able to increase root hair length (Pitts et al., 1998) in a concentration-dependent manner, the compartmented bioassay permitted us to check whether ethylene was produced at a high enough concentration to induce root hair elongation. In the compartmented bioassay, mycelium grown on pure malt extract stimulated root hair growth (Supplemental Fig. S4). Root hair growth was further stimulated by supplying mycelium with the ethylene precursor l-Met (Supplemental Fig. S4, C and E). When an ethylene trap was included in the bioassay, root hair elongation was reduced (Supplemental Fig. SSD).
In the compartmented bioassay, primary root length was only inhibited when ethylene production was induced by supplying the mycelium with 10 mM L-Met (Supplemental Fig. S4, A and D), and the inhibition was reduced in the presence of an ethylene trap (Supplemental Fig. S5B). Root branching was also slightly increased (approximately 1.6 times) by volatiles released by the mycelium grown on malt extract (not supplemented with L-Met; Supplemental Fig. S4B).

In summary, in the compartmented bioassay root hair length was affected by mycelial volatiles and the extent of the effect could be modulated with an ethylene precursor and a trap for volatiles. This corroborates the hypothesis that Arabidopsis seedlings are sensing ethylene released by the mycelium.

Response of the Host and Nonhost to IAA and ACC

To investigate whether IAA and ethylene could account for the morphological changes observed with host and nonhost plants, dose-response curves for both hormones were established. Ethylene is difficult to handle in the bioassays because of its volatility, and consequently ACC, its direct nonvolatile precursor in plants was used. ACC was chosen rather than L-Met because it is converted to ethylene in a single enzymatic step compared to three steps for L-Met. The bioassay setup shown in Figure 1 (without mycelium) was supplied with varying concentrations of IAA (from 10 to 0.01 mM) alone, or including the ethylene precursor ACC (1 mM). The results are displayed in Figure 5. The extent of root growth inhibition, lateral root density, and root hair elongation caused by T. borchii (strain 1) and T. melanosporum (strain 1) were mimicked by IAA concentrations in the medium ranging between 1 and 0.1 mM and 0.1 and 0.01 mM, respectively (Fig. 5, A–D), well in agreement with the IAA amounts exuded by those two species into the medium (0.13 ± 0.03 μM for T. borchii strain 1 and 0.05 ± 0.02 μM for T. melanosporum strain 1; Fig. 3). While IAA treatment alone often mimicked the primary root shortening and branching response observed with both truffle species, the addi-
tive action of IAA and ACC was needed to fully restore Arabidopsis’s root hair elongation induced by the mycelium (Fig. 5, E and F). In summary, a combined exogenous application of IAA and ethylene induced root responses equivalent to the presence of truffle mycelium in both host and nonhost plant.

Truffle Metabolites Are Perceived by Arabidopsis through IAA and Ethylene Signaling Pathways

To address more specifically whether Arabidopsis reacts on mycelial auxin or ethylene we made use of several Arabidopsis mutants with reduced sensitivity toward these two phytohoromones. Seedlings of Arabidopsis, including the auxin influx mutant aux1-7 that has reduced auxin and ethylene sensitivity (Pickett et al., 1990), the ethylene-insensitive mutant ein2-LH, and the double mutant aux1-7;ein2-LH were grown for 10 d either in the presence of T. borchii (strain 1) or mock inoculated with an agar plug (controls) as described in Figure 1. Compared to their respective controls, the mycelium inhibited primary root development to similar levels in the wild-type and ein2-LH mutant, while no or significantly smaller inhibition was observed for aux1-7 or the double mutant (Fig. 6A). Lateral root density was equally strongly induced.

Figure 5. Comparison of root morphology induced by truffles or IAA + ACC. Root length (A and B), branching (C and D), and root hair length (E) of Arabidopsis (A, C, and E) or Cistus (B and D) subjected to mycelial metabolites of T. borchii strain 1 or T. melanosporum strain 1 (gray bars) or synthetic IAA alone (black bars), or IAA and ACC (1 μM; white bars). Error bars represent SEs; n = 15 seedlings per treatment. The same symbols (*, ○) represent values that are statistically the same (P<0.05, ANOVA on ranks with posthoc Dunn’s test). Note that the root hair phenotype induced by the mycelium in Arabidopsis was only fully restored by supplying IAA and ACC together (E and F: root hair of 15-d-old seedlings, scale bars in F = 0.25 mm; ND = not determined).
by *T. borchii* mycelium in *aux1-7* as in wild type. However, the *ein2-LH* and the double mutant *aux1-7; ein2-LH* were significantly less sensitive (both to similar levels) to lateral root induction than the wild type (Fig. 6B). The shortened root hair phenotype of *aux1-7* and *aux1-7; ein2-LH* double mutants was partially rescued by the presence of *T. borchii* mycelium (Fig. 6C). Additional auxin and ethylene mutants, including the null mutants *aux1-T* and *ein2-T* (Fischer et al., 2006) and the auxin signaling mutants *axr1-3* and *axr4-1*, were also tested and gave comparable results (Supplemental Fig. S6). In summary the changes in root morphology induced by truffle metabolites in Arabidopsis can be attributed partly to auxin transport and signaling (inhibition of primary root growth and induction of root hair growth) and to ethylene signaling (induction of lateral root formation).

To assess whether truffle metabolites modified auxin response levels in Arabidopsis roots, a reporter line transformed with the auxin-responsive *DR5* promoter driving GFP (*DR5::GFP*) was treated as in the bioassay of Figure 1, either coinoculated with *T. borchii* (strain 1) or mock inoculated with an agar plug (control). Five-day-old seedlings subjected to the mycelium showed a significant signal increase in the first tier columnella cells and epidermis compared to the untreated seedlings (Fig. 6D; Supplemental Fig. S7). Furthermore the signal increase in the first tier columnella cells was mimicked by ACC (1 μM) applied alone or in combination with IAA (0.1 μM; Supplemental Fig. S7). On the contrary only the additive effect of both hormones triggered the GFP signal observed with the mycelium in the epidermis (Supplemental Fig. S7).

**DISCUSSION**

Previous work established the role of fungal IAA in ECM interactions, while the role of ethylene has been suggested but not proven (Barker and Tagu, 2000). We report that IAA and ethylene produced by truffles act additively on plant roots to induce changes such as root shortening, increased branching, and root hair elongation.

ECM colonize plants by producing a fungal mantle enveloping short secondary roots and a Hartig net consisting of intercellular hyphae that develop between root cells (Smith and Read, 1997). ECM forma-

**Figure 6.** Screening Arabidopsis mutants for resistance to truffle metabolites. Using the bioassay setup of Figure 1, the auxin *aux1-7*, ethylene *ein2-LH*, and double mutant *aux1-7; ein2-LH* were tested for their sensitivity to truffle (*T. borchii* strain 1) metabolites and compared to the wild type. A to C, Primary root length (A), root branching (B), and root hair length (C). Bars represent average values for 10-d-old seedlings, *n > 20* seedlings/treatment; for root hair length *n = 300*, 15-d-old seedlings. Percentages represent changes versus respective controls (±SE). Different letters indicate statistically different values (*P* < 0.05, ANOVA on ranks and posthoc Dunn’s test). D, Root tips of the Arabidopsis auxin reporter line *DR5::GFP*. The mycelium increased the GFP signal intensity at the level of the first tier columnella cells (red arrows) and at the level of the epidermis (yellow arrows) compared to the mycelium control in *DR5::GFP* roots. Hormones including IAA (0.1 μM) and ACC (1.0 μM) mimicked this increase in signal intensity fully when applied together (+IAA and ACC; D). For quantification of the GFP signal, refer to Supplemental Figure S7. MeOH control = control for the IAA, ACC, and IAA and ACC treatments. Scale bars in D = 25 μm.
tion is known to induce changes in root morphology, including formation of lateral roots and in some plants root dichotomous branching in meristems (Peterson and Bonfante, 1994).

Our data highlights that lateral root formation can already be stimulated before contact between an ECM fungus and plant roots, demonstrating that the increase in branching is not the consequence of the mantel and Hartig net formation but rather the response of the root to diffusible fungal metabolites.

In our bioassays, IAA and ethylene were the major signals controlling root development before contact with the mycelium. Other signals might however be involved either at this early interaction stage or later on. This is highlighted by the fact that the two strains of *T. borchii* used in this study produce ECM with different efficiency and anatomical traits (Giomaro et al., 2000; Sisti et al., 2003), however in our bioassays they affected root morphology to a comparable extent (Fig. 2). Root morphology was also affected by volatiles released from the mycelium (Supplemental Fig. S4). As ethylene generally decreases root branching (Negi et al., 2008), the increased branching observed in our compartmented system (Supplemental Fig. S4B; 0 mM l-Met) suggests the presence of a volatile signal different from ethylene. Carbon dioxide is known to induce such root branching in Arabidopsis while stimulating primary root elongation (Crookshanks et al., 1998). Primary root elongation was, however, not observed in our setup (Supplemental Fig. S4, A and B), suggesting that either the CO₂ concentration was relatively low or that the unidentified volatile was different from CO₂.

Ethylene had been implicated in ECM establishment mainly on a speculative basis (Barker and Tagu, 2000). Its production by ectomycorrhizal fungi has been documented for long (Graham and Linderman, 1980; Strzelczyk et al., 1994), but its effect on root morphology has only been investigated in pine (Pinus spp.; Scagel and Linderman, 1998). The latter authors highlighted that in vitro ethylene production by various ectomycorrhizal species positively correlated to root IAA content but poorly correlated with plant morphological responses.

Because the role of ethylene as compared to IAA was neglected, we addressed ethylene biosynthesis by the fungus. Fungi can synthesize ethylene through three routes. The ACC pathway, most common in plants, has been described in *Penicillium citricum* (Jia et al., 1999). The 2-oxoglutarate pathway is known to operate in different *Penicillium* species (Fukuda et al., 1986; Pazout and Pazoutova, 1989) and in *Fusarium oxysporum* (Hottiger and Boller, 1991). The last pathway, in which l-Met is deaminated to produce KMBA, has been reported for *Saccharomyces cerevisiae* and *Penicillium digitatum* (Billington et al., 1997). Strzelczyk et al. (1994) proved that l-Met could be successfully transformed to ethylene by six mycorrhizal fungi of pine, suggesting that its biosynthesis precedes either through the KMBA or ACC pathways that both share l-Met as a common precursor (Fig. 4C). Our results indicate that ethylene is synthesized in truffles from l-Met, probably through the KMBA pathway (Fig. 4, A–C). Interestingly, the ascomycete *Botrytis cinerea* is able to exudate KMBA in the culture medium where it is photooxidized by light, and without the action of any enzyme to form ethylene (Chague et al., 2002). Similarly the mycelium of *T. borchii* did not produce any ethylene in the dark (Fig. 4, C and D), suggesting that photooxidation by light might also be necessary and corroborating the KMBA hypothesis.

Considering the underground habitat of truffles and the instability of KMBA to photooxidation, the latter molecule could act as a signal in the first centimeters of soil where light can still penetrate, however whether that light intensity would suffice to degrade KMBA to ethylene is unknown. Another hypothesis is that the ethylene intermediate produced by truffle could actually be degraded enzymatically, either after being taken up inside roots or by other organisms in the rhizosphere. Supporting this possibility, peroxidases can indeed degrade KMBA into ethylene (Chague et al., 2002), and certainly they abound in the rhizosphere.

IAA production has been reported for numerous but not all ectomycorrhizal fungi. Based on the occurrence of IAA intermediates described in plants, three different pathways that share Trp as a common precursor have been reported in fungi (Reineke et al., 2008). In truffles the IAA synthesis has not yet been investigated. In our study, IAA was produced by all truffle species and strains, and accumulated in the medium in the dark. Since Slankis’s (1973) auxin theory stating that auxin is responsible of ECM morphogenesis, many studies have demonstrated that even if partly correct, the theory was an oversimplification (Smith and Read, 1997). One advantage of this investigation compared to earlier ones (Scagel and Linderman, 1998; Sirrenberg et al., 2007) was to quantify IAA directly in the bioassays. By doing so and establishing a dose response of the test plants to synthetic IAA, we could demonstrate that IAA alone could explain many of the changes observed in root morphology, but not all (i.e. root hair; Fig. 5E). Ethylene (or ACC) was necessary to fully express the morphological changes induced on plants by truffle mycelia. Scagel and Linderman (1998) had examined the effect of both hormones on conifers. They highlighted that in vitro fungal IAA and ethylene production positively correlated with root IAA content, suggesting that both hormones could act on the root endogenous IAA level. Two years later Barker and Tagu (2000) hypothesized that a local increase in IAA concentration due to the inhibition of IAA transport by ethylene could trigger ECM-like root morphogenesis. In this study we focused on an early interaction stage, when both partners are not yet in physical contact. We demonstrated that IAA and ethylene indeed act together on plants to induce changes in root morphology. As a matter of fact the action of both hormones is
such a strategy could be more cost-effective for the hormonal signals that are recognized by most plants. Interestingly, Arabidopsis developed longer root hairs (Peterson and Massicotte, 2004), and are in the con-

longer root hairs are not involved in ECM colonization (Peterson and Massicotte, 2004), and are in the contrary repressed by some ECM fungi (Jambois et al., 2005). Interestingly, Arabidopsis developed longer root hairs in the presence of truffles. Longer root hairs might mechanically hinder root colonization by ECM fungi, but whether this is specific of a nonhost is unclear considering that the host plant Cistus did not develop any root hair. In conclusion, truffles might use hormonal signals that are recognized by most plants. Such a strategy could be more cost-effective for the fungus than producing more complex and specific signals, especially if the fate of ECM formation is controlled by the plant.

Regarding the second point, one can conceive that truffles produce IAA and ethylene in the field at a stage of their life cycle different from the symbiotic one. For instance the burnt, a zone around the host plant devoid of vegetal cover observed with some truffle species (Pacioni, 1991; Splivallo, 2007) could be explained by IAA and ethylene. Because at high concentrations these molecules act as potent herbicides (Hansen and Grossmann, 2000; Grossmann, 2003), their production by truffle mycelium could explain the scarcity of the herbaceous cover observed inside the burnt. In this case both hormones might not have a symbiotic signaling role but could rather reflect a change in the metabolism of the fungus. This is further supported by the observation that the burnt generally appears 1 to 2 years before the formation of fruiting bodies (Splivallo, 2007).

CONCLUSION

Ethylene and IAA produced by ECM fungi have long been suspected to act together to induce ECM formation. We have demonstrated that in laboratory bioassays and at an early stage of interaction (without direct contact), truffles release both hormones at levels that indeed explain all morphological changes induced in the roots of the host Cistus and the nonhost Arabidopsis. Is KMB (or another ethylene precursor) secreted in the soil before being photooxidized or is it degraded enzymatically/chemically to ethylene inside the mycelium? In this study, metabolites potentially involved in truffle-plant signaling were identified by coculturing both organisms on agarized sterile media. In future work we intend to test the occurrence of these metabolites in truffle fields.

MATERIALS AND METHODS

Biological Material

Cistus incanus was chosen as a model of host plant because of its capacity to form ECM with truffles (Comandini et al., 2006). Arabidopsis (Arabidopsis thaliana) was selected as a nonhost model. Arabidopsis was chosen as a model of nonhost plant because of the mutant and reporter lines available (accession nos. are given for the Nottingham Arabidopsis Stock Centre [http://Arabidopsis.info/]). Arabidopsis ecotype Columbia-0 was tested as wild type (N1092), ethylene and auxin mutants ein2-T (N586500) and aux1-7 (N520355; Fischer et al., 2006), ein2-LH (N9719; Hobbie et al., 2000), aux1-7 (N9883; Pickett et al., 1990), axr4-T (N8018; Hobbie and Estelle, 1995), and axr4-3 (N3075; Lincoln et al., 1990), double mutant aux1-7;ein2-LH (N8843; Hobbie et al., 2000), and the auxin reporter line carrying the DRS3::GFP construct (Friml et al., 2003). Truffle mycelia of Tuber borchii (strains ATCC 96540 = strain 1, and 43BO = strain 2) were donated by Prof. Bonfante (University of Turin, Italy), while Dr. Chevalier (Institut National de la Recherche Agronomique, Clermont, France) provided Tuber melanosporum strains Ball (strain 1) and Rey.1 (strain 2). Mycelial strains were grown in the dark at 23°C ± 2°C and regularly subcultured on malt extract agar (10 g L−1 malt extract broth, 15 g L−1 agar-agar, pH 7.0).
Bioassays

Dual Culture Mycelium/Plants, Uncompartmented

The experimental setup is exemplified in Figure 1. Square petri dishes (10 × 10 cm²) were filled with 40 mL malt extract (10 g L⁻¹ malt extract broth, Difco Laboratories; 15 g L⁻¹ agar-agar, Carl Roth GmbH; pH adjusted to 7.0 with KOH). After solidification half the malt extract agar was removed with a spatula and replaced by Murashige and Skoog agar (2.2 g L⁻¹ Murashige and Skoog medium including vitamins, Duchefa Biochemie B.V.; 15 g L⁻¹ Suc, Sigma Aldrich Biochemie GmbH; 15 g L⁻¹ agar-agar; pH adjusted to 5.8–6.0). The malt extract side of the petri dishes was inoculated with a 1.0 cm mycelial plug of the different strains of T. melanosporum and T. borchii (taken from the colony margin of a ≈1-month-old colony grown on malt extract) or with a malt extract agar plug (mock control). Inoculated plates (including the control plates without fungus) were kept horizontally in darkness for 10 days (23°C ± 2°C) to allow mycelial biomass buildup and exudation in the medium. Ten sterilized seeds of Arabidopsis (wild type or mutants) or of Cistus incanus were placed on the Murashige and Skoog agar part of the petri dish, which was then positioned vertically in a growth chamber kept at a constant 20°C ± 1°C with a 16-h photoperiod and a light intensity of 95 μmol m⁻² s⁻¹.

Dual Culture Mycelium/Plants, Compartmented without Volatile Trap

The experimental setup is shown in Supplemental Figure S1. For the media composition, refer to the uncompartmented bioassay. Ten seeds of Arabidopsis were placed on Murashige and Skoog agar in the upper part of a 10 × 10 cm² petri dish. A round open petri dish filled with malt extract agar (supplemented with 0 ms, 1 ms, or 10 ms i-Met) and inoculated either with truffle mycelium (pregrown for 10 d on malt extract agar on a cellophane membrane) or with an agar plug (mock control) was placed in the bottom part of the square petri dish. In this setup the mycelial exudates do not diffuse in the Murashige and Skoog agar and only the mycelial volatiles can reach the seedlings. Seeds of Arabidopsis (wild type) were placed on the Murashige and Skoog agar part of the petri dish, which was then positioned vertically in a growth chamber kept at a constant 20°C ± 1°C with a 16-h photoperiod and a light intensity of 95 μmol m⁻² s⁻¹.

Dual Culture Mycelium/Plants, Compartmented with Volatile Trap

A volatile trap was included in some of the compartmented bioassays as exemplified in Supplemental Figure S5A. A single trap was made of 62.5 mm activated charcoal (60-100 mesh [powder, Sigma-Aldrich] wrapped in filter paper). The traps were activated by autoclaving followed by 3 h drying at 105°C. Ten sterilized seeds of Arabidopsis and C. incanus were placed on the Murashige and Skoog agar part of the petri dish, which was then positioned vertically in a growth chamber kept at a constant 20°C ± 1°C with a 16-h photoperiod and a light intensity of 95 μmol m⁻² s⁻¹.

Bioassays with Synthetic Hormones (ACC, IAA)

IAA (98%, Carl Roth GmbH) and the ethylene precursor ACC (98%, Sigma Aldrich Biochemie GmbH) were used to establish a dose response of Arabidopsis and C. incanus to IAA and ethylene. The metabolites were added separately or together to the agar of the uncompartened bioassay, reaching final concentrations of 10⁻⁴ to 10⁻¹ M (IAA) and 1 μM (ACC) in the agar.

Determination of Root Length, Branching, and Root Hair Length

Primary root length and root branching (secondary roots) were monitored every 5 d up to 15 d. Primary root length was determined with the image analysis software ImageJ (http://rsb.info.nih.gov/ij/image) after scanning the petri dishes at a resolution of 400 dpi. Root branching was determined for each seedling by counting the number (abbreviated nb in the figures) of secondary roots visible under a stereo microscope at a magnification of 30 times (Leica Wild M10). Root hair length was quantified with ImageJ from digital images obtained from the primary root section located 1.0 cm above the root tip under the stereo microscope at a magnification of 40 times (a Leica DFC300FX digital camera was mounted on the stereo microscope; image acquisition with Leica IM, version 4 software).

Conical Laser-Scanning Microscopy on DR5::GFP

Root Tips

Conical laser-scanning microscopy was performed using a Leica TCS SP5 scanning system mounted on a Leica DMR5000CS inverted microscope with a water-corrected 63× objective. The GFP was excited with an argon laser (488 nm) and fluorescence was detected between 496 and 551 nm. Seedlings were individually mounted in water and immediately subjected to analysis. The GFP signal was quantified by (1) counting the number of first tier columella cells where the GFP was expressed and (2) calculating how frequently a signal was visible in the epidermis (data pooled from three petri dishes, n = 12 seedlings).

IAA Quantification by HPLC-ESI-MS/MS

IAA Extraction from Agar

IAA was quantified in the upper Murashige and Skoog agar part of the dual culture mycelium/plant (uncompartmented) bioassays at two time points: 10 d after inoculation (equivalent to the beginning of the bioassay with plants) and after 10 additional days in the growth chamber. A quantity of 10 to 15 g Murashige and Skoog agar was removed from each plate with a scalpel, placed in a 50 mL falcon tube, and shortly homogenized in a mixer with 7.0 mL water:MeOH (1:1, v/v) containing 37.5 mg mL⁻¹ of deuteriated IAA (2,4,5,6,7-²H₅-IAA, Euroisotop) as an internal standard. The sample was acidified with 50 μL fuming acetic acid, mixed with 7.0 mL ethyl acetate, vortexed for 30 s, and centrifuged at 4,500 rcf for 10 min to force phase separation. The upper phase was concentrated to dryness at 40°C under vacuum, redissolved in 1.0 mL of water:MeOH containing 7.0 μs acetic acid, and filtered on a 0.2 μm polytetrafluoroethylene filter for HPLC-MS analysis.

Quantification of IAA by HPLC-ESI-MS/MS

The protocol was modified from Sirrenberg et al. (2007). In short, analyses were performed on a Varian system equipped with an autosampler (ProStar 430), a binary pump system (ProStar 210), a column oven, and a reversed-phase column (Polaris C18-A, 100 × 2 mm; particle size 5 μm, mounted with a ChromSep guard column, both from Varian). Samples (10 μL injection volume) were eluted at 40°C with a flow rate of 0.2 mL/min as follows. Hold for 1 min, 90% solvent A (95:5 water:ACN) and 10% solvent B (MeOH). Ramp to 98% solvent B in 7 min and hold for 7 min. The detector was a 1200LC triple quadrupole mass spectrometer (Varian) equipped with an electrospray interface. Drying gas (nitrogen) pressure was 18 psi. Nebulizing gas (air) was set to 50 psi, and the pressure of collision gas (argon) was 1.4 mTorr. Voltage was set to ~4,400 V (needle), ~600 V (shield), and 40 V (capillary). Multiple reaction monitoring modus was used to operate the mass spectrometer. Mass transitions were: for IAA 173.9/130.0 (collision energy 9.0 eV), and for D₅-IAA 178.8/134.0 (collision energy 11.5 eV). A calibration curve of the ratio of peak areas of unlabeled standards to peak area of deuterium-labeled standard was used for the quantification of IAA.

Ethylene Quantification by GC

Truffle mycelium (T. borchii strain 1) was cultured in a 20 mL solid-phase microextraction vial containing 10 mL malt extract agar and sealed air tight with a silicon/polytetrafluoroethylene septum. Control vials were inoculated with an agar plug. The samples were kept either under the same conditions in which the bioassays were performed (growth chamber conditions) or in complete darkness.

Various ethylene precursors/inhibitors were added to the medium to investigate the ethylene biosynthetic pathway in truffles. i-Met and i-Gln were tested as potential ethylene precursors. ACC (98%, Sigma Aldrich Biochemie GmbH) and KMBA (98%, Sigma-Aldrich GmbH, Germany) were used as possible intermediates and AOA (98%, Sigma-Aldrich GmbH) as an inhibitor of the ACC pathway (Cristescu et al., 2002). All chemicals, except the
Splivallo et al.

heat unstable KMBA, were mixed in 0.5 mL malt extract agar at 60°C to reach a final concentration of 10 mM and then added as a 2.0 mm layer on the top of 9.5 mL malt extract agar in the solid-phase microextraction vial. KMBA was added (50 μL of a 10 mg mL⁻¹ solution in water) to vials containing 10 mL malt extract agar once the agar had solidified and cooled down to room temperature. Vials containing the chemicals but mock inoculated with an agar plug were used as controls.

Ethylene measurements were performed on a GC equipped with a flame ionization detector (Agilent Technologies GC 6890 N) and a GC-GASPRO J&W column (30 m × 320 μm). Helium was used as a carrier gas at 2.0 mL mL⁻¹ min⁻¹. A volume of 100 μL taken from the headspace of 10-d-old samples was injected in the inlet heated to 150°C (split 0:2:1). Temperature program was 60°C for 2 min, ramp to 200°C min⁻¹ to 150°C, and hold 1 min.

For quantification a calibration curve was established with pure ethylene (≥99.95%, Sigma-Aldrich GmbH). Average ethylene production was calculated for each treatment using four replicates.

Data and Statistical Analysis

Each bioassay was repeated at least three times independently. All data were first checked for normality (Kolmogorov-Smirnov test) and depending on the result analyzed with a parametric or nonparametric test. All morphological data (primary root length, branching, root hair length) were analyzed with a nonparametric ANOVA on ranks followed by Dunn’s test that performs multiple comparisons of group of unequal sizes. The remaining data (IAA, ethylene, and GFP) were analyzed by a t test in case of normal distribution and otherwise with the nonparametric Mann-Whitney test (SigmaPlot 11.0, Systat Software Inc.).

Supplemental Data

The following materials are available in the online version of this article.

Supplemental Figure S1. Uncompartmented bioassay setup: no contact between the plant roots and mycelium.

Supplemental Figure S2. Experimental setup for IAA and ethylene determination.

Supplemental Figure S3. Compartmented bioassay.

Supplemental Figure S4. Effect of mycelial volatiles on Arabidopsis.

Supplemental Figure S5. Effect of activated charcoal in the compartmented bioassay.

Supplemental Figure S6. Screening Arabidopsis mutants for resistance to truffle metabolites.

Supplemental Figure S7. GFP quantification in root tips of DRS-GFP Arabidopsis.

ACKNOWLEDGMENTS

We wish to acknowledge Caroline Gutjahr for editing and commenting on the manuscript. We would like to thank the following people for providing biological material: Prof. Paola Bondanè (T. borchii mycelia); Dr. Gérard Chevalier (T. melanosporum mycelia); Dr. Rafaela Balestrini (C. inanum); Prof. Christiane Gatz, Hella Tappe, and Christoph Weiste (axr mutants of Arabidopsis); and Dr. Thomas Teichmann for the auxin reporter line carrying the DRS-GFP construct. We are also thankful to Prof. Peter Schu for providing access to the confocal microscope and to Michael Reusche for introducing us to the machine.

Received May 12, 2009; accepted June 12, 2009; published June 17, 2009.
