Multiple motor memories are learned to control different points on a tool

James B. Heald*, James N. Ingram, J. Randall Flanagan and Daniel M. Wolpert

Skilful object manipulation requires learning the dynamics of objects, linking applied force to motion. This involves the formation of a motor memory, which has been assumed to be associated with the object, independent of the point on the object that one chooses to control. Importantly, in manipulation tasks, different control points on an object, such as the rim of a cup when drinking or its base when setting it down, can be associated with distinct dynamics. Here, we show that opposing dynamic perturbations, which interfere when controlling a single location on an object, can be learned when each is associated with a separate control point. This demonstrates that motor memory formation is linked to control points on the object, rather than the object per se. We also show that the motor system only generates separate memories for different control points if they are linked to different dynamics, allowing efficient use of motor memory. To account for these results, we develop a normative switching state-space model of motor learning, in which the association between cues (control points) and contexts (dynamics) is learned rather than fixed. Our findings uncover an important mechanism through which the motor system generates flexible and dexterous behaviour.

Understanding how humans learn to use tools is a central challenge in neuroscience. Tool use requires knowledge of the dynamics of objects (relating applied force to motion), which depends on both the physical properties of objects (for example, mass, mass distribution and friction) and how objects are used to interact with the environment (for example, for transport or percussion). Numerous paradigms have been developed to explore how humans learn the dynamics of objects. In conventional object-manipulation tasks, participants grasp and lift physical objects with familiar dynamics. When lifting an object for the first time, visual cues about size and surface material strongly influence lift forces. However, after several lifts, participants learn the dynamics of the object, as demonstrated by adaptation of grip and lift forces measured at the fingertips before object lift off. If the dynamics of the object is simple, learning can occur in a single trial. However, even for objects with simple dynamics, interference can be seen when alternately lifting the same object and grasping it at different locations.

Robotic manipulanda offer an alternative testbed for object-manipulation studies. These interfaces can simulate objects with unfamiliar dynamics and provide an opportunity to manipulate the relationship between haptic and visual feedback. In a typical adaptation experiment, participants grasp the handle of a robotic manipulandum and make reaching movements that are perturbed by the robot. For example, a perturbation that has been examined extensively is a viscous curl field that generates forces on the hand that act perpendicular to the velocity of the hand and proportional to its speed. Over repeated movements, participants learn to generate the forces required to compensate for the perturbation, forming a motor memory of the grasped object. However, the capacity to learn different dynamics in such paradigms appears to be surprisingly limited when the same movement is made under veridical visual feedback in force fields that act in opposite directions.

In the standard force-field adaptation paradigm, the object being moved to a target is a small disc and the task involves controlling the centre of the disc. However, in natural object-manipulation tasks involving objects with more complex geometries, we can exert control over different locations, or ‘control points’, on the object. For example, when using a wide broom to sweep along a wall, we could control the edge of the broom that is nearest to the wall to make contact with the wall. Such contact will perturb the head of the broom, rotating it in opposite directions for walls on the left and right; that is, when controlling the left and right side of the broom. Similarly, when drinking from a wine glass, we can control the near rim as we lift the glass to our mouth and then control the base of the stem as we replace the glass. Numerous studies of object manipulation have examined how memories of object dynamics transfer across changes in grasp configurations. However, none of these previous studies have explicitly manipulated the location of the control point independently of either the grasp location or the required movement of the object.

Here, we tested the hypothesis that the motor system can flexibly engage separate memories when controlling different points on a single object, allowing different dynamics to be learned and associated with these control points. Using a planar robotic interface and virtual-reality system, we linked the movement of a rectangular virtual object to the motion of the hand. The hand was clearly visible at all times and located at the centre of the object (Fig. 1). There were two control points, located on the left and right of the object, and two corresponding targets. The two control points were linked to opposing viscous curl fields. On each trial, the participant was required to generate a straight ahead hand movement to align either the left or right control point with its corresponding target. Thus, the required movement was the same for both control points.

We found that participants could learn opposing dynamics when it was linked to these different points. By testing generalization, we show that this learning is associated with control points, rather than hand or target locations. In addition, we show that the motor system only assigns distinct memories to control points if they are linked to different dynamics, allowing flexible and efficient use of motor memory. Finally, we show that our results are best accounted for by a normative switching state-space model (SSSM). Unlike standard state-space models (SSMs), the SSSM can learn the probability of cues (that is, control points) given the context (that is, force field)
and infer the state for each context based on motor errors. Our results uncover an important mechanism through which the human motor system can generate flexible and dextrous motor behaviour.

We carried out two experiments to examine the mapping of motor memories to control points. In experiment 1, we examined the ability of participants to learn opposing dynamics when they are associated with either different control points or a single control point. We then examined the reference frame in which control points are represented by testing generalization of learning. In experiment 2, we tested whether the assignment of separate memories to control points is obligatory or whether this only occurs when necessary.

Participants grasped the handle of a robotic interface (Fig. 1a), and a semi-silvered mirror was used to display a rectangular virtual object centred on the hand. The object translated with the hand. The workspace under the mirror was illuminated so that both the hand and the object were always visible (Fig. 1b). The object had three visible control points: circles displayed on the left and right of the object and a cross at the centre of the object. For participants in the two-control-points group (n = 10), a target appeared above one of the two lateral control points at the start of each trial and participants were instructed to move the corresponding control point to the target (Fig. 1c). The target location (left or right) cued the direction of the force field on exposure trials (see below). For participants in the single-control-point group (n = 8), the central control point was used. The direction of the field applied to the hand was determined by the target/control point. The generalization phase was performed by the two-control-points group (n = 10), but omitted for the single-control-point group (n = 8).

**Fig. 1** Separate motor memories are formed for different control points. Experimental paradigm and learning curves for experiment 1. a, Participants grasped the handle of a robotic manipulandum. A semi-silvered mirror allowed the participant to view their hand as well as a virtual object that was reflected from the monitor. LCD, liquid-crystal display. b, Photograph of the hand, virtual object and target as seen from the perspective of the participant. Depending on the experiment and trial type, one of three control points on the object had to be aligned with a target placed above it. c, Participants in the two-control-points group moved the left or right control point to its corresponding target. The direction of the force field applied to the hand was determined by the target/control point. d, Participants in the single-control-point group moved the central control point to a central target. The direction of the field applied to the hand was cued by which lateral 'target' was displayed. e, Kinematic error measured as the MPE (deviation from a straight line to the target) over the course of the experiment. Data were first averaged over blocks of eight exposure trials and then plotted as mean ± s.e.m. across participants. The grey background shows the period when the force field was turned on. f, Same as e, but for percentage adaptation measured on channel trials. The generalization phase was performed by the two-control-points group (n = 10), but omitted for the single-control-point group (n = 8).
participants in the single-control-point group (n = 8), a central target appeared above the central control point and participants were instructed to move the central control point to this target (Fig. 1d). In this group, as in the two-control-points group, a lateral ‘target’ was also displayed to cue the direction of the force field. Crucially, for both groups, the start position of the hand and the required final position of the hand were the same in all trials.

In the pre-exposure phase, participants made movements in a null field. In the exposure phase, opposing force fields were associated with the two lateral targets. Hence, for participants in the two-control-points group, each force field was also associated with the point on the object that had to be controlled. To produce the same movement of the hand in both force fields, participants needed to learn the opposing dynamics.

Participants performed 52 blocks of 8 trials (416 trials) in the exposure phase with an equal number of trials for each target in a pseudorandom order. So that predictive force compensation could be assessed independently from co-contraction, one randomly selected trial in each block was a channel trial \( \pm 2 \times 10^{-5} \), in which the movement was confined to a simulated mechanical channel to the target. On these trials, the forces generated by participants into the wall of the channel could be measured.

To assess performance, we measured kinematic error, defined as the maximum perpendicular error (MPE), between the actual and ideal (that is, straight) hand path. We also measured force compensation on channel trials, defined as the percentage of the force required to fully compensate for the force field (adaptation). During the pre-exposure phase, as expected, the kinematic error and adaptation were close to zero (Fig. 1e,f). At the start of the exposure phase, the force fields produced substantial deviations of the hand path from a straight line (Supplementary Fig. 1). To assess learning, we compared adaptation, which unlike MPE is not influenced by stiffness, in the final two blocks of the pre-exposure and exposure phases. This revealed a significant interaction between group and epoch (mixed-design analysis of variance (ANOVA), \( F_{1,14} = 73.31, P = 2 \times 10^{-5} \)). Adaptation reached \( 68.1 \pm 6.6\% \) and \(-0.2 \pm 4.3\%\) of full force compensation by the end of the exposure phase for the two- and single-control-point groups (Fig. 1f), respectively. For the two-control-points group, the increase in adaptation was significant (two-tailed paired \( t \)-test, \( t = 10.99, P = 2 \times 10^{-5} \)).

The failure to learn when controlling a single control point is consistent with previous studies showing that arbitrary visual cues do not facilitate learning of opposing force fields \( \pm 2 \times 10^{-5} \), and indicates that the learning observed when controlling two different control points—despite making similar hand movements—is not simply due to the contextual cues provided by the lateral targets.

We performed two additional control experiments. In the first (Supplementary Fig. 2), we show that participants (n = 8) can learn opposing fields, linked to different control points, even when they are required to fixate a central fixation point. This rules out the possibility that learning is due to associating field direction with gaze position. The second control was designed to rule out the possibility that subjects might be treating the two control points (small circles) as separate objects, despite the fact that they move coherently and are bound by a rectangle. In this control, we used an object where the control points were defined by the geometry of the object and there were no distinct visual elements (Supplementary Fig. 3). We show that participants (n = 8) can still learn opposing fields linked to these different control points (Supplementary Fig. 3).

Our hypothesis that separate memories can be formed for different control points on manipulated objects assumes that these points are represented in object-centred coordinates; that is, that translating the object would not interfere with the learned memories associated with these points. However, other interpretations are possible based on the results for the two-control-points group. Specifically, whereas our hypothesis assumes that memories formed for the two fields are linked to the locations of the control points relative to the object (object-centred representation), it is possible that these memories are linked to the locations of the targets relative to the body (body-centred representation) or the locations of the targets and control points relative to the hand (hand-centred representation).

Based on our hypothesis and pilot data, we anticipated that participants in the two-control-points group would learn the two force fields. Therefore, for this group only, we included a generalization phase following the exposure phase in which we tested the alternative interpretations outlined above. As shown in Fig. 1e,f, performance—measured by both the kinematic error and adaptation—was stable during this phase.

In the generalization phase, we used channel trials to measure the forces produced in four configurations (Fig. 2a) where: (1) the hand and object were in the original exposure configuration; (2) both the object and hand translated; (3) only the hand translated; and (4) only the object translated. Note that Fig. 2a shows the generalization trials involving the left target. In trials involving the right target, the hand and/or object were translated in the opposite direction. In all configurations, the object moved with the hand with the appropriate offset throughout the movement. Fig. 2b shows the direction of force we expect the participants to generate for each possible representation (that is, body-, hand- or object-centred) for each configuration. All predictions are for the case in which the left and right targets/control points were associated with clockwise (CW) and counterclockwise (CCW), respectively. In the exposure configuration, we expect participants to generate forces in the appropriate (in this case, leftward) direction, and this is consistent with all three possible representations (Fig. 2b, left). Importantly, however, the pattern across the other three configurations is different for each possible representation.

The thick black bars in Fig. 2c show the measured force compensation (signed adaptation) in all four configurations relative to the force required to fully compensate for the force field in the exposure configuration. The thin grey bars show the force compensation in trials involving the target in which all predicted forces were in the opposite direction. Separate t-tests revealed that adaptation was significantly different from zero for both the left and right targets in the object-and-hand (two-tailed one-sample \( t \)-test, left target: \( 32.6 \pm 9.2\%, t_9 = 3.75, P = 0.005 \); right target: \(-48.0 \pm 8.3\%, t_9 = 6.12, P = 2 \times 10^{-4} \)) and hand translation configurations (two-tailed one-sample \( t \)-test, left target: \(-34.4 \pm 5.9\%, t_9 = 6.14, P = 2 \times 10^{-4} \); right target: \(34.5 \pm 5.0\%, t_9 = 7.28, P = 5 \times 10^{-5} \)). Furthermore, the direction of adaptation in these configurations was only consistent with the object-based predictions. Although adaptation was not significantly different from zero for either target in the object translation configuration (two-tailed one-sample \( t \)-test, left target: \(12.5 \pm 6.5\%, t_9 = 2.03, P = 0.072 \); right target: \(-3.5 \pm 9.9\%, t_9 = 0.38, P = 0.714 \)), the sign of adaptation was again consistent with the object-based predictions. Note that the magnitude of force compensation (that is, length of the bars) relative to the exposure configuration decreased in all three generalization configurations, involving translation of the hand and object, object or hand. This decrease is consistent with a large body of literature showing that motor learning is generally local, with graded reduction with changes in context \( \pm 2 \times 10^{-5} \). Overall, these results clearly support the hypothesis that separate memories are formed for control points represented in object-centred coordinates.

Having established that participants can form separate motor memories for different control points, we asked whether this process is obligatory or flexible. Specifically, we tested whether separate memories are formed even when the dynamics experienced for the different control points is the same. In contrast with experiment 1, here, a single motor memory would be sufficient for representing the dynamics of both control points and would also support
efficient allocation of neural resources. Two groups were examined: participants in the opposing-field group (n = 8) experienced a different (opposing) force field for each control point, whereas participants in the same-field group (n = 8) experienced the same force field for each control point. To assess the separation of motor memories, after learning we de-adapted one control point with null-field trials and then assessed the state of adaptation when controlling the other control point (Fig. 3). If the memories are separate, de-adapting one control point should not de-adapt the memory for the other control point.

Both groups learned to compensate for the perturbation (Fig. 3a,c, MPE; Fig. 3b,d, adaptation) and, as expected, learning was greater for the group who learned the same field for both control points. By the final block of the exposure phase, there was no significant difference in adaptation between the opposing-field group (52.8 ± 12.1%) and the two-control-point group (experiment 1) (68.9 ± 5.9%) who performed the same task (two-tailed unpaired t-test, 16.1 ± 13.1%, t \(_{17} = 1.27, P = 0.222\)). To assess whether de-adapting one memory led to de-adaptation of the other memory, we compared the mean of the last two channel trials in the post-exposure phase for the first control point with the first channel trial in the post-exposure phase for the second control point. For the group who learned opposing force fields, after de-adapting one control point, substantial adaptation re-emerged (Fig. 3b; two-tailed paired t-test, 37.6 ± 8.6%, t \(_{7} = 4.69, P = 0.002\)) when controlling the other control point. Although this effect is primarily driven by the first channel trial, this first trial provides a critical test for the separation of memories. This suggests that separate representations existed for each control point. In contrast, for the group that experienced the same force field for both control points, when we de-adapted one control point there was minimal adaptation remaining (Fig. 3d; two-tailed paired t-test, 9.4 ± 7.8%, t \(_{7} = 1.31, P = 0.232\)) when switching to the other control point. This was despite the greater adaptation observed in the same-field group, which increased the power to detect a difference in adaptation between the two control points during de-adaptation. This suggests that a single representation existed for both control points in this case.

We fit several candidate models to the data and performed model comparison. Context-dependent SSMs have been used to account for motor learning of opposing perturbations. Briefly, these models assume that each context (force field) is associated with separate states of adaptation that are updated based on the error from the previous trials. Contexts can be coupled such that errors in one context update the states associated with the other context, and states associated with both contexts contribute to the final output. However, critically, these models assume that the coupling between contexts is known in advance and remains fixed over time. Therefore, they predict that: (1) with no coupling, two separate memories will be formed; (2) with complete coupling, a single memory will be formed; and (3) with partial coupling, two overlapping memories will be formed. While it is difficult to account for our results with either no coupling or complete coupling, it is possible that a context-dependent SSM with partial coupling could explain the data.

Context-dependent SSMs can be either single-rate or dual-rate, in which the total adaptation involves two memory processes: (1) a fast process that both adapts and decays quickly; and (2) a slow process that adapts and decays more gradually. We examined seven variants of the context-dependent SSM (Supplementary Table 1), which vary as to whether single- or dual-rate states are included and also which states are coupled (see Methods for details).

As an alternative, we also developed a normative SSSM of motor learning. The SSSM is a generalization of the SSM to systems with multiple operating modes (here, contexts), each of which can be associated with different, and even evolving, dynamics. On each trial, the system is in one context that determines both the dynamics experienced and the cues observed. Between trials, contexts switch stochastically. On each trial, the learner must infer the probability of each context (from control-point cues and prediction errors) and use this information to partition control and learning between two context-specific dual-rate states (see Methods for details). Importantly, although the association between cues and contexts is deterministic (the control point perfectly predicts the force-field direction), this association must be learned through experience. We therefore reasoned that the formation of separate motor memories may arise from participants learning the association between cues and contexts. Critically, in the SSSM, the probabilities of cues (control points) given contexts (force fields) are therefore learned online.

![Fig. 2](https://www.nature.com/naturehumanbehav)
We fit each model to the data from both the opposing- and same-field groups simultaneously, and performed model comparison using the Bayesian information criterion (BIC) (Supplementary Table 2). Although the context-dependent SSMs qualitatively capture the difference in post-washout adaptation between the same- and opposing-field groups (Supplementary Fig. 4), the SSSM fits the overall time course of adaptation and de-adaptation in the opposing-field group better (Fig. 3b,d, solid lines; slow and fast states shown in Supplementary Fig. 5) and has much stronger support ($\Delta$BIC of 112.4 relative to the next-best model).

To understand how the SSSM works, we examined how the estimated probability of each context given a cue evolves for each group. As shown in Fig. 4, at the start of the experiment both contexts are activated equally by the right control point (that is, the probability of each context given the right control point is 0.5). Therefore, the model starts naive with respect to how control points relate to contexts. In the same-field group, both contexts are activated equally throughout the experiment, regardless of the control point, leading effectively to a single motor memory. In contrast, in the opposing-field group, each context becomes paired with a different control point, resulting in separate motor memories.

Our results demonstrate that the motor system can form separate memories for different control points on the same object, even when the movements associated with these points are the same. By examining generalization, we found that learning was associated with control points on the object and not with the location of the object in extrinsic space or the location of the control point relative to the hand. Moreover, we found that the motor system forms distinct memories if the dynamics of the control points differs, allowing efficient and flexible allocation of motor memory. Finally, we developed a normative model of context-dependent control point 1

---

**Fig. 3** | The encoding of dynamics for different control points depends on the fields experienced. a, b, MPE ± s.e.m. (a) and adaptation ± s.e.m. (b) for each control point in the group that experienced opposing force fields at each control point ($n=8$). Data in the pre-exposure (Pre) and exposure phases were first averaged over blocks of eight trials. The post-exposure phase (Post) has been expanded for clarity. For simplicity, the sign of adaptation for control point 2 has been inverted. c, d, Same as a and b, respectively, but for the group that experienced the same force field at each control point ($n=8$). Solid lines in b and d show the mean SSSM fits across participants.

---

**Fig. 4** | Learning to associate contexts with cues in the SSSM. The SSSM estimates the probability of each context given the cue (plotted here for the right control point cue before movement). Following exposure to opposing force fields, participants learn to differentiate between the two contexts given the right control point. Participants trained on the same force field at each control point do not learn to differentiate between contexts, leading to a single motor memory. Traces show mean model fits across participants. The plot for the left control point (not shown) is the mirror image about the line 0.5.
motor adaptation that can account for such flexible parcellation of motor memories.

Humans have a remarkable capacity to manipulate objects with different dynamics, and a central focus of research in motor control has been to elucidate how the brain learns and represents these dynamics. To investigate how contextual information can be used to learn different dynamics, numerous studies have used opposing novel dynamics (for example, viscous curl fields) that perturb the hand in opposite directions. This work has shown that the ability to learn opposing dynamics, when each is associated with a visual cue, such as the colour of the cursor or background, is generally highly limited. Similarly, when lifting physical objects with different mass distributions, substantial interference is observed when each mass distribution is associated with a different visual geometric cue. In agreement with these findings, we show that when controlling a single control point, participants cannot learn opposing fields when they are associated with the location of peripheral visual cues that correspond to the targets in the two-control-points group.

Several studies have shown that opposing fields can be learned if the perturbed movement is preceded or followed by a separate movement that differs for each field, or if the perturbed movement is accompanied by a concurrent movement of the other hand that again differs for each field. Furthermore, previous studies have shown that opposing fields can be learned if they are associated with different states of the limb, as when the arm operates in a different region of the workspace for each field or a visual–prospect discrepancy is introduced so that the perceived state of the limb is different for each field. Critically, in our experiment, and in contrast with these previous studies, veridical visual feedback of the hand was provided throughout the movement, and the movement start and end points were the same for the opposing fields. Consequently, participants’ estimates of the state of the limb did not differ for the two fields. Therefore, we can be confident that it is the control of different points on the object that allows the formation of separate memories for different dynamical contexts. Moreover, we show clearly that the learning of each control point is linked to the location on the object.

Tool use generally involves controlling a specific location, or ‘control point’, on the tool as it interacts with the environment, such as the face of a hammer striking a nail or the eraser of a pencil rubbing a page. Skilled performance when using tools requires knowledge of the dynamics of the tool (relating applied force to motion) as well as contact mechanics, which may vary across control points. Most natural manipulation tasks involve a series of action phases separated by contact events. Consider, for example, grasping a pencil, lifting it out of a container and transporting it to a piece of paper, using it to erase a pencil mark and then replacing it in the container. Here, contact between the fingertips and pencil marks the end of the reach phase, contact between the pencil and paper marks the end of the transport phase, the breaking of contact between the pencil and paper marks the end of the erase phase, and so on. By comparing predicted and actual sensory signals associated with these contact events, the motor system can monitor task progress, learn corrective actions as needed, and calibrate internal models of objects and their interactions. Critically, both the control point on the object and the dynamics may change from phase to phase. For example, while erasing, the eraser end of the pencil is controlled and the dynamics includes the friction between the eraser and paper. The ability to form separate motor memories for different control points may thus be an essential component of skilled object manipulation and tool use.

Recent studies in neurophysiology, neuroimaging and neuropsychology support the idea that tools are incorporated into a body schema. For example, monkeys have been trained to use a rake to retrieve a pellet of food that could not be reached by hand. Following tool use, the visual receptive fields of intraparietal neurons expanded beyond the space surrounding the hand to include the tip of the rake. Similar incorporation of tools is supported by studies in humans making temporal order judgements of tactile stimuli on the hand. Importantly, such incorporation is seen only for the functional part of a tool and a tool must be actively controlled for assimilation to occur. This suggests that the point being controlled on a tool determines how the body schema changes with tool use. Interestingly, the body schema is thought to consist of distinct neural modules that represent different body parts. It is therefore conceivable that different control points are assimilated by different body schema modules. Indeed, one may expect to find intraparietal neurons that respond differently for different control points on a tool. Furthermore, following incorporation of control points into the body schema, the effective ‘state’ of the body may include the control point, allowing different dynamics to be associated with different states linked to control points.

We found that the formation of distinct motor memories for different control points is not obligatory, but only occurs if the dynamics for each control point is different. Therefore, the allocation of motor memory is both flexible and efficient. To explain this result, we developed a model of motor adaptation based on an SSSM, which is a generalization of the mixture-of-experts architecture in neural networks to dynamical systems. The SSSM is, unlike these previous models, normative and therefore derived from first principles. Moreover, although the context-dependent SSSMs could qualitatively capture the difference in post-washout adaptation between the same- and opposing-field groups, model comparison convincingly selected the SSSM over existing models. SSSMs combine a hidden Markov model with linear dynamical systems and can be used to model systems with multiple discrete operating regimes, termed modes. An SSSM with one mode is an SSM. The key innovation of the SSSM is that only one of the state-space modes is active at any one time and, over time, the system can transition between modes. For example, an SSSM would be appropriate when handling different objects. The transition between the use of different objects can be considered as a Markov process specifying the probability of switching from one object to another (for example, from kettle to cup) and the dynamics of each object can be different and change over time (for example, as the kettle empties and the cup fills).

Within this framework, the problem for the sensorimotor system in our experiment is twofold. First, it must infer the current mode (for example, the context) and the state of the dynamics (for example, the force-field perturbation) based on the parameters of the SSSM. The expected perturbation is then a weighted sum of the perturbations expected for each mode, with weights given by the probability of each mode. Second, it must update the parameters of the SSSM online to ensure that these inferences are as accurate as possible. Here, we provide evidence to support the idea that motor adaptation involves not only state inference but also parameter learning or system identification.

For simplicity, the SSSM we used had two modes. However, in general, SSSMs can have any number of modes. Central to the performance of the model here is its capacity to learn through experience (that is, during the experiment) the associations between cues (for example, control points) and context (for example, force fields) via online parameter estimation. To reduce the degrees of freedom of the model, we restricted the simulation to only update the parameters that determine the probabilities of the cues given the contexts. However, in general, all parameters of the model can be updated online. The fits of the SSSM suggest that participants only develop distinct memories for each control point if the dynamics are different. In non-parametric extensions of the standard SSSM, the number of modes is learned through experience, rather than fixed a priori. Such a model would allow the motor system to be efficient by recruiting additional context-dependent memories (that is, modes) when control points have different dynamics.
and, conversely, removing modes that are redundant when control points have the same dynamics.

Our results suggest that objects are not represented by the motor system as holistic entities, but are instead parcelled in a task-dependent manner according to control points. Interestingly, the results of the SSSM suggest that effective contextual cues, such as control points, do not necessarily engage distinct motor memories a priori. Instead, they engage online parameter-learning processes that form distinct motor memories only if and when needed.

Methods

Participants. A total of 30 neurologically intact participants (22 males and 28 females; age 20.2±7.8, mean±s.d.) were recruited to participate in four experiments, which had been approved by the Cambridge Psychology Research Ethics Committee. All participants provided written informed consent and were right-handed according to the Edinburgh handedness inventory 64.

Experimental apparatus. All experiments were performed using a vBOT planar robotic manipulandum with a virtual-reality system and air table 70. The position of the handle was measured using optical encoders sampled at 1 kHz, and torque motors allowed forces to be generated on the handle. A monitor mounted above the vBOT projected virtual images into the plane of movement via a horizontal semi-silvered mirror (Fig 1a). Participants were seated in front of the vBOT and grasped its handle with their right hand. A lamp was used to illuminate the hand below the mirror with the illumination adjusted so that both the vBOT, hand, arm and virtual images were clearly visible (Fig 1b). This was done to ensure that participants always had an accurate estimate of the state of their hand and arm. The right forearm was supported on an air sled, which constrained arm movements to the horizontal plane and reduced friction. On each trial, the vBOT could generate forces associated with either a velocity-dependent curl field (force-field trials) or a force channel (channel trials). Alternatively, in the case of the null field, no forces were generated (null-field trials). For the curl field, the force generated on the hand was given by

\[
\begin{align*}
\vec{f}_x &= f_g \left( \frac{1}{y} - 1 \right) \\
\vec{f}_y &= f_g \left( 1 - \frac{x}{y} \right)
\end{align*}
\]

where \( f_g \), \( f_s \), \( x \) and \( y \) are the forces and velocities at the handle in the \( x \) and \( y \) directions (medialateral and anteroposterior, respectively). The field gain \( f_g \) was set to \( \pm 15 \text{ Nm}^{-1} \) and the sign of \( f_g \) specified whether the curl field was CW or CCW. On channel trials, the hand was constrained to move along a straight line to the target. This was achieved by simulating forces associated with a stiff spring and damper, with the forces acting perpendicular to the long axis of the channel. A spring constant of \( 6,000 \text{ Nm}^{-2} \) and a damping coefficient of \( 5 \text{ Nm s}^{-1} \) were used. Channel trials allowed the feedforward forces generated by participants to be measured orthogonal to the direction of reach 63, 64.

In all experiments, participants first performed a familiarization phase of between 96 and 128 trials, consisting of null-field trials and channel trials for each control point in a pseudorandomized order. To have precise control over vision and dynamics in our experiment, we used a robotic interface and virtual-reality system. Importantly, a number of previous object-manipulation studies using robotic manipulanda have been shown to produce similar results to experiments that use real-world physical objects 71,72,73,74,75.

Experiment 1: encoding of motor memories by control points. Two-control-points condition. In the two-control-points condition, we investigated whether participants could learn opposing (CW and CCW) force fields when each field consisted of the same pre-exposure (4 blocks/32 trials), exposure (51 blocks/408 trials) and de-adaptation (12 blocks/96 null-field trials) phases. Each target appeared an equal number of times within a block in a pseudorandom order.

During the exposure phase, the location of the target (left or right) determined the direction of the force field (CW or CCW) applied during the movement. As such, the field direction was associated with the particular control point on the object (left or right) and its corresponding target (Fig 1c). The direction of the force field for each control point was counterbalanced across participants. A 4.5 s rest break was given after blocks 12, 25, 38 and 51 of the exposure phase.

Generalization. The generalization phase (immediately after the exposure phase) was used to investigate the representation of the memories for the two force fields. Specifically, we tested whether the representations were object-centred (associated with the location of the control points on the object), body-centred (associated with the locations of the targets/control points relative to the body) or hand-centred (associated with the location of the targets/control points relative to the hand). The generalization phase included force-field trials (to maintain adaptation), as well as channel trials (to monitor ongoing adaptation and examine generalization). To monitor adaptation, participants performed channel trials with the hand and object in the original exposure configuration. To examine generalization, participants performed channel trials during lateral translations (±14 cm) of either the object or the hand, or both the object and the hand. This gave three kinds of generalization trial (Fig 2a).

In this condition, the object tracked the hand during the movement with the fixed offset associated with the particular generalization type maintained throughout the trial. A 2.5 s delay was imposed at the start of each channel trial to allow time for the participant to translate their hand and/or the object, if required. A 15 s rest break was given every 9 blocks during the generalization phase starting at block 8. A block of force-field trials (with no channel trials) followed each rest break to mitigate the effects of any time-dependent decay of motor memory. Each of the channel types (2 to monitor ongoing adaptation and 6 for generalization) was repeated 8 times and there were 7 pure exposure blocks post-rest, giving 71 blocks (568 trials).

In all conditions, the object-hand and targets were always aligned along the y-axis, thus requiring a straight movement.

On hand translation trials, participants translated their hand ±14 cm along the y axis while the object remained in the centre of the workspace. For lateral translations of the hand, the left target was cued and the participant moved the right control point toward the target (which was now aligned with the left target). The converse was true for rightward translations. Importantly, as on all trials in the study, the control points and targets were always aligned along the y-axis, thus requiring a straight movement.

On object-and-hand translation trials, participants translated the hand and the object ±14 cm along the x-axis before the trial started. For leftward translations of the object and hand, the left target was cued and the participant moved the right control point toward the target (which was now aligned with the left target). The converse was true for rightward translations.

Generalization. To monitor adaptation, participants performed channel trials during lateral translations (±14 cm) of either the object or the hand, or both the object and the hand. This gave three kinds of generalization trial (Fig 2a).

In this condition, the object tracked the hand during the movement with the fixed offset associated with the particular generalization type maintained throughout the trial. A 2.5 s delay was imposed at the start of each channel trial to allow time for the participant to translate their hand and/or the object, if required. A 15 s rest break was given every 9 blocks during the generalization phase starting at block 8. A block of force-field trials (with no channel trials) followed each rest break to mitigate the effects of any time-dependent decay of motor memory. Each of the channel types (2 to monitor ongoing adaptation and 6 for generalization) was repeated 8 times and there were 7 pure exposure blocks post-rest, giving 71 blocks (568 trials).

Note that the familiarization phase in the two-control-points condition included trials for each of the generalization conditions described above.

Single-control-point condition. In the single-control-point condition, we examined whether the visual targets alone could provide a contextual cue for learning. A separate group of participants (n = 8) performed the single-control-point condition task. As for the two-control-points condition (described above), the left and right control points were set to ±14 cm along the x-axis, and the targets were displayed and were always associated with the particular field direction (CW or CCW). However, participants were instructed to move the central control point (yellow cross) on the object to a central target (which remained on the screen at all times) (Fig 1d) and to ignore the lateral targets. Participants were thus required to control a single control point. The paradigm consisted of the same pre-exposure (4 blocks/32 trials), exposure (51 blocks/408 trials) and de-adaptation (12 blocks/96 null-field trials) phases as for the two-control-points condition. However, in this condition the generalization phase was omitted.
Gaze fixation control. During target-directed reaches, people tend to fixate the target. The gaze fixation experiment (n = 8) was performed to exclude the possibility that gaze direction, rather than the control point on the object, was the contextual cue responsible for adaptation to opposing force fields. An EyeLink 1000 eye tracker was used to track the position of the left eye at 500 Hz. The eye tracker was mounted at an oblique angle between the handle of the manipulandum and a transparent reflective sheet of plastic that was used to project visual feedback (replacing the semi-silvered mirror). A forehead rest was used to stabilize the head. The eye tracker was calibrated at the start of the experiment and after every rest break using a nine-point grid.

The paradigm included both fixation and free-gaze trials. On fixation trials, participants had to fixate a small cross (located 8 cm above the home position) while performing the task (moving the left or right control point to the left or right target, respectively). Because movements were guided by peripheral vision, the spatial tolerance of the target was increased to 0.6 cm. If the participant broke fixation (>2 cm), the trial was aborted and repeated. The central control point on the object was not displayed to prevent participants from using it to guide the movement towards the fixation point. The home position was indicated by a rectangular frame that was visible at all times during the experiment. On free-gaze trials, no fixation cross was displayed and eye movements were unconstrained. After familiarization (described above), participants performed a fixation pre-exposure phase (4 blocks/32 trials), a fixation exposure phase (65 blocks/520 trials), a free-gaze exposure phase (64 blocks/512 trials) and a free-gaze de-adaptation phase (12 blocks/96 trials). The direction of the force field associated with each control point was counterbalanced across participants. Each block had the same structure as for the two-control-points condition, with seven exposure trials and one channel trial. A 45 s rest break was given every 13 blocks during the exposure phase starting at block 12. A block of force-field trials (with no channel trials) followed each rest break to mitigate the effects of any time-dependent decay of motor memory.

Uniform object control. The object used in the main experiment consisted of different visual elements (green circular control points embedded in a red rectangle) that could conceivably be interpreted as distinct objects. We therefore repeated the exposure phase in the two-control-points group using an object that no longer contained different visual elements. A separate group of participants (n = 8) controlled a new uniform object with control points that were not discriminable from the rest of the object by colour (Supplementary Fig. 3). The red rectangle was removed from the original object and the control points (green discs with a radius of 0.4 cm) were connected by a bar (solid green rectangle of 14 cm × 0.6 cm) that was the same colour as the control points. Importantly, these control points were the same size and in the same location as those of the original experiment. We reduced the size of the central cross so that it would fit inside the connecting bar. As in the two-control-points experiment (described above), participants moved the corresponding control point to the displayed target, which was always associated with a particular field direction (CW or CCW). The paradigm consisted of the same pre-exposure (4 blocks/32 trials), exposure (51 blocks/408 trials) and de-adaptation (12 blocks/96 trials) phases as in the single-control-point experiment.

Experiment 2: are separate motor memories obligatory for different control points? This experiment was performed to investigate whether separate motor memories are formed even when the dynamics experienced at the two control points on the object are the same. After familiarization, participants performed a pre-exposure phase, an exposure phase and a de-adaptation phase. The pre-exposure (4 blocks/32 trials) and exposure phases (51 blocks/408 trials) were the same as in experiment 1. Participants performed blocks of eight trials consisting of seven null (pre-exposure) or field (exposure) trials and one channel trial. In the exposure phase, half the participants (n = 8) experienced opposing fields at each control point (as in experiment 1) and the other half (n = 8) experienced the same field at each control point. In both the opposing-field and same-field conditions, the direction of the force field for each control point was counterbalanced across participants. A 45 s rest break was given after blocks 12, 25 and 38 of the exposure phase. A block of force-field trials (with no channel trials) followed each rest break to mitigate the effects of any time-dependent decay of motor memory. The exposure phase was followed by 50 blocks of de-adaptation, with each block consisting of 1 null-field trial and 1 channel trial. Importantly, one control point was cued throughout the second half of the de-adaptation phase (the first 25 blocks/50 trials) and the other control point was cued throughout the second half (the last 25 blocks/50 trials). The order in which each control point (left or right) was cued was counterbalanced across participants. If the dynamics at both control points is encoded by a single representation, de-adaptation at one control point should also lead to de-adaptation at the other control point. Alternatively, if the representations are separate, de-adaptation at one control point should have minimal effect on the representation associated with the other control point.

Data analysis. Data analysis was performed using MATLAB R2017a. Two measures of performance were calculated. On null-field and force-field trials, we calculated the maximum distance between the path of the hand and a straight line connecting the start position and the target (that is, the MPE). On channel trials, we calculated the percentage of the force field that was compensated for (adaptation) by regressing the actual force  \( f(t) \) generated by participants in the channel on the ideal forces  \( f(t) \) that would fully compensate for the forces on a force-field trial (defined in equation (1)):}

\[
f(t) = bx f(t)
\]

adaptation = \( b \times 100\%\)

where \( b \) is the regression coefficient and \( t \) is the discrete time step in the trial. The offset of the regression was constrained to zero. For this analysis, we used the portion of the movement where the hand velocity was greater than 1 cm s\(^{-1}\). To combine MPE and adaptation results across participants, data from individual participants were signal-processed according to the direction of the field. To identify changes in MPE and adaptation within and between experiments, mixed-design ANOVAs and paired t-tests were performed. Comparisons of the final level of adaptation between experiments were performed using between-subjects ANOVAs and unpaired t-tests. All statistical tests were two-sided with significance set to \( P < 0.05 \). Where values are reported, they represent the mean ± s.e.m.

Models. We fit two classes of model to experiment 2. The first class was a deterministic, context-dependent SSM based on refs 35–37. The second class was a probabilistic SSM. We did not fit the models to experiment 1 as this experiment was not designed to distinguish between the model classes. Note, however, that the initial part of experiment 1 was identical to the initial part for the opposing-field group in experiment 2.

Context-dependent SSM. We used a context-dependent SSM that included separate states for different contexts and also different rates of adaptation (slow versus fast adaptive processes). In the current study, there were two contexts (the left and right control points) and each context could include states that updated with slow and fast rates. This gave a total of four states (two contexts and two rates) that could be represented by the elements of a state vector:

\[
x = \begin{bmatrix} x^{(1)} \ \ x^{(2)} \end{bmatrix}^T
\]

where the superscripts represent which context the state is associated with (for example, 1 = left and 2 = right control points), the subscripts represent the slow (s) and fast (f) adaptation processes, and \( T \) is the transpose operator. The motor output on trial \( t \) was a weighted sum of the elements in the state vector, with the weighting determined by the context:

\[
y(t) = x(t)^T \cdot c(t)
\]

where the context weighting vector, \( c \), varies according to the context for the trial (left or right control point). The error on a trial is the difference between the motor output and the task perturbation:

\[
e(t) = f(t) - y(t)
\]

In the current study, the task perturbation, \( f \), is zero for null-field trials, +1 for CW field trials and −1 for CCW field trials. The state vector is updated across trials:

\[
x(t + 1) = a \odot x(t) + e(t) \cdot b \odot c(t)
\]

where \( \odot \) represents element-wise multiplication. Trial-by-trial decay is determined by the retention vector \( a \). Error-dependent adaptation of states is determined by the context weighting vector and the learning-rate vector \( b \).

We considered seven variants of the model which determine the way \( a, b \) and \( c \) are parameterized (Supplementary Table 1). The models vary as to whether there is a single context-dependent state (SSM 1), a slow/fast context-independent state and a fast/slow context-dependent state (SSMs 2–4), or both fast and slow context-dependent states (SSMs 5–7). For context-dependent states, the values in the context weighting vector determine the coupling (if any) between contexts. Models that include the parameters \( a, b \) and \( c \) can have coupling between the contexts for the slow and/or fast processes, respectively.

SSSM. The generative model. Here, we develop a probabilistic SSSM that allows the sensorimotor system to optimally partition learning across contexts. We assume that the environment consists of distinct contexts that switch in a probabilistic manner according to a hidden Markov model (Supplementary Fig. 6). Each context is associated with its own perturbations, which evolve according to linear-Gaussian dynamics. We assume that participants possess an internal generative model of perturbations that matches the environment. We characterize this model as an
SSSM—a generalization of the SSM to systems with multiple operating regimes or modes. SSSMs define a probability density over a time series of discrete and continuous states. Here, the discrete states represent contexts and the continuous states represent perturbations. We implement the model with two contexts, although the extension to more than two contexts is straightforward.

On trial $t$, the environment is in one of two contexts, $c_t \in \{1, 2\}$, and between trials the context either remains the same or switches in a stochastic manner. The context transition probabilities are defined by the matrix $P$, where

$$ p_{ij} = P(c_t = j | c_{t-1} = i) $$

To reduce the number of free parameters in the model, we assume that the context remains the same or switches with equal probability; that is, $p_{ij} = 0.5$ for all $i, j$. This is consistent with the exposure phase of our experiment in which each force field is presented with equal frequency and in a pseudorandom order.

On trial $t$, the context gives rise to one of two observable cues, $q_t \in \{1, 2\}$, corresponding to the location of the control point. The cue emission probabilities are defined by the matrix $\Phi$, where

$$ \phi_{ij} = P(q_t = j | c_t = i) $$

The perturbations in each context evolve independently according to linear-Gaussian dynamics, as defined by the state transition function

$$ x_{t+1} = Ax_t + w_t $$

where $x_t = \left( x_{t1}^{(1)}, x_{t2}^{(1)}, x_{t1}^{(2)}, x_{t2}^{(2)} \right)^T$ is a vector of slow and fast states (subscripts) for contexts 1 and 2 (superscripts), $A$ is a diagonal matrix of the form $\text{diag}(a_1, a_2, a_1, a_2)$ and $w_t$ is zero-mean Gaussian process noise with covariance $Q = \text{diag}(q_1, q_1, q_2, q_2)$. Thus, we implement a context-dependent dual-rate model.

The context determines which perturbations are observed, as defined by the output function

$$ y_t = h(x_t, q_t) = h^{q_1}(x_t) + q_2 $$

where $h^{q_1} = (1 \ 0 \ 0 \ 0)$ is the observation vector for context 1, $h^{q_2} = (1 \ 0 \ 1 \ 0)$ is the observation vector for context 2 and $q_t$ is the zero-mean Gaussian observation noise with variance $\sigma_r^2$.

State inference. To operate effectively, the sensorimotor system must keep track of perturbations in the environment, as well as the contexts in which they occur. However, both perturbations and contexts are latent variables that cannot be inferred from a sequence of observations $(q_t, c_t)$. Several techniques have been developed to infer the joint state, $(c_t, x_t)$, of an SSSM—a generalization of the SSM to systems with multiple operating regimes or modes. Here, we focus on a technique known as the generalized pseudo-Bayesian estimator of order 1 (GPB1; ref. 1), which we adapt for an SSSM in which the context, $c_t$, emits observable cues $q_t$. The GPB1 is an assumed-density filtering method that approximates the exact posterior of the state (a mixture of Gaussians with $m$ components, where $m$ is the number of modes and $l$ is the number of trials) with a single Gaussian.

To maintain an estimate of the state, two Kalman filters operate in parallel (Supplementary Fig. 6). Each filter has a different observation vector, $h^{q_1}$ (defined above), and is thus specialized for a different context; all remaining parameters are the same for both filters. On trial $t$, both filters operate on the same Gaussian estimate of the continuous state from the previous trial, with mean $\hat{x}_{t-1|t-1}$ and covariance $\hat{V}_{t-1|t-1}$. To generate a Gaussian estimate of the continuous state on the current trial, with mean $\hat{x}_{t|t}^{(q_1)}$ and covariance $\hat{V}_{t|t}^{(q_1)}$. This produces a mixture of Gaussians with mixing weights given by the probability of each context $p_t^{(q_1)}$. Because the number of possible context sequences doubles with every trial, the number of components in this mixture will also double if no approximations are made, making inference intractable. Therefore, after each trial, the mixture of Gaussians is approximated by a single Gaussian via moment matching (Supplementary Fig. 6), rendering inference tractable but approximate.

Upon observation of the contextual cue $q_t$, but before movement, the probability of each context (assuming equiprobable context transitions) is

$$ p_t^{(q_1)} = \frac{\phi_t^{(q_1)}}{\sum_{j=1}^{m} \phi_t^{(j)}} $$

The predicted observation used for control is

$$ \tilde{y}_t = \sum_{j=1}^{m} \phi_t^{(j)} y_t^{(j)} $$

where $y_t^{(j)} = h^{q_1}(\hat{x}_{t|t}^{(j)}, q_t)$ is the observation predicted for each context. We assume that the predicted observation is expressed through a motor action that is corrupted by zero-mean Gaussian noise (see section ‘Model fitting’).

After the movement, the likelihood of the observation $y_t$ given each context is

$$ l_t^{(q_1)} = N(y_t^{(q_1)}, \sigma_r^2) $$

Here, we use $N(y_t^{(j)}, \sigma_r^2)$ to denote the probability density function for the normal distribution with mean $y_t^{(j)}$ and variance $\sigma_r^2$, where $\sigma_r^2$ is the standard Kalman filter innovation covariance. The final probability of each context is given by Bayes’ rule:

$$ p_t^{(q_1)} = \frac{l_t^{(q_1)} p_t^{(q_1)}}{Z} $$

where $Z = \sum_{j=1}^{m} l_t^{(j)} p_t^{(j)}$.

Finally, a single Gaussian estimate of the perturbations is obtained via moment matching:

$$ \hat{x}_{t|t} = \sum_{j=1}^{m} \tilde{y}_t^{(j)} \phi_t^{(j)} $$

Parameter learning. To perform state inference, the sensorimotor system must set the parameters, $\theta = \{A, Q, H^{q_1}, H^{q_2}, r, P, \Phi\}$, of the SSSM. Importantly, these parameters need not be fixed but may be learned online. In general, the sensorimotor system could learn all of these parameters online. However, to reduce the degrees of freedom of the model for our dataset, we assume that the sensorimotor system only learns the cue emission probabilities and that all other parameter estimates are fixed.

To learn the cue emission probabilities, we perform expectation maximization (EM)—an iterative method for obtaining maximum-likelihood estimates of unknown parameters in probabilistic models involving latent variables. We utilize an online formulation of EM that can be interpreted as a stochastic approximation recursion on the expected sufficient statistics. A detailed description of this method can be found in refs 1-3. Here, we provide a brief outline as applied to our perturbation study.

The algorithm iterates between an E step, in which the joint probability of $c_t$ and $q_t$ is estimated, and an M step, in which the joint probability of $c_t$ and $q_t$ is normalized to obtain the probability of $q_t$ given $c_t$.

Stochastic E step. The aim of the E step is to count the number of times that each value of $c_t$ and $q_t$ co-occur. If both $c_t$ and $q_t$ were known, this would involve summing (over trials) a count of these co-occurrences:

$$ S_t = \sum_{j=1}^{m} S_t^{(q_t, c_t)} $$

where the matrix $S_t^{(q_t, c_t)}$ is the complete-data sufficient statistic for a multinomial distribution and has a single unity entry defined by the indicator function

$$ S_t^{(q_t, c_t)} = \begin{cases} 1 & \text{if } q_t = k, c_t = j \\ 0 & \text{otherwise} \end{cases} $$

To avoid storing the entire history of sufficient statistics, this sum can be calculated in a recursive manner:

$$ S_t = S_{t-1} + S_t^{(q_t, c_t)} $$

with $S_0$ initialized to a matrix of zeros. However, because $c_t$ is a latent variable, this recursion must be modified in the following two ways. First, $S_t^{(q_t, c_t)}$ is estimated in the form of an expectation:

$$ E_{\theta_{t-1}}[S_t^{(q_t, c_t)}] = \sum_{j=1}^{m} q_t^{(j)} S_t^{(q_t, c_t)} $$

where the hat notation is used to indicate an estimated value. Second, because of observation noise, the expectations in equation (21) will show trial-to-trial variability. Therefore, an adaptive stepsize, $\alpha = \alpha / (t + \epsilon)$, is used to average the sequence of expectations and promote convergence. Because the stepsize decreases to zero according to the requirements of stochastic approximation theory, $\sum_{t=0}^{\infty} \alpha = \infty$ and $\sum_{t=1}^{\infty} \alpha^2 < \infty$, the effects of noise are eliminated in the long run. Increasing $\alpha$ slows the rate at which the stepsize decreases, placing greater weight on more recent observations compared with older observations. We treat $\alpha$ as a parameter to be estimated from the data.
as a free parameter of the model. Taken together, these two modifications lead to the following recursion:

\[
S_t = (1-\eta)S_{t-1} + \eta S_{t-1}S_t(\phi_t, c_t)S_{t-1}^{-1}
\]

(22)

which computes a running average of the expected complete-data sufficient statistics. It is useful to note that the convex combination in equation (22) ensures that all elements of \(S_t\) sum to 1. As such, \(S_t\) can be interpreted as an estimate of the joint probability of \(c_t\) and \(q_t\), which is proportional to the expected number of times that each value of \(c_t\) and \(q_t\) co-occurred. While it is possible to compute smoothed estimates of the complete-data sufficient statistics, exact computation of these smoothed estimates is intractable, requiring sequential Monte Carlo sampling techniques. For simplicity, we only compute filtered estimates of the complete-data sufficient statistics, as in equation (21).

\[M\] step. To calculate \(\Phi_t\), we normalize \(S_t\) by dividing each element by its corresponding column sum to ensure that the probability of either cue being emitted in each context is 1. Note that all elements of \(S_t\) must be non-zero for the solution of the expectation maximization algorithm to be well defined (otherwise some probabilities will always remain zero). Therefore, we omit the \(M\) step for the first eight trials to ensure that both contextual cues have been observed.

Importantly, to infer the probability of each context given an observed cue, the model of how contexts emit cues (equation (9)) is inverted (equation (12)).

**Model implementation.** We applied the above inference and learning algorithms to a sequence of noiseless observations, \(y_{ij}\), assigned values of 0 (null-field trials) or 1 (force-field trials), corresponding to the actual perturbations delivered by the robot. We also examined adding zero-mean Gaussian noise (variance \(\tau\)) to the delivered sequence of perturbations to include observation noise. However, because the actual observation noise that participants perceived is unknown to us, it must be marginalized out (for example, using Monte Carlo integration). The inclusion of observation noise also results in a stochastic objective function, which requires alternative parameter optimization techniques.

For simplicity, we only report fits to noiseless observations as the addition of observation noise complicates the model, which requires alternative parameter optimization techniques. The inclusion of observation noise also results in a stochastic objective function, which requires alternative parameter optimization techniques. Therefore, we omit the \(M\) step for the first eight trials to ensure that both contextual cues have been observed.

Model fitting. We simulated each model separately for each participant using the particular sequence of cues they observed. We then calculated the mean model data across participants for each group and each control point. We assume that adaptation measured on channel trials represents predicted observations that have been corrupted by independent and identically distributed Gaussian motor noise. Maximum-likelihood estimates of the free parameters of the models (Supplementary Table 2) were therefore obtained by minimizing the sum-of-squared errors between the mean model data (equation (5)) for the SSMS and equation (13) for the SSSM) and the mean experimental data measured on channel trials (\(p(t)\) in equation (2)). As each model involved fitting both same- and opposite-context trials jointly with the same set of parameters, we chose to fit the mean adaptation data across participants to reduce variability in the dataset.

Model comparison. Model selection was performed using the BIC:

\[
\text{BIC} = n \ln(n) - \ln[-\ln(1-R^2)/n] + k \ln(n) + \text{constant}
\]

(24)

where \(n=204\) is the number of data points, \(k\) is the number of free parameters and the constant does not depend on the model. The first term in the BIC penalizes underfitting, whereas the second term penalizes model complexity, as measured by the number of free parameters in the model. Taking the difference in BIC values for two competing models approximates half the log of the Bayes factor \(\Delta\). A BIC difference of greater than 4.6 (a Bayes factor of greater than 10) is considered to provide strong evidence in favour of the model with the lower BIC value.

**Acknowledgements**

We thank G. Zalalut and A. Pantelides for assistance with the experiments, and S. Singh for advice on the model. We thank the Wellcome Trust, Royal Society (Noreen Murray Professorship in Neurobiology to D.M.W.), Engineering and Physical Sciences Research Council and Canadian Institutes of Health Research for support. The funders had no role in the study design, data collection and analysis, decision to publish or preparation of the manuscript.

Author contributions
All authors conceived and designed the experiments. J.B.H. performed the experiments, and developed and fit the SSSM. All authors wrote the paper, discussed the results and edited the manuscript.

Competing interests
The authors declare no competing interests.

Additional information
Supplementary information is available for this paper at https://doi.org/10.1038/s41562-018-0324-5.

Reprints and permissions information is available at www.nature.com/reprints.

Correspondence and requests for materials should be addressed to J.B.H.

Life Sciences Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form is intended for publication with all accepted life science papers and provides structure for consistency and transparency in reporting. Every life science submission will use this form; some list items might not apply to an individual manuscript, but all fields must be completed for clarity.

For further information on the points included in this form, see Reporting Life Sciences Research. For further information on Nature Research policies, including our data availability policy, see Authors & Referees and the Editorial Policy Checklist.

1. **Experimental design**

   1. **Sample size**
      
      Describe how sample size was determined.
      
      To provide sufficient power, sample sizes were chosen on the basis of the typical between-subject variability observed in similar motor adaptation studies.

   2. **Data exclusions**
      
      Describe any data exclusions.
      
      Only pilot data (which was all run on lab members) was excluded from the published results.

   3. **Replication**
      
      Describe whether the experimental findings were reliably reproduced.
      
      Our main finding that opposing dynamics can be learned when controlling different points on an object was replicated in three of the presented experiments.

   4. **Randomization**
      
      Describe how samples/organisms/participants were allocated into experimental groups.
      
      Participant allocation was randomized prior to data collection.

   5. **Blinding**
      
      Describe whether the investigators were blinded to group allocation during data collection and/or analysis.
      
      The investigators were not blinded to group allocation during data collection and/or analysis. Analysis is fully objective requiring no experimenter input.

      Note: all studies involving animals and/or human research participants must disclose whether blinding and randomization were used.

6. **Statistical parameters**

   For all figures and tables that use statistical methods, confirm that the following items are present in relevant figure legends (or in the Methods section if additional space is needed).

   n/a  Confirmed

   - The exact sample size \( (n) \) for each experimental group/condition, given as a discrete number and unit of measurement (animals, litters, cultures, etc.)
   - A description of how samples were collected, noting whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
   - A statement indicating how many times each experiment was replicated
   - The statistical test(s) used and whether they are one- or two-sided (note: only common tests should be described solely by name; more complex techniques should be described in the Methods section)
   - A description of any assumptions or corrections, such as an adjustment for multiple comparisons
   - The test results (e.g. \( P \) values) given as exact values whenever possible and with confidence intervals noted
   - A clear description of statistics including central tendency (e.g. median, mean) and variation (e.g. standard deviation, interquartile range)
   - Clearly defined error bars

See the web collection on [statistics for biologists](https://nature-writing-policy.nature.com/research/what-to-submit/1/stats.html) for further resources and guidance.
7. Software

Describe the software used to analyze the data in this study.

Data were analyzed in Matlab 2017a.

For manuscripts utilizing custom algorithms or software that are central to the paper but not yet described in the published literature, software must be made available to editors and reviewers upon request. We strongly encourage code deposition in a community repository (e.g. GitHub). Nature Methods guidance for providing algorithms and software for publication provides further information on this topic.

8. Materials availability

Indicate whether there are restrictions on availability of unique materials or if these materials are only available for distribution by a for-profit company.

No unique materials were used in the study.

9. Antibodies

Describe the antibodies used and how they were validated for use in the system under study (i.e. assay and species).

n/a

10. Eukaryotic cell lines

a. State the source of each eukaryotic cell line used.

n/a

b. Describe the method of cell line authentication used.

n/a
c. Report whether the cell lines were tested for mycoplasma contamination.

n/a
d. If any of the cell lines used are listed in the database of commonly misidentified cell lines maintained by ICLAC, provide a scientific rationale for their use.

n/a

11. Description of research animals

Provide details on animals and/or animal-derived materials used in the study.

No non-human animals were used in the study.

12. Description of human research participants

Describe the covariate-relevant population characteristics of the human research participants.

Fifty neurologically intact participants (22 males and 28 females; age 28.2 ± 7.8, mean ± SD) were recruited to participate in four experiments. All participants were right-handed according to the Edinburgh handedness inventory.
