Abstract

We study analytically the dynamics of a network of sparsely connected inhibitory integrate-and-fire neurons in a regime where individual neurons emit spikes irregularly and at a low rate. In the limit when the number of neurons $N \to \infty$, the network exhibits a sharp transition between a stationary and an oscillatory global activity regime where neurons are weakly synchronized. The activity becomes oscillatory when the inhibitory feedback is strong enough. The period of the global oscillation is found to be mainly controlled by synaptic times, but depends also on the characteristics of the external input. In large but finite networks, the analysis shows that global oscillations of finite coherence time generically exist both above and below the critical inhibition threshold. Their characteristics are determined as functions of systems parameters, in these two different regimes. The results are found to be in good agreement with numerical simulations.

1 Introduction

Oscillations are ubiquitous in neural systems and have been the focus of several recent studies (for reviews see e.g. Gray 1994, Singer and Gray 1995, Buzsáki and Chrobak 1995, Ritz and Sejnowski 1997). In particular, fast global oscillations in the gamma frequency range ($> 30$ Hz) have been reported in the visual cortex (Gray et al 1989, Eckhorn et al 1993, Kreiter and Singer 1996), in the olfactory cortex (Laurent and Davidowitz 1994) and in the hippocampus (Bragin et al 1995). Even faster oscillations ($200$ Hz) occur in the hippocampus of the rat (Buzsáki et al 1992, Ylinen et al 1995). In some experimental data, (see e.g. Eckhorn et al 1993, Csicsvari et al 1998, Fisahn et al 1998) individual neuron recordings show irregular spike emission, at a rate which is low compared to the global oscillation frequency. This raises the question of whether a network composed of neurons firing irregularly at low rates can exhibit fast collective oscillations, which theoretical analyses and modelling studies may help to answer.

\textsuperscript{4}Fast oscillations may be due in some cases to a synchronized subset of cells with high firing rates. The observation of cells with the required property has been recently reported in (Gray and McCormick 1996).
Previous studies of networks of spiking neurons have mostly analyzed, or simulated, synchronized oscillations in regimes in which neurons behave themselves as oscillators, with interspike intervals strongly peaked around their average value (see e.g. Mirollo and Strogatz 1990, Abbott and van Vreeswijk 1993, van Vreeswijk et al 1994, Gerstner 1995, Hansel et al 1995, Gerstner et al 1996, Wang and Buzsáki 1996, Traub et al 1996). Several oscillatory regimes have been found with either full or partial synchronization. A regime particular to globally coupled systems has been described where the network breaks into a few fully synchronized clusters (Golomb and Rinzel 1994, van Vreeswijk 1996). In some simulations of networks with detailed biophysical characteristics, cells fire sparsely and irregularly during a global oscillation (Traub et al 1989, Kopell and LeMasson 1994, Wang et al 1995), but the complexity of individual neurons in these models makes it difficult to clearly understand the origin of the phenomenon. The possible appearance of fast oscillations in a network where all neurons fire irregularly with an average frequency which is much lower than the population frequency therefore remains an intriguing question. It is the focus of the present work.

Recurrent inhibition plays an important role in the generation of synchronized oscillations as shown by in vivo (McLeod and Laurent 1996) and in vitro experiments (Whittington et al 1995) in different systems. This has been confirmed by several modelling studies (van Vreeswijk et al 1994, Gerstner et al 1996, Wang and Buzsáki 1996, Traub et al 1996). It has also been recently shown using simple models that networks in which inhibition balance excitation (Tsodyks and Sejnowski 1995, Amit and Brunel 1997a, van Vreeswijk and Sompolinsky 1996) are naturally composed of neurons with low and irregular firing. Simulations (Amit and Brunel 1997b) have shown that, in one such model composed of sparsely connected integrate-and-fire (IF) neurons, the highly irregular single neuron activity is accompanied by damped fast oscillations of the global activity.

In order to study the coexistence of individual neurons with low firing rates and fast collective oscillations in its simplest setting, we analyze in the present paper a sparsely connected network entirely composed of identical inhibitory IF neurons. Our aim is to provide a clear understanding of this type of synchrony and to precisely determine:

- i) under which conditions collective excitations of high frequencies arise in such networks
- ii) what controls the different characteristics (amplitude, frequency, coherence time,...) of the global oscillation.

Simulation results are presented first which shows that the essence of the phenomenon is present even in this simple system. Both the neurons firing rates and the auto-correlation of the global activity are very similar to those reported in (Amit and Brunel 1997b).

We begin by presenting simple arguments which give an estimation of the firing rate of individual neurons and the frequency of the global oscillation and which lead to think that the global oscillation only appears above a well-defined parameter threshold.

In order to make the analysis more precise and complete, we then generalize the analytic approach of Amit and Brunel (1997a) which was restricted to the compu-
tation of firing rates in stationary states. The sparse random network connectivity leads the firing patterns of different neurons to be only weakly correlated. As a consequence, the network state can be described by the instantaneous distribution of membrane potentials of the neuronal population, together with the firing probability in this population. We obtain the coupled temporal evolution equations for these quantities, the time-independent solution of which coincides with the stationary solution of (Amit and Brunel 1997a).

A linear stability analysis shows that this time-independent solution becomes unstable only when the strength of recurrent inhibition exceeds a critical level, in agreement with our simple arguments. When this critical level is reached, the stationary solution becomes unstable and an oscillatory solution develops (via a Hopf bifurcation). The time scale of the period of the corresponding global oscillations is set by a synaptic time, independently of the firing rate of individual neurons, but the period precise value also depends on the characteristics of the external input.

The analysis is then pushed to higher orders. We obtain a reduced evolution equation describing the network collective dynamics. The effects coming from the finite size of the network are also discussed. We show that having a large but finite number of neurons gives a small stochastic component to the collective evolution equation. As a result, it is shown that cross-correlations in a finite network present damped oscillations both above and below the critical inhibition level. Below the critical level, the noise controls the oscillation amplitude which decreases as the number of neurons is increased (at a fixed number of connections per neuron). Above the critical level, the main effect of the noise is to produce a phase diffusion of the global oscillation. An increase in the number of neurons results in an increase of the global oscillation coherence time and in a reduced damping in average cross-correlations.

Finally, the effect of some of our simplifying assumptions is studied. We shortly discuss the effect of allowing variability in synaptic times and number of synaptic connections from neuron to neuron. We also consider the effect of introducing a more detailed description of postsynaptic currents into the model. The technical aspects of our computations are detailed in several appendices.

2 Description of the network and simulations

We analyse the dynamics of a network composed of $N$ identical inhibitory single compartment integrate-and-fire (IF) neurons. Each neuron receives $C$ randomly chosen connections from other neurons in the network. It also receives $C_{ext}$ connections from excitatory neurons outside the network (see Fig. 1). We consider a sparsely connected case with $\epsilon = C/N \ll 1$.

Each neuron is simply described by its membrane potential. Let us suppose that neuron $i$ receives an inhibitory (excitatory) connection from neuron $j$. When the presynaptic neuron $j$ emits a spike at time $t$, the potential of the postsynaptic neuron $i$ is decreased (increased) by $J$ at time $t + \delta$ and returns exponentially to the resting potential in a time $\tau$ which represents the integration time constant of the membrane. In this simple model, the single time $\delta$ is meant to represent the
Figure 1: Schematic diagram of the connections in the network of \( N \) neurons; each neuron (indicated as an open disk) receives \( C \) inhibitory connections (indicated as black) from within the network and \( C_{\text{ext}} \) excitatory connections (indicated as grey) from neurons outside the network.

Figure 2: Comparison of the synaptic response characteristics in our model and in a more realistic model. The top trace shows the presynaptic spike. The middle trace shows the corresponding postsynaptic current (PSC). The bottom trace shows the corresponding postsynaptic potential (PSP) for a neuron initially at resting potential. Full lines: our model, in which the synaptic current is described by a delta function a time \( \delta \) after the presynaptic spike. Dashed lines: a more realistic synaptic response, in which the PSC is described by an \( \alpha \)-function with latency (transmission delay) \( \tau_L \) and synaptic time constant \( \tau_S \): 
\[
(t - \tau_L) \exp\left(-\frac{(t - \tau_L)}{\tau_S}\right)/\tau_S.
\]
Our synaptic characteristic time \( \delta \) can roughly be identified with the sum of latency and synaptic decay time, \( \tau_L + \tau_S \). See the discussion in Section 4.3.
transmission delays but also and most importantly, the longer time needed to obtain the full hyperpolarization of the post-synaptic neuron corresponding to a given presynaptic spike. Therefore, finding the correspondence between $\delta$ and the different synaptic time scales of a more realistic description needs some care. As pictorially shown in Fig. 2, $\delta$ should roughly be identified to the characteristic duration of the synaptic currents. In the following, we thus refer to $\delta$, which plays a crucial role in the generation of global oscillations, as the "synaptic time". The correspondence between $\delta$ and the different synaptic time scales of a more realistic description is further elaborated in Section 4.3 where synaptic current of finite duration are considered.

Mathematically, the depolarization $V_i(t)$ of neuron $i$ ($i = 1, \ldots, N$) at its soma obeys the equation,

$$\tau \frac{dV_i(t)}{dt} = -V_i(t) + RI_i(t)$$

where $I_i(t)$ are the synaptic currents arriving at the soma. These synaptic currents are the sum of the contributions of spikes arriving at different synapses (both local and external). These spike contributions are modelled as delta functions in our basic IF model:

$$RI_i(t) = \tau \sum_j J_{ij} \sum_k \delta(t - t_{jk}^k - \delta)$$

where the first sum on the r.h.s is a sum on different synapses ($j = 1, \ldots, C + C_{ext}$), with postsynaptic potential (PSP) amplitude (or efficacy) $J_{ij}$, while the second sum represents a sum on different spikes arriving at synapse $j$, at time $t = t_{jk}^k + \delta$, where $t_{jk}^k$ is the emission time of $k$-th spike at neuron $j$. For simplicity, we take PSP amplitudes equal at each synapse, i.e. $J_{ij} = J_{ext} > 0$ for excitatory synapses and $J_{ij} = -J$ for inhibitory ones. External synapses are activated by independent Poisson processes with rate $\nu_{ext}$.

A firing threshold $\theta$, completes the description of the IF neuron: when $V_i(t)$ reaches $\theta$, an action potential is emitted by neuron $i$, and the depolarization is reset to $V_r < \theta$ after a refractory period $\tau_{rp}$ during which the potential is insensitive to stimulation. A typical value would be $\tau_{rp} \sim 2$ ms. We are interested here in network states in which the frequency is much lower than the corresponding maximal frequency $1/\tau_{rp} \sim 500$ Hz. In this regime, we have checked that the exact value of $\tau_{rp}$ does not play any role. Thus in the following we set $\tau_{rp}$ to zero, for the sake of simplicity.

The outcome of a typical simulation is shown in Figs. 3. Neurons are driven by the random external excitatory input above threshold; however, since feedback interactions are inhibitory, the global activity stays at rather low levels (about 5 Hz for the parameters indicated in Fig. 3). For weak external noise levels ($\sigma_{ext} = 1$ mV), the global activity (total number of firing neurons in 0.4 ms bins) is strongly oscillatory with a period of about 7 ms, as testified by Fig. 3C. On the other hand, increasing the external noise level strongly damps and decreases the amplitude of the global oscillation. Note that the global activity should roughly correspond to the local field potential (LFP) often recorded in neurophysiological experiments. On the other hand, even when the global activity is strongly oscillatory, individual firing is extremely irregular as shown in the rasterfile of 50 neurons, Fig. 3C (above the LFP), and in the inter-spike interval histogram (to the right of the spike rasters). In each oscillatory event only a small fraction of the neurons fire.
Figure 3: Left: Time evolution of the global activity (LFP) during a 100ms interval of the dynamics of a network of 5,000 neurons (total number of firing neurons in 0.4ms bins), together with spike rasters of 50 neurons, for different values of the external noise: $\sigma_{\text{ext}} = 5$ mV (A), 2.5 mV (B), and 1 mV (C). Right: autocorrelation of the global activity (AC) and inter-spike interval (ISI) histogram averaged over 1000 neurons, corresponding to the left pictures. Note the different time scales of AC and ISI in abscissa. Parameters: $\theta = 20$ mV, $V_r = 10$ mV, $\tau = 20$ ms, $\delta = 2$ ms, $C = 1000$, $J = 0.1$ mV, $\mu_{\text{ext}} = 25$ mV.
This oscillatory collective behavior is also shown by fast oscillations in the temporal autocorrelation (AC) of the global activity which are damped on a longer time scale (Fig. 3, to the right of the LFP). It is also reflected in the cross-correlations (CC) between the spike trains of a pair of neurons, which are typically equal to the AC of the global activity.

These simulation results raise several questions on the origin and characteristics of the observed oscillations. What is the mechanism of the fast oscillation? In which parameter region is the network oscillating? What are the network parameters which control the amplitude and the different time scales (frequency, damping time constant) of the global oscillation? How do they scale with the network size? The model is simple enough and an analytical study gives precise answers to these questions as shown in the following sections.

3 An analysis of the network dynamics

Several features simplify the analysis as noted in a previous study (Amit and Brunel 1997a) of the neuron mean firing rates. First, as a consequence of the network sparse random connectivity \((C \ll N)\), two neurons share a small number of common inputs and pair correlations can be neglected in the limit \(C/N \to 0\). Second, we consider a regime where individual neurons have a firing rate \(\nu\) low compared to their inverse integration time \(1/\tau\) and receive a large number of inputs per integration time \(\tau\), each input making a contribution small compared to the firing threshold \((J \ll \theta)\). In this situation, the synaptic current of a neuron can be approximated by an average part plus a fluctuating gaussian part, and the spike trains of all neurons in the network can be self consistently described by Poisson processes with a common instantaneous firing rate \(\nu(t)\) but otherwise uncorrelated from neuron to neuron (that is, between \(t\) and \(t + dt\), a spike emission has a probability \(\nu(t)dt\) of occurring for each neuron but these events occur statistically independently in different neurons).

The synaptic current at the soma of a neuron (neuron \(i\)) can thus be written as,

\[
RI_i(t) = \mu(t) + \sigma \sqrt{\tau \eta_i(t)}
\]  

(3)

The average part \(\mu(t)\) is related to the firing rate at time \(t - \delta\) and is a sum of local and external inputs

\[
\mu = \mu_l + \mu_{ext} \quad \text{with} \quad \mu_l = -CJ\nu(t - \delta)\tau, \quad \mu_{ext} = C_{ext}J_{ext}\nu_{ext}\tau
\]  

(4)

Similarly the fluctuating part, \(\sigma \sqrt{\tau \eta_i(t)}\), is given by the fluctuation in the sum of internal and external poissonian inputs of rate \(C\nu\) and \(C_{ext}\nu_{ext}\). Its magnitude is given by

\[
\sigma^2 = \sigma_l^2 + \sigma_{ext}^2 \quad \text{with} \quad \sigma_l = J\sqrt{C\nu(t - \delta)\tau}, \quad \sigma_{ext} = J_{ext}\sqrt{C_{ext}\nu_{ext}\tau}
\]  

(5)

5Typical numbers in cortex are \(C = 5000, \tau = 20\text{ms}, \nu = 5\text{Hz}, J = 0.1\text{mV}, \theta = 20\text{mV}\) so that \(C\nu\tau\) is typically several hundreds while \(\theta/J\) is of order 100 (Abeles 1991, Braitenberg and Shutz 1991). In the simulation shown in Fig. 3 \(C\nu\tau \sim 100, \theta/J \sim 200\).
and $\eta_i(t)$ is a gaussian white noise uncorrelated from neuron to neuron, $\langle \eta_i(t) \rangle = 0$ and $\langle \eta_i(t) \eta_j(t') \rangle = \delta_{i,j} \delta(t-t')$.

Before describing our precise results, it may be useful to give simple estimates which show how the neuron firing rates, the collective oscillation frequency and the oscillatory threshold can be obtained from Eqs.(3-5).

Let us first consider the stationary case. The case of interest corresponds to $\mu < \theta$. When expression (3) is used for the synaptic current, the dynamics of the neuron depolarization (1) is a stochastic motion in the harmonic potential $(V - \mu)^2$ truncated at the firing threshold $V = \theta$. The neuron firing rate $\nu_0$ is the escape rate from this potential. For a weak noise, it is given by the inverse of the time scale of the motion $1/\tau$ diminished by an Arrhenius activation factor. So, one obtains the simple estimate (up to an algebraic prefactor),

$$\nu_0 \sim \frac{1}{\tau} \exp \left( -\frac{(\theta - \mu)^2}{\sigma^2} \right)$$

This becomes a self-consistent equation for $\nu_0$ once $\mu$ and $\sigma$ are expressed in terms of $\nu_0$ using Eq. (4,5). The simple estimate (6) is made precise below by following Kramers’s classic treatment of the thermal escape over a potential barrier (Chandrasekhar 1943).

The origin of the collective oscillation can also be simply understood. An increase of activity in the network due to a fluctuation provokes an increase in the average feedback inhibitory input. Thus after a period of about one synaptic time the activity should decrease due to the increase of the inhibitory input. This decrease will itself provoke a decrease in the inhibitory input, and a corresponding increase in the activity after a new period equal to the synaptic time. This simple argument predicts a global oscillation period of about a couple of times the synaptic time $\delta$, not too far from the period observed in the simulations. However, it does not seem to have been noted previously that a global oscillation of period $\delta$ can in fact occur only if it is not masked by the intrinsic noise in the system. The resulting oscillation threshold can be simply estimated in the limit where $\delta$ is short compared to the time scale of the depolarization dynamics. During a short time interval $\delta$, a neuron membrane potential receives from the local network an average input of magnitude $C\nu_0 \delta J$. The fluctuation in its membrane potential in the same time interval (due to intrinsic fluctuations in the total incoming current) is $\sigma \sqrt{\delta/\tau}$. The change in the average local input can be detected only if it is larger than the intrinsic potential fluctuations. A global oscillation can therefore occur only when

$$\frac{CJ\nu_0 \tau}{\sigma} = -\frac{\mu}{\sigma} \gtrsim \sqrt{\frac{\tau}{\delta}}.$$

These simple estimations are confirmed by the analysis presented below and replaced by precise formulas.

### 3.1 Dynamics of the distribution of neuron potentials

When pair correlations are neglected, the system can be described by the distribution of the neuron depolarization $P(V,t)$, i.e. the probability of finding the depolarization
of a randomly chosen neuron at $V$ at time $t$. This distribution is the (normalized) histogram of the depolarization of all neurons at time $t$ in the large $N$ limit $N \to \infty$. The stochastic equation (13) for the dynamics of a neuron depolarization can be transformed into a Fokker-Planck equation describing the evolution of their probability distribution (Chandrasekhar 1943)

$$\tau \frac{\partial P(V,t)}{\partial t} = \frac{\sigma^2(t)}{2} \frac{\partial^2 P(V,t)}{\partial V^2} + \frac{\partial}{\partial V} \left[ (V - \mu(t))P(V,t) \right]$$ (7)

The two terms in the r.h.s. of (7) correspond respectively to a diffusion term coming from the current fluctuations and a drift term coming from the average part of the synaptic input. $\sigma(t)$ and $\mu(t)$ are related to $\nu(t - \delta)$, the probability per unit time of spike emission at time $t - \delta$, by Eq. (4). Note that the Fokker-Planck equation has been used previously in studies of globally coupled oscillators (Sakaguchi et al 1988, Strogatz and Mirollo 1991, Abbott and van Vreeswijk 1993, Treves 1993).

The resetting of the potential at the firing threshold ($V = \theta$) imposes the absorbing boundary condition $P(\theta, t) = 0$. Moreover, the probability current through $\theta$ gives the probability of spike emission at $t$,

$$\frac{\partial P}{\partial V}(\theta, t) = -\frac{2\nu(t)\tau}{\sigma^2(t)}$$ (8)

At the reset potential $V = V_r$, $P(V, t)$ is continuous but the entering probability current imposes the following derivative discontinuity,

$$\frac{\partial P}{\partial V}(V_r^+, t) - \frac{\partial P}{\partial V}(V_r^-, t) = -\frac{2\nu(t)\tau}{\sigma^2(t)}$$ (9)

At $V = -\infty$, $P$ should tend sufficiently quickly toward zero to be integrable, i.e.

$$\lim_{V \to -\infty} P(V, t) = 0 \quad \lim_{V \to -\infty} VP(V, t) = 0.$$ (10)

Last, $P(V, t)$ is a probability distribution and should satisfy the normalization condition

$$\int_{-\infty}^{\theta} P(V, t) dV = 1$$ (11)

### 3.2 Stationary states

We first consider stationary solutions $P(V, t) = P_0(V)$. Time independent solutions of Eq. (7) satisfying the boundary conditions (8,9,10) are given by

$$P_0(V) = 2\frac{\nu_0\tau}{\sigma_0} \exp \left( -\frac{(V - \mu_0)^2}{\sigma_0^2} \right) \int_{\frac{\theta - \mu_0}{\sigma_0}}^{\frac{V_r - \mu_0}{\sigma_0}} \Theta \left( u - \frac{V_r - \mu_0}{\sigma_0} \right) e^{u^2} du$$ (12)

with

$$\mu_0 = -CJ\nu_0\tau + \mu_{ext}, \quad \sigma_0^2 = CJ^2\nu_0\tau + \sigma_{ext}^2$$ (13)
The neuron firing rate vs $\sigma_{\text{ext}}$: simulation ($\Diamond$); solution of Eq. (14) (full line); solution of the approximate asymptotic form (15) (dashed line). Others parameters are fixed as in Fig. 2: $\tau = 20\,\text{ms}$, $J = 0.1\,\text{mV}$, $C = 1000$, $N = 5000$, $\theta = 20\,\text{mV}$, $V_r = 10\,\text{mV}$, $\mu_{\text{ext}} = 25\,\text{mV}$, $\delta = 2\,\text{ms}$.

(in (12), $\Theta(x)$ denotes the Heaviside function, $\Theta(x) = 1$ for $x > 0$ and $\Theta(x) = 0$ otherwise). The normalization condition (11) provides the self-consistent condition which determines $\nu_0$

\[
\frac{1}{\nu_0\tau} = 2\int_{\theta - \mu_0}^{\theta - \mu_0} du e^{u^2} \int_{-\infty}^{u} dv e^{-v^2} = \int_{-\infty}^{0} du e^{-u^2} \left[ e^{2y_\theta u} - e^{2y_r u} \right]
\]

with $y_\theta = \frac{\theta - \mu_0}{\sigma_0}$, $y_r = \frac{V_r - \mu_0}{\sigma_0}$. In the regime $(\theta - \mu_0) \gg \sigma_0$, Eq. (14) becomes

\[
\nu_0\tau \approx \frac{(\theta - \mu_0)}{\frac{\sigma_0}{\sqrt{\pi}}} \exp \left( -\frac{(\theta - \mu_0)^2}{\sigma_0^2} \right)
\]

In Fig. (4), the firing rates obtained by solving Eq. (14) and (15) are compared with those obtained from simulations of the network. It shows an almost linear increase in the rates as a function of $\sigma_{\text{ext}}$ in the range 3-6Hz and a good agreement between Eq. (14) and the results of simulations. The asymptotic expression (15) is also rather close to the simulation results in this range of $\sigma$.

### 3.3 Linear stability of the stationary states

We can now investigate in which parameter regime the time independent solution $(P_0(V), \nu_0)$ is stable. To simplify the study of the Fokker-Planck equation (7), it is convenient to rescale $P$, $V$ and $\nu$ by

\[
P = \frac{2\tau \nu_0}{\sigma_0} Q, \quad y = \frac{V - \mu_0}{\sigma_0}, \quad \nu = \nu_0(1 + n(t))
\]
$y$ is the difference between the membrane potential and the average input in the stationary state, in units of the average fluctuation of the input in the stationary state. $n(t)$ corresponds to the relative variation of the instantaneous frequency around the stationary frequency. After these rescalings, Eq. (7) becomes

$$\tau \frac{\partial Q}{\partial t} = \frac{1}{2} \frac{\partial^2 Q}{\partial y^2} + \frac{\partial}{\partial y} (yQ) + n(t - \delta) \left( G \frac{\partial Q}{\partial y} + \frac{H}{2} \frac{\partial^2 Q}{\partial y^2} \right),$$

where $G$ is the ratio between the mean local inhibitory inputs and $\sigma_0$, and $H$ is the ratio between the variance of the local inputs and the total variance (local plus external):

$$G = \frac{CJ \tau v_0}{\sigma_0} = \frac{-\mu_0}{\sigma_0}, \quad H = \frac{CJ^2 \tau v_0}{\sigma_0^2} = \frac{\sigma_0^2}{\sigma_0^2},$$

These parameters are a measure of the relative strength of the recurrent inhibitory interactions.

Eq. (17) holds on the two intervals $-\infty < y < y_r$ and $y_r < y < y_\theta$. The boundary conditions on $Q$ are imposed at $y_\theta = \frac{\theta - \mu_0}{\sigma_0}$ and $y_r = \frac{\nu_r - \mu_0}{\sigma_0}$. Those on the derivatives of $Q$ read,

$$\frac{\partial Q}{\partial y}(y_\theta, t) = \frac{\partial Q}{\partial y}(y_r^+, t) - \frac{\partial Q}{\partial y}(y_r^-, t) = -\frac{1 + n(t)}{1 + H n(t - \delta)}$$

The linear stability of the stationary solution is studied in detail in Appendix A. This can be done in a standard way (Hirsch and Smale, 1974) by expanding $Q = Q_0 + Q_1 + \ldots$ and $n = n_1 + \ldots$ around the steady state solution. The linear equation obtained at first order has solutions which are exponential in time, $Q_1 = \exp(wt/\tau)Q_1$, $n_1 = \exp(w/\tau)n_1$, where $w$ is a solution of the eigenvalue equation (16) of the Appendix. The stationary solution becomes unstable when the real part of $w$ becomes positive.

When the synaptic time $\delta$ becomes much smaller than $\tau$, the roots $w$ of this equation become large. We consider the regime $\delta/\tau \ll 1$ but $\delta/\tau \gg 1/C$, which is the relevant case in simulations and correspond to the realistic regime. $\delta/\tau \gg 1/C$ is needed because otherwise the equations giving $G$ and $H$ become inconsistent with the condition $\tau v_0 \ll 1$. At the oscillatory instability onset, $w$ is purely imaginary $w = i\omega_c$, where $\omega_c/\tau$ is the frequency of the oscillation which develops. The eigenvalue equation takes in the limit $\delta/\tau \to 0$, $\omega \to \infty$ the form

$$\left[ \frac{G}{\sqrt{\omega_c}} (i - 1) + H \right] \exp(-i\omega_c \delta/\tau) = 1.$$  

In this limit, the instability line in the parameter space $(G, H)$ is obtained parametrically as

$$G = \sqrt{\omega_c} \sin \left( \frac{\omega_c \delta}{\tau} \right)$$

$$H = \sin \left( \frac{\omega_c \delta}{\tau} \right) + \cos \left( \frac{\omega_c \delta}{\tau} \right)$$

11
Figure 5: Left: instability line in the plane \((H, G\sqrt{\delta/\tau})\). Full line: instability line for parameters of Fig. 3, and \(\delta = 0.1\tau\). Long-dashed line: \(\delta = 0.05\tau\). Short-dashed line: asymptotic limit \(\delta/\tau \to 0\). The stationary state (SS) is unstable to the right of the instability line, where an oscillatory instability develops (OS). Right: instability line in the plane \((\mu_{ext}, \sigma_{ext})\). Full line: parameters of Fig. 2, and \(\delta = 0.1\tau\). Short-dashed line is constructed taking the asymptotic instability line in the plane \((H, G\sqrt{\delta/\tau})\), and calculating the corresponding instability line in \((\mu_{ext}, \sigma_{ext})\) with \(\delta = 0.1\tau\). The stationary state (SS) becomes unstable above the instability line. The long dashed line shows the average \((\mu_{ext})\) and the fluctuations \((\sigma_{ext})\) of the external inputs when the frequency of a Poissonian external input through synapses of strength \(J_{ext} = 0.1\text{mV}\) is varied. For low external frequencies the network is in its stationary state. When the external frequency increases the network goes to its oscillatory state (OS).

\(H\) is by definition constrained to be between 0 and 1 (it is the ratio between local and total variances): \(H = 0\) corresponds to the limit of very large external fluctuations, \(\sigma_{ext} \gg \sigma_l\), while \(H = 1\) corresponds to \(\sigma_{ext} = 0\). We find that the frequency of the oscillation varies from

\[
\frac{\omega_c}{\tau} = \frac{3\pi}{4\delta} \quad \text{when } H = 0, \quad \frac{\omega_c}{\tau} = \frac{\pi}{2\delta} \quad \text{when } H = 1.
\]

(21)

This corresponds to an oscillation with a period between \(8\delta/3\) and \(4\delta\), not too far from the value \(2\delta\) obtained by simple arguments. At the same time the critical value of \(G\) goes from

\[
G_c = \sqrt{\frac{3\pi \tau}{8\delta}} \quad \text{when } H = 0, \quad G_c = \sqrt{\frac{\pi \tau}{2\delta}} \quad \text{when } H = 1.
\]

Again we find that it is proportional to \(\sqrt{\tau/\delta}\) as anticipated.

This instability line can be translated in terms of the parameters \(\mu_{ext}, \sigma_{ext}\), and calculated numerically using Eq. (66) for any value of the network parameters. This line of instability in the plane \((\mu_{ext}, \sigma_{ext})\) is shown in the right part of Fig. 5. The stationary solution is unstable above the full line. Thus, if the external input is
Poissonian, an increase in the frequency of external stimulation will typically bring
the network from the stationary to the oscillatory regime, as indicated by the dashed
line in Fig. 3, which represents the average ($\mu_{ext}$) and the fluctuations ($\sigma_{ext}$) of
the external inputs when the frequency of a Poissonian external input through synapses
of strength $J_{ext} = 0.1$mV is varied.

3.4 Weakly non-linear analysis

The linear stability analysis of the previous section shows that a small oscillation
grows when one crosses the instability line in the plane $\mu_{ext}, \sigma_{ext}$. But it does not
say much on the resulting characteristics of the resulting finite amplitude oscillation.
In order to describe it and to be able to quantitatively compare analytic results to
simulation data, one needs to compute the non linear terms which saturate the in-
stability growth. This can be done in a standard manner (Bender and Orszag, 1987)
by computing terms beyond the linear order in an expansion around the stationary
state. The explicit computation is detailed in Appendix B. The collective oscillation
is determined by the deviation $n_1$ of the neuron firing rate from its stationary value:

$$n_1(t) = \hat{n}_1(t) \exp(i\omega_c t/\tau) + \hat{n}_1^*(t) \exp(-i\omega_c t/\tau)$$

$\hat{n}_1$ determines the amplitude of the collective oscillation as well as the nonlinear
contribution to its frequency in the vicinity of the instability line.

The analysis shows that the dynamics of the (small) deviation around the sta-
tionary firing rate can be described by the reduced equation

$$\tau \frac{d\hat{n}_1}{dt} = A\hat{n}_1 - B|\hat{n}_1|^2\hat{n}_1$$

in which $A$ and $B$ are complex numbers. The value of $A$ comes from the linear
stability analysis. If $\text{Re}(A) < 0$ a small initial value of $n_1$ decays and the stationary
state is stable. On the contrary, if $\text{Re}(A) > 0$ a global oscillation develops. When
$|\hat{n}_1|$ grows, the second nonlinear term on the r.h.s. of (22) becomes important. It is
found here that $\text{Re}(B) > 0$ (a ”normal” or ”supercritical” Hopf bifurcation) so that
the nonlinear term saturates the linear growth. The characteristics of the oscillatory
final state comes from the balance between the two terms.

The explicit expression of $A$ and $B$ is given in Eqs. (21,22) as a ratio of hyper-
geometric functions of the network parameters. $A$ depends linearly on the deviation
of the parameters $G$ and $H$ from their critical values, i.e. $G - G_c, H - H_c$. In the
limit $\delta/\tau \to 0$ the expressions of $A$ and $B$ simplify. For example, when $H = 0$ (large
external fluctuations), we find in the limit $\delta/\tau \to 0$

$$A = \frac{\tau}{\delta} \frac{1 + 2i/3\pi}{1 + 4/9\pi^2} \frac{G - G_c}{G_c} \approx \frac{\tau}{\delta} (1.35 + 0.29i) \frac{G - G_c}{G_c}$$

$$B = \frac{\tau}{\delta} \left( \frac{9\pi^2}{4 + 9\pi^2} \right) \left[ \frac{13 - 5\sqrt{2}}{10} - \frac{9 - 5\sqrt{2}}{15\pi} + i \left( 9 - \frac{13 - 5\sqrt{2}}{10} + \frac{9 - 5\sqrt{2}}{15\pi} \right) \right]$$

$$\approx \frac{\tau}{\delta} (0.53 + 0.30i)$$ (23)
Generally, the complex numbers $A$ and $B$ can be written in terms of their real and imaginary parts, $A = A_r + iA_i$, $B = B_r + iB_i$. On the critical line, i.e. for $G = G_c$, $H = H_c$, $A_r = A_i = 0$; above the critical line an instability develops, $A_r > 0$, proportionally to $G - G_c$ and $H - H_c$. The amplitude of this instability is controlled by the cubic term. The stable limit cycle solution of Eq. (22), above the critical line, is

$$\hat{n}_1(t) = R \exp \left( i \frac{\Delta \omega t}{\tau} \right)$$  \hspace{1cm} (24)

where

$$R = \sqrt{\frac{A_r}{B_r}} \quad \text{and} \quad \Delta \omega = A_i - B_i \frac{A_r}{B_r}$$

The autocorrelation (AC) of the global activity, normalized by $\nu_0$, is, when $A_r > 0$,

$$C(s) = \lim_{T \to \infty} \frac{1}{T-s} \int_0^{T-s} (1 + n_1(t))(1 + n_1(t + s))dt$$  \hspace{1cm} (25)

$$= 1 + 2R^2 \cos \left[ (\omega_c + \Delta \omega) s / \tau \right]$$

The AC is a cosine function of frequency $(\omega_c + \Delta \omega) / \tau$ and amplitude $R^2$. Compared with the AC function observed in the simulation, Fig. 3C, we see a qualitative difference: there is no damping of the oscillation. The next Section shows that the damping is due to finite size effects. We analyze them before comparing quantitatively the analytical results with simulations.

### 3.5 Finite size effects and phase diffusion of the collective oscillation

We discuss the effect of having a large but only finite number of neurons in the network. It is well-known that for stochastic dynamics, a sharp transition can only occur in the limit $N \to \infty$ and that it will be smoothened by finite size effects. In the sparse connectivity limit, which allows to treat the quenched random geometry of the lattice in an annealed fashion, the fluctuations in the input of a given neuron $i$ can be seen as the result of the randomness of two different processes: the first is the spike emission process $S(t)$ of the whole network; and the second, for each spike emitted by the network, is the presence or absence of a synapse between the neuron that emitted the spike and the considered neuron: if a spike is emitted at time $t$, $\rho_i(t) = 1$ with probability $C/N$, and 0 otherwise. The input to the network is then

$$RI_i(t) = -J \tau \rho_i(t) S(t - \delta)$$

Both processes can be decomposed between their mean and their fluctuation,

$$\rho_i(t) = \frac{C}{N} + \delta \rho_i(t), \quad S(t) = N \nu(t) + \delta S(t)$$

\footnote{Here we do not consider the correlations due to the quenched connectivity for finite $\epsilon$. These correlations would give small corrections to the parameters calculated in the limit $\epsilon \to 0$, but do not give rise to qualitatively new effects for the global activity such as the phase diffusion phenomenon discussed in this section.}
Thus the input becomes

$$RI_i(t) = \mu(t) - J\tau N\nu(t)\delta\rho_i(t) - J\tau\frac{C}{N}\delta S(t)$$

in which $\mu(t)$ is given by Eq. (4). The input is the sum of a constant part $\mu$, and of two distinct random processes superimposed on $\mu$: the first is uncorrelated from neuron to neuron, and we have already seen in Section 3 that it can be described by $N$ uncorrelated Gaussian white noises $\sigma\sqrt{\tau}\eta_i(t)$, $i = 1, \ldots, N$ where $<\eta_i(t)\eta_j(t')> = \delta_{ij}\delta(t-t')$. The second part is independent of $i$: it comes from the intrinsic fluctuations in the spike train of the whole network which are seen by all neurons. This part becomes negligible when $\epsilon = C/N \to 0$, but can play a role as we will see when $C/N$ is finite. The global activity in the network is essentially a Poisson process with instantaneous frequency $N\nu(t)$. Such a Poisson process has mean $N\nu(t)$, which is taken into account in $\mu$, and variance $N\nu(t)\delta(t-t')$. The fluctuating part of this process is well approximated by a Gaussian white noise $\sqrt{N\nu_0}\xi(t)$, where $\xi(t)$ satisfies $<\xi(t)\xi(t')> = \delta(t-t')$. Note that for simplicity we take the variance of this noise to be independent of time, which is the case for $n_1(t) \ll 1$. These fluctuations are global and perceived by all neurons in the network. Thus, the mean synaptic input received by the neurons becomes

$$CJ\tau\nu(t) + J\sqrt{\epsilon\nu_0}\tau\sqrt{\tau}\xi(t) + \mu_{ext}$$

Inserting this mean synaptic input in the drift term of the Fokker-Planck equation, we can rewrite Eq. (17) as

$$\tau \frac{\partial Q}{\partial t} = \frac{\partial}{\partial y} \left\{ [y + G\nu(t - \delta) + \eta\sqrt{\tau}\xi(t)]Q \right\} + \frac{1}{2} \frac{\partial^2 Q}{\partial y^2}$$

(26)

where $\eta$ denotes the intensity of the noise stemming from these global fluctuations. $\eta$ tends to zero as the network size increases

$$\eta = \sqrt{\epsilon\sigma_0^1}$$

(27)

Taking into account this global noise term in the derivation of the reduced equation, we obtain, after some calculations described in Appendix C,

$$\tau \frac{d\hat{n}_1}{dt} = A\hat{n}_1 - B|\hat{n}_1|^2\hat{n}_1 + D\sqrt{\tau}\zeta(t)$$

(28)

in which $A$, $B$ and $D$ are given by Eqs. (91,92,94), and $\zeta$ is a complex white noise such that $<\zeta(t)\zeta^*(t')> = \delta(t-t')$. $D$ is proportional to $\eta$, i.e. to both the square root of the connection probability and to the ratio between local and total fluctuations.

Thus, the effect of the finite size of the network is to add a small stochastic component to the evolution equation of $n_1$, Eq. (28). Its main effect is to produce a phase diffusion of the collective oscillation $\hat{n}_1$; this global phase diffusion in a network of finite size is well-known (see e.g. (Rappel and Karma, 1996) for a simple example) which leads to the damping of the oscillation in the autocorrelation function.

---

7T
Amplitude of the autoco"rrelation

From the reduced Eq. (28), one can compute exactly the autoco"rrelation at zero time $C(0)$ as shown in Appendix C. This gives:

- In the stationary regime far from the critical line, $A_r < 0$, $|D|/|A_r| \ll 1$:

  $$C(0) - 1 \sim \frac{|D|^2}{|A_r|} \sim O \left( \frac{C}{N} \right)$$  

  The amplitude of the fluctuations in the global activity are proportional to $C/N$ and thus vanish when the connection probability goes to zero.

- On the critical line, $A_r = 0$

  $$C(0) - 1 = \frac{2|D|}{\sqrt{\pi B_r}} \sim O \left( \frac{C}{\sqrt{N}} \right)$$  

  The amplitude of the fluctuations are proportional to the square root of the connection probability.

- In the oscillatory regime far from the critical line, $A_r > 0$, $|D|/A_r \ll 1$

  $$C(0) - 1 \sim \frac{2A_r}{B_r} \sim O(1)$$  

  In this regime the amplitude of the oscillation is to leading order independent of the noise amplitude.

Oscillations below the critical line

In the stationary regime far from the critical line, the fluctuations of activity $n_1$ provoked by the noise term can be considered small and thus we can neglect the cubic term. It is then easy to calculate the autocorrelation (AC) of the activity,

$$C(s) = 1 + \frac{|D|^2}{|A_r|} \exp \left( -\frac{|A_r|s}{\tau} \right) \cos \left( [\omega_c + A_i] \frac{s}{\tau} \right)$$  

It is a damped cosine function. The damped oscillation has frequency $(\omega_c+A_i)/\tau$ and damping time constant proportional to $\tau/|A_r|$. The amplitude of the autocorrelation function is proportional to $C/N$.

Oscillations above the critical line

In the oscillatory regime far from the critical line, we find in Appendix C an AC function of the form

$$C(s) = 1 + 2 \frac{A_r}{B_r} \cos \left( (\omega_c + \Delta \omega) s/\tau \right) \exp \left( -\gamma^2(s)/2 \right)$$  

16
It is again a damped cosine function. The damping factor \( \exp \left( -\gamma^2(s)/2 \right) \) is different from an exponential only at short times \( s \sim \delta \). At longer times, \( s \gg \delta \), we obtain again an exponential

\[
\exp \left( -\frac{\gamma^2(s)}{2} \right) = \exp \left( -\frac{|D|^2}{4R^2} \left( 1 + \frac{B^2}{B_r^2} \right) \frac{s}{\tau} \right) \left[ 1 + \frac{|D|^2}{2A_r} + O\left(|D|^4\right) \right]
\]

The damping time constant is proportional to leading order in \(|D|\) to \( 1/|D|^2 \sim N/C \), i.e. to the inverse of the connection probability. When \( N \) goes to infinity at \( C \) fixed the ‘coherence time’ of the oscillation increases linearly with \( N \).

This ‘phase diffusion’ effect is the main finite size effect above the critical line. Both the amplitude and frequency of the oscillation are essentially unaffected by these finite size effects.

### 3.6 Comparison between simulations and theory

The autocorrelation (AC) of the global activity was computed for each set of parameters from a simulation of 20 seconds. Few longer simulations were performed as a check. The autocorrelation obtained in the longer simulations are essentially identical to the one obtained in the 20s simulation.

Since the analysis predicts AC functions described by damped cosine functions, a least square fit of all AC functions was performed with such functions. Thus the full AC is reduced to three parameters, its amplitude at zero lag \( C_0 \), its frequency \( \omega \), and its damping time constant (or coherence time) \( \tau_c \)

\[
C(s) = 1 + C_0 \exp \left( -\frac{|s|}{\tau_c} \right) \cos(\omega s)
\]

We then compared the result of the fitting procedure with the analytical expressions.

We have varied the magnitude of the external noise \( \sigma_{ext} \) from 0 to 5 mV. This brings the network from the ‘oscillatory’ to the ‘stationary’ state.

In Fig. 6 we plot together the results of simulations and theory. In these figures the diamonds are the simulation results; the dashed lines, the analytical results. In A, the short-dashed line indicates the amplitude in the limit \( N \to \infty \), while the long-dashed line indicates the amplitude calculated analytically taking into account finite size effects. Last, the crosses are obtained simulating numerically the reduced equation, Eq. [28]. We find that, in the ‘stationary’ regime as well as in the oscillatory regime close to the bifurcation point, the amplitude of the oscillation obtained in the simulation is in very good agreement with the calculation (Fig. 6.A). On the other hand, as the amplitude of the oscillation becomes of the same order as the average frequency, \( C_0 \sim 1 \), higher order effects become important and the calculation overestimates the amplitude of the AC. For the frequency of the oscillation (Fig. 6.B), the calculation reproduces quite well the results of the simulations, except for very low noise levels, for which we are rather far from the bifurcation point. Note that the frequency ranges for this set of parameters from 70 to 180Hz, depending on the level of external noise. Thus, without varying the time constants \( \tau \) and \( \delta \), we find that the same network is able to sustain a collective oscillation at quite different frequencies.
Figure 6: Parameters of the AC function vs $\sigma_{ext}$. A. Amplitude of the AC at zero lag. B. Frequency. C. Damping time constant. Diamonds: simulation of the full network. Crosses: simulation of the reduced equation. Dashed lines: theory. In A, the short-dashed line represents the amplitude in the limit $N \to \infty$ Parameters: $\tau = 20 \text{ms}$, $J = -0.1 \text{mV}$, $C = 1000$, $N = 5000$, $\theta = 20 \text{mV}$, $V_r = 10 \text{mV}$, $\mu_{ext} = 25 \text{mV}$, $\delta = 2 \text{ms}$. 

\[ \]
Last, the approximate analytical expressions for the damping time constant agree well with the simulation away from the bifurcation point, as expected (Fig. 6.C). On the other hand, the simulation of the reduced equation is in good agreement with the network simulations in the whole range of $\sigma_{\text{ext}}$.

In Fig. 7 we compare the full AC functions from theory (simulation of the reduced equation) and network simulations in three regimes, to show the good agreement between both.

4 Extensions

In the previous sections a very simple network has been analyzed and the question of the effect of some of our simplifying assumptions legitimately arises. In particular, we have chosen exactly identical neurons. It can be wondered how the results are modified when some variations in neuron properties are taken into account. In order to address this question, we show how the previous analysis can be generalized in two cases. Since we have seen that the oscillation frequency is tightly linked to synaptic times, the effect of a fluctuation in synaptic times is investigated first. We then consider the effect of a fluctuation in the number of connections per neuron which has been found to result in a wide spectrum of neuron steady discharge rates (Amit and Brunel, 1997b). In both cases, it is reassuring to find that the picture obtained from the simple model analysis remains accurate. We finally consider a model with synaptic currents of finite duration to analyse more precisely which time scale plays the role of our ”synaptic time” in this more realistic case.

4.1 Effect of inhomogeneous synaptic times

The analysis can easily be extended to the case in which time constants at each synaptic site are drawn randomly and independently from an arbitrary probability density function (pdf) $Pr(\delta)$ (see Appendix D). In the following we consider the case of a uniform pdf between 0 and $2\delta$.

Fig. 8 shows how the instability line is modified by random synaptic times. The region where the oscillatory instability appears shrinks to the area above the dashed line. As the distribution of synaptic times widens, the stationary state becomes more stable. The introduction of random synaptic times also slightly reduces the frequency of the oscillation.

The critical line is thus quite sensitive to the distribution of synaptic times. In fact, distributions of synaptic times can be found such that the stationary state is always stable (e.g. for an exponential distribution $Pr(\delta) = \exp(-\delta/\delta_0)/\delta$).

4.2 Effect of inhomogeneous connectivity

The analysis can also be extended to the case when the number of connections impinging on a neuron is no longer fixed at $C$, but rather connections are drawn at random independently at each site. In that case the number of connections received by a neuron is a random variable with mean $C$ and standart deviation $\sim \sqrt{C}$.  

19
Figure 7: AC for: A. $\sigma_{ext} = 2mV$. B. $\sigma_{ext} = 3mV$. C. $\sigma_{ext} = 4mV$. Parameters as in Fig. 6. Full lines: network simulation. Dashed lines: theory (simulation of the reduced equation).
Figure 8: Instability line in the plane \((\mu_{ext}, \sigma_{ext})\) for \(\tau = 20 \text{ms}, J = 0.1 \text{mV}, C = 1000, \theta = 20 \text{mV}, V_r = 10 \text{mV}, \delta = 2 \text{ms}\). Full line: all synaptic times equal to \(\delta\). Dashed line: synaptic times drawn from a uniform distribution from 0 to 2\(\delta\).

Figure 9: Effect of inhomogeneity in the connections on the instability line in the plane \((\mu_{ext}, \sigma_{ext})\) for \(\tau = 20 \text{ms}, J = -0.1 \text{mV}, C = 1000, \theta = 20 \text{mV}, V_r = 10 \text{mV}, \delta = 2 \text{ms}\). Full line: all neurons receive \(C\) connections. Dashed line: connections are drawn randomly and independently at each synaptic site with probability \(C/N\).
This inhomogeneity in the connectivity provokes a significant inhomogeneity in the individual spike rates even for $C$ large, because differences between the average input received by two neurons are of the same order as the SD of the synaptic input. The distribution of frequencies for an arbitrary network of excitatory and inhibitory neurons has been obtained in (Amit and Brunel 1997b). The main steps leading to this distribution are described in appendix E. Next we study how inhomogeneity affects the dynamical properties of the network. Fig. 9 shows that the instability line is almost unaffected by the inhomogeneity. The frequency of the global oscillation is also very close to the one of the homogeneous case.

Amit and Brunel (1997b) had shown by simulations that the degree of synchronization of a neuron with the global activity is strongly affected by its spike rate: neurons with low firing frequencies tend to be more synchronized with the global activity than neurons with high frequencies. In appendix E we calculate analytically the degree of synchronization of individual neurons as a function of their frequency. The result is shown in Fig. 10 in which the relative amplitude $C(\nu)$ of the cross-correlation between neurons firing at frequency $\nu$ and the global activity obtained analytically is compared with the result of simulations. It shows indeed that low-rate neurons are more synchronized with the global activity than high-rate neurons. The relative amplitude of the cross-correlation between two neurons of frequency $\nu_1$ and $\nu_2$ is given by the product of the two amplitudes, $C(\nu_1)C(\nu_2)$. Note that the heterogeneity in rates and cross-correlations is not very pronounced here, because near the critical line the fluctuations in the external input dominate the local fluctuations, which tends to suppress this heterogeneity. In a network with both excitatory and inhibitory neurons with an external excitatory input of the same order than the internal excitatory contribution, this heterogeneity is much more pronounced (Amit and Brunel 1997b).
4.3 Effect of more realistic synaptic responses

Our analysis has been carried out for synaptic currents which are described by a delta pulse. One may wonder how the analysis generalizes for more realistic postsynaptic currents. We consider a function $f(t)$ describing the shape of the postsynaptic current when a spike is emitted at time $t = 0$ (see e.g. Gerstner 1995 for a review of different types of synaptic responses). $f(t)$ is chosen such as

$$\int dt f(t) = 1$$

An example often used in modelling studies and shown in Fig. 2 is the $\alpha$-function with a latency $\tau_L$ and a characteristic synaptic time $\tau_S$:

$$f(t) = \begin{cases} \frac{t - \tau_L}{\tau_S} \exp\left(-\frac{t - \tau_L}{\tau_S}\right) & \text{for } t > \tau_L \\ 0 & \text{otherwise.} \end{cases} \quad (34)$$

The total synaptic current arriving at neuron $i$ is now

$$R_i(t) = \tau \sum_j J_{ij} \sum_k f(t - t_{kj}^k)$$

In the diffusion approximation the synaptic current becomes

$$R_i(t) = \mu(t) + \Xi_i(t)$$

in which the average part is given as a function of the frequency $\nu$ and the synaptic response function $f$ by

$$\mu(t) = \mu_{ext} - CJ \int dt' \nu(t') f(t - t') \tau.$$  

On the other hand, the fluctuating part $\Xi_i(t)$ can no longer be approximated by a pure white noise and exhibits temporal correlations at the scale of the width of the PSC function $f(t)$. These temporal correlations in the currents complicate significantly the analysis, since the evolution of the distribution of the membrane potentials is no longer given by a simple one-dimensional Fokker-Planck equation. For the case of the $\alpha$-function, we would need to solve the problem described by a three dimensional Fokker-Planck equation. Such an analysis is beyond the scope of the present paper. Here, we choose to ignore, as a first approximation, these temporal correlations. Thus we consider only the effect of the PSC function on the average synaptic currents. In this approximation, the effect of the PSC function becomes equivalent to that of a distribution of synaptic times in the delta pulse PSC case considered in section 4.1. For example, in the limit in which $\tau_S$ and $\tau_L$ are small compared to the integration time constant, the equations for the bifurcation point are

$$G = \sqrt{\omega} \left[ 2 \frac{\tau_S}{\tau} \omega \cos \left( \omega \frac{\tau_L}{\tau} \right) + \left( 1 - \frac{\tau_S^2}{\tau^2} \omega^2 \right) \sin \left( \omega \frac{\tau_L}{\tau} \right) \right]$$

$$H = \left( 1 - \frac{\tau_S^2}{\tau^2} \omega^2 \right) \left[ \cos \left( \omega \frac{\tau_L}{\tau} \right) + \sin \left( \omega \frac{\tau_L}{\tau} \right) \right] + 2 \frac{\tau_S}{\tau} \omega \left[ \cos \left( \omega \frac{\tau_L}{\tau} \right) - \sin \left( \omega \frac{\tau_L}{\tau} \right) \right]$$

(35)
Figure 11: Dependence of the frequency of the oscillation near the bifurcation threshold on the synaptic decay time constant $\tau_S$, for $\tau_L = 2\text{ms}$. Network parameters as in Fig. 3. External inputs have $\mu_{\text{ext}} = 25\text{mV}$, $\sigma_{\text{ext}} = 2\text{mV}$. This point is near the bifurcation line in the whole range of $\tau_S$. $\diamond$: simulations. Full lines: frequency given by the approximate analysis, Eq. (35) for $H = 1$ (lower curve), and $H = 0$ (upper curve).

In the case $\tau_L = 0$ (zero latency) the equations simplify to

$$G = 2\sqrt{\frac{\omega \tau_S}{\tau}}$$

and

$$H = 1 - \frac{\tau_S^2}{\tau^2} \omega^2 + 2\frac{\tau_S}{\tau} \omega$$

In the case $H = 1$, the frequency of the oscillation near the bifurcation point is equal to $1/(\pi \tau_S)$. Note that the dependence of the frequency on $\tau_S$ in the $\alpha$ function PSC case is similar to the dependence on $\delta$ in the delta pulse PSC case, Eq. (21).

To check the validity of this approximation, we have performed numerical simulations with fixed latency $\tau_L = 2\text{ms}$, varying the decay time constant of the inhibitory post synaptic currents (IPSC) $\tau_S$. The results are shown in Fig. 11. The approximate analysis predicts the frequency is in the region between the two full lines (corresponding to $H = 0$ and $H = 1$). Simulation results deviate from the approximate analysis already at rather small values of $\tau_S$, because of the effect of temporal correlations in the synaptic currents, which have the same scale as the period of the oscillation. Nonetheless the approximation gives a good qualitative picture of the dependence of the frequency on $\tau_S$.

Note that the frequencies obtained in this way can be directly compared to the data of (Whittington et al 1995, Traub et al 1996) since the decay time constant of the PSCs can be identified with their parameter $\tau_{\text{GABA}}$. The frequencies obtained in the simulations are very close to the ones obtained in that study. For example, we obtain a frequency of about 40Hz when $\tau_S = 10\text{ms}$, in agreement with the in vitro recordings and the simulations of the more complex model of (Whittington et al 1995, Traub et al 1996). However, one has to be careful with such a comparison, since in that in vitro study, interneurons seem to fire at population frequency.
5 Conclusion

We have studied the existence of fast global oscillation in networks where individual neurons show irregular spiking at a low rate. We have first shown that the phenomenon can be observed in a sparsely connected network composed of basic integrate and fire neurons. In this very simplified setting, the phenomenon has been precisely analyzed. At the simplest level, it differs from other modes of synchronization which lead to global oscillation in that recording at the individual neuron level shows a stochastic spike emission with nearly Poissonian interspike intervals and little indication of the collective behavior (see the ISI histograms in Fig. 3). This oscillation regime has some similarity with that obtained in Wang et al (1995) where a hyperpolarization-activated cation current seems to play the role of our random external inputs in generating intermittent activity in the network. This type of weak synchronization has sometimes been rationalized as coming from filtering of external noise by recurrent inhibition (Traub et al 1989 and refs. therein). Our analysis leads to a somewhat different picture.

We have found that, in the limit of an infinite network, the global oscillation is due to an oscillatory instability (a supercritical Hopf bifurcation) of the steady state. This instability occurs at a well defined threshold and arises from the competition between the recurrent inhibition which favors oscillations and the intrinsic noise in the system which tends to suppress it.

We have found that the global oscillation period is controlled by the synaptic time. This appears to agree with previous experimental findings on slices of the rat hippocampus and with simulations results (Whittington et al 1995, Traub et al 1996) where it is however assumed that neurons fire at population frequency, unlike those of our model. A similar decrease in population frequency when the GABA characteristic time is varied is also observed in a recent in vitro experiment in which neurons fire sparsely (Fisahn et al 1998). More work is necessary to clarify the relative roles of the different time constants (latency, IPSC rise time, IPSC decay time) that are commonly used to describe the synaptic response.

The oscillation period also depends on the characteristics of the external input, and particularly on the magnitude of the external noise, as shown by Fig. 3. The initial rise in the frequency when one increases $\sigma_{ext}$ followed by a saturation at sufficiently large $\sigma_{ext}$ looks in fact similar to the dependence of the frequency on the amount of glutamate applied to hippocampal CA1 region in vitro (Traub et al 1996). Our network is in a stationary state when external inputs are low and switches to an oscillatory regime when the magnitude of the external inputs is increased. This phenomenon resembles the induction of a gamma rhythm in the hippocampal slice mediated by carbachol (Fisahn et al 1998), and the induction of faster 200Hz rhythms, believed to be provoked by a massive excitation of CA1 cells through Schaeffer collaterals (see e.g. Buzsáki et al 1992). It is also interesting to note that a single network, with its internal parameters fixed, is able to sustain collective oscillations in different frequency ranges, when the characteristics of the external input are varied.

In a finite network, the sharp transition is smoothened but the global oscillation has different characteristics above and below the critical threshold. Below thresh-
old, its amplitude decreases as the network size is increased. Above threshold, an increase in the neuron number does not greatly modify the oscillation amplitude but increases its coherence time. It has been shown that the whole picture of a Hopf bifurcation with a well-defined threshold remains accurate when some of our simplifying assumptions are relaxed. It would be interesting to extend this finding to more realistic descriptions.

Our analysis also raises the important question of the synchronisation mode used in real neural systems. Do neocortical or hippocampal neurons behave as oscillators with a frequency equal to the population frequency, or irregularly with firing rates lower than the population frequency? In hippocampus, pyramidal cells seems clearly to be in an irregular, low rate regime, during in vivo gamma (Bragin et al 1995), in vivo 200Hz (Buzsáki et al 1992) and in vitro gamma oscillations (Fisahn et al 1998). More recent experimental data indicates that interneurons also typically fire at a lower frequency than the population frequency during 200Hz oscillations in CA1 (Csicsvari 1998). Further experimental work is needed in order to clarify this important issue.

We have obtained a reduced description of the collective dynamics. The analysis can certainly be extended to more complicated networks, composed of neurons of different types or that are spatially extended. This reduced description will hopefully prove useful in clarifying the mechanisms of long range synchrony and in studying propagation phenomena (Delaney et al 1996, Prechtl et al 1997).

Finally, and most importantly, the exact roles of fast oscillations remain, at present, unclear. Are they useful for putting in resonance different neuronal populations as it has been suggested? Can they serve to build a fast detector with slowly firing neurons? Are they used as a clock mechanism? Or do they reflect the usefulness of having a network where different neuronal populations fire in succession on a short time scale, to code spatial information in the temporal domain? Recent experiments (MacLeod and Laurent 1996, Stopfer et al 1997) make us hope that elucidating the real meaning of these collective oscillations, at least in some neural systems, is now an attainable goal. This is a question to which we hope to return in the future.

Acknowledgments. We are grateful to A. Karma for discussions and for his very stimulating role at the beginning of this work, and to T. Bal, R. Gervais and P. Salin for informing us on real neural networks. N.B. is grateful to S. Fusi for useful discussions. V.H. is glad to thank at last A. Babloyantz for an invitation to a stimulating ESF workshop in Lanzarote which was a nice opportunity to first learn about fast neuronal oscillations. We thank D. Amit and anonymous referees for their helpful comments on the manuscript.

Appendix

The details of our computations are given in the following. We have found it convenient to use the rescaled variables,

\[ P = \frac{2\tau \nu_0}{\sigma_0} Q, \quad G = \frac{C J \tau \nu_0}{\sigma_0} \frac{\mu_0.1}{\sigma_0}, \quad H = \frac{C J^2 \tau \nu_0}{\sigma_0^2} = \frac{\sigma_{0.1}^2}{\sigma_0^2}, \]

(38)
\[ y = \frac{V - \mu_0}{\sigma_0}, \quad y_\theta = \frac{\theta - \mu_0}{\sigma_0}, \quad y_r = \frac{V_r - \mu_0}{\sigma_0}, \quad \nu = \nu_0(1 + n(t)) \] (39)

\( J \) and \( G \) are positive.

Using Eqs. (38,39) the Fokker-Planck equation, Eq. (7) becomes

\[ \tau \frac{\partial Q}{\partial t} = \mathcal{L}[Q] + \nu(t - \delta) \left( G \frac{\partial Q}{\partial y} + \frac{H}{2} \frac{\partial^2 Q}{\partial y^2} \right) \] (40)

where the linear operator \( \mathcal{L} \) is defined as

\[ \mathcal{L}[Q] = \frac{1}{2} \frac{\partial^2 Q}{\partial y^2} + \frac{\partial}{\partial y} (yQ) \]

The equation is valid on the two intervals \(-\infty < y < y_r \) and \( y_r < y < y_\theta \).

The boundary conditions at \( y_r \) and \( y_\theta \) become: at \( y_\theta \)

\[ Q(y_\theta, t) = 0, \quad \frac{\partial Q}{\partial y}(y_\theta, t) = -\frac{1 + n(t)}{1 + Hn(t - \delta)}; \quad (41) \]

at \( y_r \)

\[ [Q]_{y_r}^y = 0, \quad \left[ \frac{\partial Q}{\partial y} \right]_{y_r}^y = -\frac{1 + n(t)}{1 + Hn(t - \delta)} \] (42)

(the square bracket denotes the discontinuity of the function at \( y \) namely, \([f]_{y_r}^y = \lim_{\epsilon \to 0} \{ f(y + \epsilon) - f(y - \epsilon) \}\)). Note the term in the r.h.s. of Eqs. (41,42) are identical. Thus, when we study the Fokker-Planck equation at different orders, we will mention only the condition at \( y_\theta \). The condition at \( y_r \) can be obtained by replacing the value of the corresponding function at \( y_\theta \) by the discontinuity of the function at \( y_r \). Moreover \( Q(y, t) \) should vanish sufficiently fast at \( y = -\infty \) to be integrable.

The steady state solution obeys

\[ \mathcal{L}[Q_0] = 0 \] (43)

and

\[ \frac{\partial Q_0}{\partial y}(y_\theta) = -1, \quad \left[ \frac{\partial Q_0}{\partial y} \right]_{y_r}^y = -1 \] (44)

It is given by

\[ Q_0(y) = \begin{cases} \exp(-y^2) \int_{y_r}^{y_\theta} du \exp(u^2) & y > y_r \\ \exp(-y^2) \int_{y_r}^{y_\theta} du \exp(u^2) & y < y_r \end{cases} \] (45)

From (43,44), one easily obtains the values of higher derivatives of \( Q_0 \) at \( y = y_\theta \) and their discontinuities at \( y = y_r \), which will be used in the following, using the recurrence relation

\[ \frac{\partial^n Q_0}{\partial y^n}(y) = -2y \frac{\partial^{n-1} Q_0}{\partial y^{n-1}}(y) - 2(n - 1) \frac{\partial^{n-2} Q_0}{\partial y^{n-2}}(y) \] (46)
A Linear stability

The function $Q$ can be expanded around the steady state solution $Q_0(y)$ as

$$Q(y) = Q_0(y) + Q_1(y,t) + Q_2(y,t) + \cdots$$

$$n(t) = n_1(t) + n_2(t) + \cdots$$

(47)

At first order, one obtains the linear equation

$$\tau \frac{\partial Q_1}{\partial t} = L[Q_1] + n_1(t - \delta) \left( G \frac{dQ_0}{dy} + H \frac{d^2Q_0}{dy^2} \right)$$

(48)

together with the boundary conditions

$$Q_1(y_\theta, t) = 0, \quad \frac{\partial Q_1}{\partial y}(y_\theta) = -n_1(t) + H n_1(t - \delta)$$

(49)

and

$$[Q_1]^y_{y_r} = 0, \quad \left[ \frac{\partial Q_1}{\partial y} \right]^y_{y_r} = -n_1(t) + H n_1(t - \delta)$$

(50)

Eigenmodes of (48) have a simple exponential behaviour in time

$$Q_1(y, t) = \exp(\lambda t/\tau) \hat{n}_1(\lambda) \hat{Q}_1(y, \lambda), \quad n_1(t) = \exp(\lambda t/\tau) \hat{n}_1(\lambda)$$

and obey an ordinary differential equation in $y$

$$\lambda \hat{Q}_1(y, \lambda) = L[\hat{Q}_1](y, \lambda) + \exp(-\lambda \delta/\tau) \left( G \frac{dQ_0}{dy} + H \frac{d^2Q_0}{dy^2} \right)$$

(51)

together with the boundary conditions

$$\hat{Q}_1(y_\theta, t) = 0, \quad \frac{\partial \hat{Q}_1}{\partial y}(y_\theta) = -1 + H \exp(-\lambda \delta/\tau),$$

and similar conditions at $y_r$.

The general solution of Eq. (51) can be written as a linear superposition of two independent solutions $\phi_{1,2}$ of the homogeneous equation $1/2\phi'' + y\phi' + (1 - \lambda)\phi = 0$ plus a particular solution which can be obtained by differentiating Eq. (43) with respect to $y$,

$$\hat{Q}_1(y, \lambda) = \left\{ \begin{array}{ll}
\alpha_1(\lambda)\phi_1(y, \lambda) + \beta_1(\lambda)\phi_2(y, \lambda) + \hat{Q}_p^1(y, \lambda) & y > y_r \\
\alpha_1(\lambda)\phi_1(y, \lambda) + \beta_1(\lambda)\phi_2(y, \lambda) + \hat{Q}_p^1(y, \lambda) & y < y_r
\end{array} \right.$$  

(52)

with

$$\hat{Q}_p^1(y, \lambda) = e^{-\lambda \delta/\tau} \left( \frac{G}{1 + \lambda} \frac{dQ_0(y)}{dy} + \frac{H}{2(2 + \lambda)} \frac{d^2Q_0(y)}{dy^2} \right)$$

(53)

Solutions of the homogeneous equation $1/2\phi'' + y\phi' + (1 - \lambda)\phi = 0$ can be obtained by their series expansion around $y = 0$. They are found to be a linear combination of two functions. The first one can be chosen as

$$\phi_1(y, \lambda) = 1 + \sum_{n=1}^{+\infty} (-1)^n \frac{(2y)^{2n}}{(2n)!} \prod_{k=0}^{n-1} \left( k + \frac{1 - \lambda}{2} \right)$$

(54)
It coincides with the confluent hypergeometric function $M[(1 - \lambda)/2, 1/2, -y^2]$ (see e.g. Abramovitz and Stegun 1970). A second independent solution can also be expressed in terms of the hypergeometric function $M$ as

$$2yM \left(1 - \frac{\lambda}{2}, \frac{3}{2}, -y^2\right) = 2y + \sum_{n=1}^{+\infty}(-1)^n \frac{(2y)^{2n+1}}{(2n+1)!} \prod_{k=1}^{n} (k - \frac{\lambda}{2})$$  (55)

The asymptotic behaviour of both functions can conveniently be obtained from the following integral representations valid for $\text{Re}(\lambda) < 1/2$

$$\phi_1(y, \lambda) = \frac{1}{\Gamma(\frac{1-\lambda}{2})} \int_{0}^{+\infty} dt e^{-t} \cos(2y\sqrt{t})(t - \frac{1+\lambda}{2})$$

$$2yM \left(1 - \frac{\lambda}{2}, \frac{3}{2}, -y^2\right) = \frac{1}{\Gamma(1 - \frac{\lambda}{2})} \int_{0}^{+\infty} dt e^{-t} \sin(2y\sqrt{t})(t - \frac{1+\lambda}{2})$$  (56)

(after replacing the cosine and sine in (56) by their series expansions it is easily checked that the obtained series in powers of $y^n$ coincide with (54) and (55)). The following asymptotic behaviours are found for $y \to -\infty$

$$2yM \left(1 - \frac{\lambda}{2}, \frac{3}{2}, -y^2\right) \sim -\frac{\sqrt{\pi}}{|y|^{1-\lambda} \Gamma(1/2 + \lambda/2)}$$  (58)

We find it convenient to choose $\phi_2(y, \omega)$ as the particular combination of these two functions which decays exponentially (i.e. like $|y|^{-\lambda} \exp(-y^2)$) at $y = -\infty$,

$$\phi_2(y, \omega) = \frac{\sqrt{\pi}}{\Gamma(\frac{1+\lambda}{2})} M \left(1 - \frac{\lambda}{2}, \frac{1}{2}, -y^2\right) + \frac{\sqrt{\pi}}{\Gamma(\frac{\lambda}{2})} 2yM \left(1 - \frac{\lambda}{2}, \frac{3}{2}, -y^2\right)$$  (59)

Thus for $\hat{Q}_1(y, t)$ to be integrable on $[\infty, y_0]$ we need to require $\alpha_1^{-} = 0$ in (52).

For further reference, we give the asymptotic behaviour for $\lambda_2 = \text{Im}(\lambda) \to +\infty$,

$$\phi_1(y, \lambda_1 + i\lambda_2) \sim \cosh[y\sqrt{\lambda_2 - i\lambda_1 (1 + i)}] \exp(-y^2/2)$$  (60)

$$\phi_2(y, \lambda_1 + i\lambda_2) \sim \frac{\sqrt{\pi}}{\Gamma(\frac{1+\lambda}{2})} \exp[y\sqrt{\lambda_2 - i\lambda_1 (1 + i) - y^2/2}]$$  (61)

where the determination of the square root is fixed by requiring it to be positive for $\lambda_1 = 0$.

Finally, we note that the Wronskian $W\ell$ of $\phi_1$ and $\phi_2$ obeys the first order equation $W\ell' = -2yW\ell$ and has therefore the simple expression

$$W\ell(\phi_1, \phi_2) \equiv \phi_1 \phi_2' - \phi_1' \phi_2 = \frac{2\sqrt{\pi}}{\Gamma(\lambda/2)} \exp(-y^2)$$  (62)

(the prefactor being fixed by (51, 52)).
The four boundary conditions \((13,50)\) give a linear system of four equations for the four remaining unknowns \(\alpha^+_1, \alpha^-_1, \beta^+_1, \beta^-_1\). The condition \(\alpha^-_1 = 0\) needed to obtain an integrable \(\tilde{Q}_1(y, t)\) gives the eigenfrequencies of the linear equation \((18)\). To obtain the required solvability condition and the allied solutions, we find it convenient to use first the two boundary conditions \((49)\) to obtain \(\alpha^+_1\) and \(\beta^+_1\). This gives

\[
\alpha^+_1 = \frac{1}{\text{Wr}(y_\theta)} \left\{ \phi_2(y_\theta)(1 - H e^{-\lambda\delta/\tau}) - W_2 \left[ \tilde{Q}^p_1 \right](y_\theta) \right\} \quad (63)
\]

\[
\beta^+_1 = -\frac{1}{\text{Wr}(y_\theta)} \left\{ \phi_1(y_\theta)(1 - H e^{-\lambda\delta/\tau}) - W_1 \left[ \tilde{Q}^p_1 \right](y_\theta) \right\} \quad (64)
\]

where \(\text{Wr}\) denotes the Wronskian of \(\phi_1, \phi_2\), Eq. \((52)\), and \(W_j(j = 1, 2)\) the Wronskian of the function in its argument and \(\phi_{1,2}\)

\[
W_j \left[ \tilde{Q} \right] = \tilde{Q}\phi'_j - \tilde{Q}'\phi_j \quad \text{for } j = 1, 2.
\]

For matters of convenience we define \(\tilde{\phi}_{1,2}\) and \(\tilde{W}_{1,2}\) by

\[
\tilde{\phi}_{1,2} = \frac{\phi_{1,2}}{\text{Wr}}, \quad \tilde{W}_{1,2} \left[ \tilde{Q}^p_1 \right] = \frac{W_{1,2} \left[ \tilde{Q}^p_1 \right]}{\text{Wr}}
\]

The two boundary conditions at \(y = y_r\) \((50)\) give similar equations for \(\alpha^-_1 - \alpha_1\) and \(\beta^-_1 - \beta_1\) with \(y_\theta\) replaced by \(y_r\)

\[
\alpha^-_1 = \alpha^+_1 - \tilde{\phi}_2(y_r)(1 - H e^{-\lambda\delta/\tau}) - \left[ \tilde{W}_2 \left[ \tilde{Q}^p_1 \right](y) \right]_{y_r}^{y^+_r} \quad (65)
\]

\[
\beta^-_1 = \beta^+_1 + \tilde{\phi}_1(y_r)(1 - H e^{-\lambda\delta/\tau}) - \left[ \tilde{W}_1 \left[ \tilde{Q}^p_1 \right](y) \right]_{y_r}^{y^+_r} \quad (66)
\]

The two expressions \((63,65)\) together with \(\alpha^-_1 = 0\) give the solvability condition and the equation for the eigenfrequencies of \((18)\)

\[
\left( \tilde{\phi}_2(y_\theta) - \tilde{\phi}_2(y_r) \right)(1 - H e^{-\lambda\delta/\tau}) = \tilde{W}_2 \left[ \tilde{Q}^p_1 \right](y_\theta) - \left[ \tilde{W}_2 \left[ \tilde{Q}^p_1 \right](y) \right]_{y_r}^{y^+_r} \quad (66)
\]

When the synaptic time \(\delta\) becomes much smaller than \(\tau\), the roots \(\lambda\) of this equation become large. Considering for definiteness roots \(\lambda = \lambda_1 + i\lambda_2\) with \(\lambda_2 > 0\), in the limit \(\lambda \rightarrow +\infty, \lambda_2 \rightarrow +\infty\), one obtains from \((61)\) that \(\partial_y \phi_2(y_\theta) \gg \partial_y \phi_2(y_r)\) and \(\partial_y \phi_2(y_\theta) \sim \sqrt{\lambda_2 - i\lambda_1(1 + i)\phi_2}\). We then note that for Eq. \((60)\) to have such a root, we need \(G \sim \sqrt{\lambda}\). Since \(H < 1\) by definition, we can neglect the terms proportional to \(H\) in \(\tilde{Q}^p_1\) and finally obtain

\[
G e^{-\lambda\delta/\tau} \frac{\lambda}{\sqrt{\lambda_2 - i\lambda_1(1 + i)}} = -1 + H e^{-\lambda\delta/\tau}
\]

\[
(67)
\]

We focus on the root with the largest real part (together with its complex conjugate). Its real part becomes positive, \(\lambda = i\lambda_2 = i\omega_c\) when

\[
1 - H e^{-i\omega_c\delta/\tau} + \frac{(1 - i)G e^{-i\omega_c\delta/\tau}}{\sqrt{\omega_c}} = 0
\]

i.e.

\[
G = \sqrt{\omega_c} \sin (\omega_c\delta/\tau)
\]

\[H = \sin (\omega_c\delta/\tau) + \cos (\omega_c\delta/\tau).\]
B Weakly non-linear analysis

Our aim is to determine the lowest non-linear terms which saturate the instability which appears when one crosses the critical line in the plane $\mu_{ext}, \sigma_{ext}$. This determines the amplitude of the collective oscillation as well as the non-linear contribution to its frequency in the vicinity of $(G_c, H_c)$. We follow the usual strategy of pushing the development (L7) to higher order. One finds that the nth-order term obey homogeneous linear equations with forcing terms formed by quadratic combinations of lowest-order terms. We first determine the second-order terms which are forced by quadratic combination of first-order terms and therefore oscillate at 0 and 2 of lowest-order terms. We first determine the second-order terms which are forced by quadratic combinations of first-order terms and therefore oscillate at 0 and 2$\omega_c$. At third order, the coupling between first and second order term generate forcing terms at $\omega_c$ and 3$\omega_c$. While there is no problem to determine the 3$\omega_c$ contribution, the $\omega_c$ forcing is resonant and generates secular terms. The dynamics of the first-order terms amplitude is determined by the requirement that it cancels the unwanted secular contribution. The computation is not specially difficult but rather long.

We substitute the developments (L7) of $Q(y, t)$ and $n(t)$ in Eq. (L7) anticipating that the development parameter is of order of the square root of the differences $G-G_c$, $H-H_c$. Departure of $G$ from $G_c$ and of $H$ from $H_c$ will therefore only affect the third-order terms.

The first-order terms have already been obtained,

$$Q_1(y, t) = e^{i\omega_c t/\tau} \hat{n}_1 \hat{Q}_1(y, i\omega_c) + c.c.$$

$$n_1(t) = e^{i\omega_c t/\tau} \hat{n}_1(\omega_c) + c.c.$$ (68)

where $\hat{Q}_1$ is given by Eqs. (L2, L3, L4, L5). In Eq. (68), we recall that c.c. means that complex conjugate terms to those explicitly written have to be added. In the following, we omit the explicit mention of the variable $\lambda$ to lighten the notation since functions of $\lambda$ will all be evaluated at $i\omega_c$ (except when explicitly specified otherwise).

By differentiation of Eq. (68), one can easily obtain recursively the values of higher derivatives of $\hat{Q}_1$ at $y = y_{th}$ and their discontinuities at $y = y_r$, which will be used in the following.

B.1 Second order

We first determine the second-order terms. They obey the equation

$$\frac{\tau}{\partial t} \partial Q_2 = L[Q_2] + n_2(t - \delta) \left( G_c \frac{dQ_0}{dy} + \frac{H_c}{2} \frac{d^2Q_0}{dy^2} \right) + n_1(t - \delta) \left( G_c \frac{\partial Q_1}{\partial y} + \frac{H_c}{2} \frac{\partial^2Q_1}{\partial y^2} \right)$$ (69)

together with the boundary conditions

$$Q_2(y_{th}, t) = 0, \frac{\partial Q_2}{\partial y}(y_{th}) = -n_2(t) + Hn_2(t - \delta) - H^2 n_1^2(t - \delta) + Hn_1(t)n_1(t - \delta)$$ (70)

and a similar condition in $y_r$.

From (68), the forcing term on the r.h.s of Eq. (69) contains terms at frequencies 2$\omega_c$ and 0. Therefore, we search $Q_2(y, t)$ and $n_2(t)$ under the form

$$Q_2(y, t) = e^{2i\omega_c t/\tau} \hat{n}_2^2 \hat{Q}_{2,2}(y) + e^{-2i\omega_c t/\tau} (\hat{n}_1^*)^2 \hat{Q}_{2,2}(y) + \hat{Q}_{2,0} \hat{n}_1^2$$ (71)

$$n_2(t) = e^{2i\omega_c t/\tau} \hat{n}_2^2 \rho_{2,2} + e^{-2i\omega_c t/\tau} (\hat{n}_1^*)^2 \rho_{2,2} + |\hat{n}_1|^2 \rho_{2,0}$$ (72)
Substitution of (72) into (75) shows that $\hat{Q}_{2,2}$ obeys the ordinary differential equation

$$(2i\omega_c - L)\hat{Q}_{2,2}(\nu) = \rho_{2,2}e^{-2i\omega_c\delta/\tau} \left( G_c\frac{dQ_0}{dy} + \frac{H_c d^2 Q_0}{2 dy^2} \right)$$

$$+ e^{-i\omega_c\delta/\tau} \left( G_c \frac{\partial \hat{Q}_1}{\partial y} + \frac{H_c \partial^2 \hat{Q}_1}{2 \partial y^2} \right)$$

(73)

together with the boundary conditions

$$\hat{Q}_{2,2}(\nu_0, t) = 0, \frac{\partial \hat{Q}_{2,2}}{\partial y}(\nu_0) = -\rho_{2,2} + He^{-2i\omega_c\delta/\tau} \rho_{2,2} - H^2 e^{-2i\omega_c\delta/\tau} + He^{-i\omega_c\delta/\tau}$$

and a similar condition in $\nu_r$.

As above, the general solution of (73) is written as a superposition of solution of the homogeneous equation and a particular solution

$$\hat{Q}_{2,2}(\nu) = \left\{ \begin{array}{ll}
\alpha^+ \phi_1(\nu, 2i\omega_c) + \beta^+ \phi_2(\nu, 2i\omega_c) + \rho_{2,2} \hat{Q}^{so}_{2,2} + \hat{Q}^{lo}_{2,2} & \nu > \nu_r \\
\alpha^- \phi_1(\nu, 2i\omega_c) + \beta^- \phi_2(\nu, 2i\omega_c) + \rho_{2,2} \hat{Q}^{so}_{2,2} + \hat{Q}^{lo}_{2,2} & \nu < \nu_r 
\end{array} \right.$$ 

(74)

where

$$\hat{Q}^{lo}_{2,2} = e^{-2i\omega_c\delta/\tau} \left( \frac{G_c}{1 + 2i\omega_c} \frac{dQ_0}{dy} + \frac{H_c}{4(1 + i\omega_c)} \frac{d^2 Q_0}{dy^2} \right)$$

$\hat{Q}_{2,2}$ can be obtained by differentiation of $Q_0$ and $\hat{Q}_1$ using (48) and (51) and involves only terms of lower order which have already been determined,

$$\hat{Q}^{lo}_{2,2}(\nu) = e^{-i\omega_c\delta/\tau} \left( \frac{G_c}{1 + i\omega_c} \frac{\partial \hat{Q}_1}{\partial y} + \frac{H_c}{2(2 + i\omega_c)} \frac{\partial^2 \hat{Q}_1}{\partial y^2} \right)$$

$$- e^{-2i\omega_c\delta/\tau} \left( \frac{G_c^2}{2(1 + i\omega_c)^2} \frac{d^2 Q_0}{dy^2} + \frac{H_c G_c}{(2 + i\omega_c)(2 + i\omega_c)} \frac{d^3 Q_0}{dy^3} + \frac{H_c^2}{8(2 + i\omega_c)^2} \frac{d^4 Q_0}{dy^4} \right)$$

The four boundary conditions for $\hat{Q}_2$ determine the four unknowns $\alpha^+, \beta^+, \beta^-, \alpha^-$ in terms of $\rho_{2,2}$ and the previously determined functions. We obtain $\rho_{2,2}$ with the integrability condition $\alpha^- = 0$

$$\left( \tilde{\phi}_2(\nu_0) - \tilde{\phi}_2(\nu_1) \right) H e^{-i\omega_c\delta/\tau} (1 - He^{-i\omega_c\delta/\tau}) + \tilde{W}_2 \left[ \hat{Q}^{lo}_{2,2}(\nu_0) \right] (\nu_0) - \tilde{W}_2 \left[ \hat{Q}^{lo}_{2,2}(\nu_1) \right] (\nu_1)$$

(75)

in which all functions are taken at argument $2i\omega_c$.

The component at frequency zero $\hat{Q}_{2,0}$ obeys

$$0 = L[\hat{Q}_{2,0}] + \rho_{2,0} \left( G_c \frac{dQ_0}{dy} + \frac{H_c d^2 Q_0}{2 dy^2} \right) + \left[ e^{-i\omega_c\delta/\tau} \left( G_c \frac{\partial \hat{Q}_1}{\partial y} + \frac{H_c \partial^2 \hat{Q}_1}{2 \partial y^2} \right) + \text{c.c.} \right]$$

(75)
together with the boundary conditions

\[ \dot{Q}_{2,0}(y_0, t) = 0, \frac{\partial \dot{Q}_{2,0}}{\partial y}(y_0) = -\rho_{2,0}(1 - H) - 2H^2 \cos(\omega_c \delta / \tau) \]

and a similar condition in \( y_r \).

Its general solution can be written

\[
\dot{Q}_{2,0}(y) = \begin{cases} 
\alpha^+_{2,0} Q_0 + \beta^+_2 \exp(-y^2) + \rho_{2,0} \dot{Q}^{so}_{2,0}(y) + \dot{Q}^{lo}_{2,0}(y) & y > y_r \\
\alpha^-_{2,0} Q_0 + \beta^-_2 \exp(-y^2) + \rho_{2,0} \dot{Q}^{so}_{2,0}(y) + \dot{Q}^{lo}_{2,0}(y) & y < y_r
\end{cases} \tag{76}
\]

where

\[ \dot{Q}^{so}_{2,0}(y) = \left( G_c \frac{dQ_0}{dy} + \frac{H_c}{4} \frac{d^2Q_0}{dy^2} \right) \]

and it is again convenient to construct the particular solution \( \dot{Q}^{lo}_{2,0} \) by differentiation

\[
\dot{Q}^{lo}_{2,0}(y) = \left[ e^{+i\omega_c \delta / \tau} \left( \frac{G_c}{1-i\omega_c} \frac{\partial \dot{Q}_1}{\partial y} + \frac{H_c}{2(2-i\omega_c)} \frac{\partial^2 \dot{Q}_1}{\partial y^2} \right) + c.c. \right] \\
- \left( \frac{G_c^2}{1+\omega_c^2} \frac{d^2Q_0}{dy^2} + \frac{H_cG_c}{(1+\omega_c^2)(4+\omega_c^2)} \frac{d^3Q_0}{dy^3} + \frac{H_c^2}{4(4+\omega_c^2)} \frac{d^4Q_0}{dy^4} \right) \tag{77}
\]

In this case, the four boundary conditions for \( \dot{Q}_{2,0} \) are not independent and are not sufficient to determine the four unknowns \( \alpha^+_{2,0}, \alpha^-_{2,0}, \beta^+_2, \beta^-_2 \) in functions of lower order terms. This comes about because some choices of \( Q_{2,0} \) are equivalent to changing the normalization of \( Q_0 \). One should therefore eliminate them by imposing the condition \( \int_{-\infty}^{\infty} dy \dot{Q}_{2,0} = 0 \). In this way, one obtains,

\[
\rho_{2,0} = \left[ \frac{\left( -2 \frac{G_c}{1+\omega_c^2} \gamma_G + \frac{H_c}{4+\omega_c^2} \gamma_H \right) e^{y^2} \int_{-\infty}^{y_0} du e^{-u^2} \right]_{y_r}^{y_0} + \gamma_t \right] \tag{78}
\]

where

\[
\gamma_G(y) = G_c y + \cos(\omega_c \delta / \tau) - \omega_c \sin(\omega_c \delta / \tau) - \frac{H_c(2y^2 + 1)}{3}
\]

\[
\gamma_H(y) = 4y \cos(\omega_c \delta / \tau) - 2y \omega_c \sin(\omega_c \delta / \tau) + \frac{4G_c(2y^2 + 1)}{3} - H_c(2y^3 + 3y)
\]

\[
\gamma_t = -2(y_0 - y_r) G_c H_c \frac{2 + \omega_c^2}{(1 + \omega_c^2)(4 + \omega_c^2)} + \frac{H_c^2(y_0^2 - y_r^2)}{4 + \omega_c^2}
\]

(the notation \([f]_{y_0}^{y_r} \equiv f(y_0) - f(y_r) \) is used). The derivatives of higher order of \( \dot{Q}_{2,2} \) and \( \dot{Q}_{2,0} \), which are used in the following, can be obtained recursively by differentiation of Eq. (73) and (75).
### B.2 Third order

We can now proceed and study the third order terms. They obey the equation

\[ \frac{\tau}{\partial t} Q_3 = L[Q_3] + n_3(t - \delta) \left( G_c \frac{dQ_0}{dy} + H_c \frac{d^2Q_0}{dy^2} \right) + n_2(t - \delta) \left( G_c \frac{dQ_1}{dy} + \frac{H_c}{2} \frac{d^2Q_1}{dy^2} \right) + n_1(t - \delta) \left( G_c \frac{\partial Q_2}{\partial y} + H_c \frac{\partial^2 Q_2}{\partial y^2} \right) + \cdot \cdot \cdot \]

\[ = \frac{\tau}{\partial t} \hat{Q}_3 + \delta Q_0 + \frac{\tau}{\partial t} \left( \hat{Q}_1 e^{i\omega_c t/\tau} + \frac{\tau}{\partial t} \hat{Q}_1 e^{i\omega_c (t - \delta)/\tau} \right) + \text{c.c.} \]

(79)

Together with boundary conditions

\[ \hat{Q}_3(y_0) = 0 \]

\[ \frac{\partial Q_3}{\partial y}(y_0) = -n_3(t) + Hn_3(t - \delta) - 2H^2n_1(t - \delta)n_2(t - \delta) + H \left( n_1(t)n_2(t - \delta) + n_1(t - \delta)n_2(t) + \frac{H}{2}n_1(t) \right) - H^2n_1(t)n_2(t - \delta) + \left( H - H_c \right)n_1(t - \delta) - H\delta \frac{\partial n_1}{\partial t} e^{i\omega_c (t - \delta)/\tau} \]

(80)

and a similar condition holds at \( y_r \).

The last two terms between brackets on the r.h.s. of (79) come from the anticipation that it will be needed to have \( \hat{n}_1 \) change on a slow time scale to cancel secular terms. The first term arises from the explicit time differentiation in Eq. (80) and does not need special explanations. The second is less usual and comes from the delayed forcing \( \nu(t - \delta) \) in (80). Formally introducing a slow time scale \( T = \epsilon t \), the delayed forcing is written \( \nu(t - \delta, T - \epsilon \delta) \). The second term between brackets in (79) is produced by the expansion to first-order in \( \epsilon \) \( \nu(t - \delta, T - \epsilon \delta) = \nu(t - \delta) - \epsilon \partial_T \nu(t - \delta) + \cdot \cdot \cdot \).

The last term in the boundary condition (80) appears in the same way.

The forcing terms on the r.h.s. of (79) oscillate at frequencies \( 3\omega_c \) and \( \omega_c \). Therefore, we search \( Q_3(y, t) \) and \( n_3(t) \) under the form

\[ Q_3(y, t) = e^{3i\omega_c t/\tau} \hat{Q}_{3,3}(y) + e^{i\omega_c t/\tau} \hat{Q}_{3,1}(y) + \text{c.c.} \]

\[ n_3(t) = e^{3i\omega_c t/\tau} \hat{n}_{3,3} + e^{i\omega_c t/\tau} \hat{n}_{3,1} + \text{c.c.} \]

(81)

We focus on the terms at frequency \( \omega_c \) which are resonant with the first order terms. They obey the equation

\[ (i\omega_c - L) \hat{Q}_{3,1}(y) = \hat{n}_{3,1} e^{-i\omega_c \delta/\tau} \left( G_c \frac{dQ_0}{dy} + H_c \frac{d^2Q_0}{dy^2} \right) \]

\[ + |\hat{n}_1|^2 \hat{n}_1 \left\{ \rho_{22} e^{-2i\omega_c \delta/\tau} \left( G_c \frac{\partial \hat{Q}_1}{\partial y} + \frac{H_c}{2} \frac{\partial^2 \hat{Q}_1}{\partial y^2} \right) + \rho_{20} \left( G_c \frac{\partial \hat{Q}_2}{\partial y} + \frac{H_c}{2} \frac{\partial^2 \hat{Q}_2}{\partial y^2} \right) \right\} \]

\[ + e^{-i\omega_c \delta/\tau} \left( G_c \frac{\partial \hat{Q}_{2,0}}{\partial y} + \frac{H_c}{2} \frac{\partial^2 \hat{Q}_{2,0}}{\partial y^2} \right) + e^{i\omega_c \delta/\tau} \left( G_c \frac{\partial \hat{Q}_{2,2}}{\partial y} + \frac{H_c}{2} \frac{\partial^2 \hat{Q}_{2,2}}{\partial y^2} \right) \]

34
\[ + \hat{n}_1 e^{-i\omega_c \delta / \tau} \left( (G - G_c) \frac{dQ_0}{dy} + \frac{(H - H_c)}{2} \frac{d^2Q_0}{dy^2} \right) \]
\[ - \tau \frac{d\hat{n}_1}{dt} \hat{Q}_1 - e^{-i\omega_c \delta / \tau} \frac{d\hat{n}_1}{dt} \left( G_c \frac{dQ_0}{dy} + \frac{H_c}{2} \frac{d^2Q_0}{dy^2} \right) \]  

The general solution of (82) can be written

\[ \hat{Q}_3(y) = \begin{cases} 
\alpha_3^+ \phi_1(y, i\omega_c) + \beta_3^+ \phi_2(y, i\omega_c) + \hat{n}_{3,1} \hat{Q}_{3,1}^0 + \hat{Q}_{3,1}^0 & y > y_r \\
\alpha_3^- \phi_1(y, i\omega_c) + \beta_3^- \phi_2(y, i\omega_c) + \hat{n}_{3,1} \hat{Q}_{3,1}^0 + \hat{Q}_{3,1}^0 & y < y_r
\end{cases} \]  

In the particular solution, \( \hat{Q}_1^p \) is the function that appears at first order, Eq. (53), and as before, we can construct \( \hat{Q}_{3,1}^p \) by differentiation of lower order terms:

\[ \hat{Q}_{3,1}^p = \tau \frac{d\hat{n}_1}{dt} \hat{Q}_{3,1}^d + \hat{n}_1 \hat{Q}_{3,1}^d + \hat{n}_1 |\hat{n}_1|^2 \hat{Q}_{3,1}^c \]  

where \( \hat{Q}_{3,1}^d \) is obtained from \( \hat{Q}_1 \) by differentiation of \( \phi_{1,2} \) and \( \hat{Q}_1^p \) with respect to \( \lambda \)

\[ \hat{Q}_{3,1}^d(y) = \begin{cases} 
\alpha_1^+ \partial_\lambda \phi_1(y, i\omega_c) + \beta_1^+ \partial_\lambda \phi_2(y, i\omega_c) + \partial_\lambda \hat{Q}_1^p(y, i\omega_c) & y > y_r \\
\beta_1^- \partial_\lambda \phi_2(y, i\omega_c) + \partial_\lambda \hat{Q}_1^p(y, i\omega_c) & y < y_r
\end{cases} \]  

and

\[ \hat{Q}_{3,1}^c = e^{i\omega_c \delta / \tau} \left( \frac{G_c}{1 - i\omega_c} \frac{\partial \hat{Q}_{2,2}}{\partial y} + \frac{H_c}{2(2 - i\omega_c)} \frac{\partial^2 \hat{Q}_{2,2}}{\partial y^2} \right) + e^{-i\omega_c \delta / \tau} \left( \frac{G_c}{1 + i\omega_c} \frac{\partial \hat{Q}_{2,0}}{\partial y} + \frac{H_c}{2(2 + i\omega_c)} \frac{\partial^2 \hat{Q}_{2,0}}{\partial y^2} \right) + \rho_2 \left( \frac{G_c}{1 + 2i\omega_c} \frac{\partial \hat{Q}_1}{\partial y} + \frac{H_c}{4} \frac{\partial^2 \hat{Q}_1}{\partial y^2} \right) + \rho_2 e^{-2i\omega_c \delta / \tau} \left( \frac{G_c}{1 + 2i\omega_c} \frac{\partial \hat{Q}_1}{\partial y} + \frac{H_c}{4(1 + i\omega_c)} \frac{\partial^2 \hat{Q}_1}{\partial y^2} \right) \]

\[ - \frac{G_c}{1 + \omega_c^2} \left( \frac{G_c}{3} \frac{\partial^2 \hat{Q}_1}{\partial y^2} + \frac{H_c}{3} \frac{\partial \hat{Q}_1}{\partial y} \right) - \frac{H_c}{4 + \omega_c^2} \left( \frac{G_c}{3} \frac{\partial \hat{Q}_1}{\partial y} + \frac{H_c}{8} \frac{\partial^2 \hat{Q}_1}{\partial y^2} \right) \]

\[ - e^{-2i\omega_c \delta / \tau} \frac{H_c}{2(2 + i\omega_c)} \left( \frac{G_c}{3 + 2i\omega_c} \frac{\partial^3 \hat{Q}_1}{\partial y^3} + \frac{H_c}{4(2 + i\omega_c)} \frac{\partial^4 \hat{Q}_1}{\partial y^4} \right) - \frac{G_c}{1 - i\omega_c} \left( \frac{G_c}{2(1 + i\omega_c)} \frac{\partial \hat{Q}_1}{\partial y} + \frac{H_c}{2(3 + 2i\omega_c)} \frac{\partial^2 \hat{Q}_1}{\partial y^2} \right) - \frac{2 + i\omega_c}{2} \left( \frac{G_c}{2(3 + 2i\omega_c)} \frac{\partial^2 \hat{Q}_0}{\partial y^2} + \frac{H_c}{2(3 + i\omega_c)} \frac{\partial^3 \hat{Q}_0}{\partial y^3} \right) - \rho_2 e^{-i\omega_c \delta / \tau} \frac{2 + i\omega_c}{1 + i\omega_c} \left( \frac{G_c}{2} \frac{d^2Q_0}{dy^2} + \frac{H_c}{2(3 + i\omega_c)} \frac{d^3Q_0}{dy^3} \right) - \rho_2 e^{-i\omega_c \delta / \tau} \frac{2 + i\omega_c}{1 + i\omega_c} \left( \frac{G_c}{2} \frac{d^2Q_0}{dy^2} + \frac{H_c}{2(3 + i\omega_c)} \frac{d^3Q_0}{dy^3} \right) - \rho_2 e^{-i\omega_c \delta / \tau} \frac{4 + i\omega_c}{4(1 + i\omega_c)(2 - i\omega_c)} \left( \frac{G_c}{3} \frac{d^3Q_0}{dy^3} + \frac{H_c}{2(4 + i\omega_c)} \frac{d^4Q_0}{dy^4} \right) - \rho_2 e^{-i\omega_c \delta / \tau} \frac{4 + i\omega_c}{4(1 + i\omega_c)(2 - i\omega_c)} \left( \frac{G_c}{3} \frac{d^3Q_0}{dy^3} + \frac{H_c}{2(4 + i\omega_c)} \frac{d^4Q_0}{dy^4} \right) \]
where

\[ W = Q^{(0)} \]

in which as we did at linear order (see Eq. (63)). We obtain obey a solvability condition. In order to obtain it, we find it convenient to proceed for \( \hat{\alpha} \) similar expressions for \( \alpha_1 \) obtained at first order which has been required to have a zero determinant. Now, upon replacing \( \alpha_3 = 0 \) one can try to determine \( \alpha_3^+, \beta_3^+, \beta_3^- \), \( \hat{n}_3 \) from the four boundary conditions on \( \hat{Q}_{3,1}(y) \). This provides a linear inhomogeneous system for the four unknowns. The inhomogeneous terms are made from \( \hat{Q}_{3,1}^{(0)}(y) \) and its derivatives evaluated at \( y_\theta \) and \( y_r \). But there is a difficulty: since we are considering the resonant part of the third order terms, the linear operator coincides with the 4x4 matrix obtained at first order which has been required to have a zero determinant. So, the equations for \( \alpha_3^+, \beta_3^+, \beta_3^- \), \( \hat{n}_3 \) are solvable only if the inhomogeneous terms obey a solvability condition. In order to obtain it, we find it convenient to proceed as we did at linear order (see Eq. (63, 65)). We obtain \( \alpha_3^+ \) and \( \beta_3^+ \) in terms of \( \hat{n}_3 \) and \( \hat{Q}_{3,1}^{(0)} \) from the 2x2 system given by the two boundary conditions at \( y_\theta \). We then obtain similar expressions for \( \alpha_3^- \) and \( \beta_3^- - \beta_3^+ \). Comparing the two obtained expressions for \( \alpha_3^+ \) and requiring them to be identical provides the solvability condition,

\[
\left( \tilde{\phi}_2(y_\theta) - \tilde{\phi}_2(y_r) \right) \Omega = \tilde{W}_2 \left[ \hat{Q}_{3,1}^{(0)} \right](y_\theta) - \left[ \tilde{W}_2 \left[ \hat{Q}_{3,1}^{(0)} \right](y) \right]^{y_\theta}_{y_r}^{y_\theta + \frac{\beta}{\alpha}} \tag{88}
\]

where

\[
\begin{align*}
\Omega &= -\frac{\delta}{\tau} H e^{-i\omega_\theta^{(a)}/\tau} \frac{d\hat{n}_1}{dt} - \hat{n}_1 \Omega_1 - \hat{n}_1 |\hat{n}_1|^2 \Omega_3 \\
\Omega_1 &= (H - H_c) e^{-i\omega_\theta^{(a)}/\tau} \\
\Omega_3 &= -2H_c^2 e^{-i\omega_\theta^{(a)}/\tau} (\rho_{22} + \rho_{20}) + 3H_c^3 e^{-i\omega_\theta^{(a)}/\tau} \\
&+ H_c \left[ \rho_{22} e^{-2i\omega_\theta^{(a)}/\tau} + e^{i\omega_\theta^{(a)}/\tau} + \rho_{20} (1 + e^{-i\omega_\theta^{(a)}/\tau}) \right] - H_c^2 (2 + e^{-2i\omega_\theta^{(a)}/\tau}) \tag{89}
\end{align*}
\]

With the help of Eqs. (84, 85, 86, 87), this gives the searched for equation of motion for \( \hat{n}_1 \)

\[
\tau \frac{d\hat{n}_1}{dT} = A \hat{n}_1 - B |\hat{n}_1|^2 \hat{n}_1 \tag{90}
\]

in which

\[
A = \frac{-\tilde{W}_2 \left[ \hat{Q}_{3,1}^{(0)} \right](y_\theta) + \left[ \tilde{W}_2 \left[ \hat{Q}_{3,1}^{(0)} \right](y) \right]^{y_\theta}_{y_r} - \left( \tilde{\phi}_2(y_\theta) - \tilde{\phi}_2(y_r) \right) \Omega_1}{\tilde{W}_2 \left[ \hat{Q}_{3,1}^{(0)} \right](y_\theta) - \left[ \tilde{W}_2 \left[ \hat{Q}_{3,1}^{(0)} \right](y) \right]^{y_\theta}_{y_r} + \left( \tilde{\phi}_2(y_\theta) - \tilde{\phi}_2(y_r) \right) \hat{\omega} H e^{-i\omega_\theta^{(a)}/\tau}} \tag{91}
\]
\[
B = \frac{\tilde{W}_2 \left[ \hat{Q}_{3,1} \right] (y_{\theta}) - \left[ \tilde{W}_2 \left[ \hat{Q}_{3,1} \right] (y) \right]^{y_r}_{y_{\theta}} + \left( \tilde{\phi}_2 (y_{\theta}) - \tilde{\phi}_2 (y_r) \right) \Omega_3}{\tilde{W}_2 \left[ \hat{Q}_{3,1}^{d} \right] (y_{\theta}) - \left[ \tilde{W}_2 \left[ \hat{Q}_{3,1}^{d} \right] (y) \right]^{y_r}_{y_{\theta}} + \left( \tilde{\phi}_2 (y_{\theta}) - \tilde{\phi}_2 (y_r) \right) \delta} 
\]

(92)

These expressions simplify in the limit \( \delta / \tau \rightarrow 0 \). In the particular case \( H = 0 \), one obtains Eq. (23) of the main text.

C Effect of noise due to finite-size effects

Inserting the noise in Eq. (79), we obtain

\[
\tau \frac{d \hat{n}_1}{dt} = A \hat{n}_1 - B |\hat{n}_1|^2 \hat{n}_1 + D \sqrt{\tau} \zeta (t) 
\]

(93)

in which \( A \) and \( B \) are given by Eqs. (91,92), while \( D \) is

\[
D = \eta \frac{-\tilde{W}_2 \left[ \hat{Q}_{\text{noise}} \right] (y_{\theta}) + \left[ \tilde{W}_2 \left[ \hat{Q}_{\text{noise}} \right] (y) \right]^{y_r}_{y_{\theta}}}{\tilde{W}_2 \left[ \hat{Q}_{3,1}^{d} \right] (y_{\theta}) - \left[ \tilde{W}_2 \left[ \hat{Q}_{3,1}^{d} \right] (y) \right]^{y_r}_{y_{\theta}}} 
\]

(94)

where

\[
\hat{Q}_{\text{noise}} = \frac{e^{-i \omega_c \delta / \tau} dQ_0}{1 + i \omega_c \frac{dy}{dy}} 
\]

\( \eta \) is given by Eq. (27), and \( \zeta \) is a complex white noise such that \(< \zeta (t) \zeta^* (t') >= \delta (t - t') \).

The autocorrelation at zero time \( C(0) \) is given by

\[
C(0) = 1 + 2 < |\hat{n}_1 (t)|^2 > 
\]

We deduce from Eq. (13) the Fokker-Planck equation describing the evolution of the p.d.f. of both real and imaginary parts of \( \hat{n}_1 \). This equation can be converted in an equation giving the stationary distribution \( Pr(\rho) \) of \( \rho \equiv |\hat{n}_1|^2 \). It satisfies

\[
\frac{\partial}{\partial \rho} \left( |D|^2 \rho \frac{\partial Pr}{\partial \rho} \right) = \frac{\partial}{\partial \rho} \left( [2A_r \rho - 2B_r \rho^2] Pr \right) 
\]

whose solution is

\[
Pr(\rho) = \frac{\exp \left( \frac{2A_r}{|D|^2} \rho - \frac{B_r}{|D|^2} \rho^2 \right)}{\int_{0}^{\infty} \exp \left( \frac{2A_r}{|D|^2} R - \frac{B_r}{|D|^2} R^2 \right) dR} 
\]

and the autocorrelation at zero lag is

\[
C(0) = 1 + 2 \frac{\int_{0}^{\infty} R \exp \left( \frac{2A_r}{|D|^2} R - \frac{B_r}{|D|^2} R^2 \right) dR}{\int_{0}^{\infty} \exp \left( \frac{2A_r}{|D|^2} R - \frac{B_r}{|D|^2} R^2 \right) dR} 
\]

From this exact expression, it is not difficult to obtain the expressions (29,30,31) of the main text.
From Eq. (93), one can compute the behavior of the autocorrelation function \( C(s) \). Far below the critical line, \(|\tilde{n}_1|\) is small and the nonlinear term can be neglected. It is then easy to obtain Eq. (32) of the main text.

In the oscillatory regime far above the critical line, finite size effects provoke fluctuations of activity around the oscillation described by Eq. (24). We consider a small perturbation, both in amplitude and in phase, of the ‘pure’ oscillation \( \tilde{n}_1 \rightarrow \tilde{n}_1(1 + r) \exp(i\phi) \). \( r \) is the perturbation in amplitude, while \( \phi \) is the perturbation in phase. To obtain the evolution equations for \( r \) and \( \phi \) we apply standard stochastic calculus techniques (see e.g. Gardiner 1983, chapter 4), and obtain,

\[
\tau \dot{r} = -A_r(2r + 3r^2 + r^3) + \epsilon \zeta_r + \epsilon^2 \frac{1}{2(1 + r)},
\]

\[
\tau \dot{\phi} = -\frac{B_i A_r}{B_r}(2r + r^2) + \epsilon \zeta_i = \frac{1 + r}{1 + r},
\]

in which \( \epsilon = |D|/R \), and \( \zeta_r, \zeta_i \) are uncorrelated white noises. Note that the last term in the r.h.s. of Eq. (95) appears due to the fact that, upon discretizing Eq. (93) with a small time step dt, \( \phi(t + dt) - \phi(t) \) is of order \( \sqrt{dt} \), not dt. The calculation of the autocorrelation in terms of \( r \) and \( \phi \) gives, keeping only the dominant term,

\[
C(s) = 1 + 2R^2 < \cos ((\omega_c + \Delta \omega)s/\tau + \phi(t + s) - \phi(t)) > .
\]

In order to calculate the autocorrelation we need to calculate the distribution of \( \Delta \phi(s) = \phi(t + s) - \phi(t) \). From Eqs. (93,94) we find that, to leading order in \( \epsilon \), it has a Gaussian distribution with mean 0 and variance

\[
\gamma^2(s) = \frac{|D|^2}{2R^2} \left[ \frac{s}{\tau} + \frac{B_i^2}{2B_r^2 A_r} \left\{ \exp \left( -\frac{2A_r s}{\tau} \right) - 1 + \frac{2A_r s}{\tau} \right\} \right]
\]

Averaging \( \cos((\omega_c + \Delta \omega)s/\tau + \Delta \phi(s)) \) with such a distribution yields

\[
C(s) = 1 + 2R^2 \cos ((\omega_c + \Delta \omega)s/\tau) \exp \left( -\frac{\gamma^2(s)}{2} \right)
\]

We find a damped cosine function as below the critical lines, but now the damping factor is no longer a simple exponential. For small times \( s \ll \tau/(R^2) \), the damping is described by

\[
\exp \left( -\frac{\gamma^2(s)}{2} \right) \sim \exp \left( -\frac{|D|^2 s}{4R^2 \tau} \right)
\]

while for long times \( s \gg \tau/(R^2) \)

\[
\exp \left( -\frac{\gamma^2(s)}{2} \right) \sim \exp \left( -\frac{|D|^2}{4R^2} \left( 1 + \frac{B_i^2}{B_r^2} \right) \frac{s}{\tau} \right)
\]

The damping time constant in both regimes is proportional to 1/\(|D|^2 \sim N/C \), i.e. to the inverse of the connection probability. When \( N \) goes to infinity at \( C \) fixed the ‘coherence time’ of the oscillation increases linearly with \( N \).

The next order in \( \epsilon \) brings (after a rather tedious calculation) a small additional contribution to the variance, so that for long times

\[
\exp \left( -\frac{\gamma^2(s)}{2} \right) = \exp \left( -\frac{|D|^2}{4R^2} \left( 1 + \frac{B_i^2}{B_r^2} \right) \frac{s}{\tau} \right) \left[ 1 + \frac{|D|^2}{2A_r} + O \left( |D|^4 \right) \right]
\]
D Randomly distributed synaptic times

The calculations performed in the case in which all synaptic times have the same value can be repeated in the more general situation in which synaptic times are drawn randomly and independently at each site with distribution $Pr(\delta)$. The difference is that, in all equations were functions of $\delta$ appears, we need to integrate these functions with the p.d.f. $Pr(\delta)$. For example, we find that the critical line where the instability appears is given by

$$\left(\hat{\phi}_2(y_\theta) - \hat{\phi}_2(y_r)\right) \left(1 - H \int Pr(\delta)e^{-w\delta/\tau} d\delta\right) = \tilde{W}_2 \left[\hat{Q}_1^p\right] (y_\theta) - \left[\tilde{W}_2 \left[\hat{Q}_1^p\right] (y)\right]_{y_r}^{y_\theta} \quad (97)$$

in which

$$\hat{Q}_1^p(y, w) = \int Pr(\delta)e^{-w\delta/\tau} d\delta \left(\frac{G}{1 + w} \frac{dQ_0(y)}{dy} + \frac{H}{2(2 + w)} \frac{d^2Q_0(y)}{dy^2}\right) \quad (98)$$

E Inhomogeneous networks

We now relax the constraint that the number of connections received by a neuron be precisely equal to $C$. The connections are randomly and independently drawn at each possible site. They are present with probability $C/N$. In this situation, the dynamics of different neurons will depend on this number of connections they receive: this number is now a random variable with mean $C$ and variance $C(1 - \epsilon)$. For example, their frequency will be a decreasing function of the number of connections. The connectivity matrix is defined by $J_{ij} = J e_{ij}$ where for all $i, j$ $e_{ij} = 1$ with probability $\epsilon$. The distribution of frequencies in the stationary state in such a situation has been obtained, for the case of a network with both excitatory and inhibitory neurons, by (Amit and Brunel 1997b). The distribution of stationary frequencies can be obtained as a special case of this analysis. We briefly recall here the main steps of this analysis, before turning to the stability analysis.

Averaging the synaptic input only on the randomness of spike emission times of presynaptic neurons, we get that the mean and the variance of local inputs are given by

$$\mu_i = J\tau \sum_j e_{ij} \nu_j, \quad \sigma_i^2 = J^2\tau \sum_j e_{ij} \nu_j. \quad \text{E}$$

Since the number of inputs to each neuron is very large, the spatial distribution of the variable $\sum_j e_{ij} \nu_j$, which determines completely the spatial distribution of $\mu$ and $\sigma$, will be close to a Gaussian whose two first moments can be calculated as a function of the two first moments of the spatial distribution of frequencies:

$$<\sum_j e_{ij} \nu_j> = C\nu$$

$$<\left(\sum_j e_{ij} \nu_j - C\nu\right)^2 > = C\left(\nu^2 - C^2\nu^2\right)$$
Thus the variable

\[ z_i = \frac{\sum j e_{ij} \nu_j - C \nu}{\sqrt{C (\nu^2 - \sigma^2)}} \]

has a Gaussian distribution, \( \rho(z) = \exp(-z^2/2)/\sqrt{2\pi} \). Thus a neuron receives, with probability \( \rho(z) \), a local input with moments

\[
\begin{align*}
\mu(z) &= -J \tau(C \nu + z \sqrt{C (\nu^2 - \sigma^2)}) \quad (99) \\
\sigma^2(z) &= J^2 \tau(C \nu + z \sqrt{C (\nu^2 - \sigma^2)}) 
\end{align*}
\]

E.1 Distribution of frequencies in stationary state

In the stationary state the frequency of a neuron with moments \( \mu(z) \) and \( \sigma(z) \) is given by

\[
\nu_0(z) = \left( \tau \sqrt{\pi} \int_{\nu = \mu(z)}^{\nu = \mu(z)} du \exp(u^2)(1 + \text{erf}(u)) \right)^{-1} \quad (101)
\]

The two first moments of the distribution of frequencies can then be determined in a self-consistent way, using

\[
\begin{align*}
\bar{\nu}_0 &= \int dz \rho(z) \nu_0(z), \\
\bar{\nu}_0^2 &= \int dz \rho(z) \nu_0^2(z)
\end{align*}
\]

These equations, together with Eqs. (99, 100, 101), fully determine the whole distribution of stationary frequencies, which can be obtained using the relation

\[
P(\nu) = \int dz \rho(z) \delta(\nu - \nu_0(z))
\]

E.2 Linear stability analysis

The linear stability analysis of Section A can be generalized to the inhomogeneous network. We give here the main steps of this analysis.

We expand the frequencies around the stationary frequency,

\[
\nu(z) = \nu_0(z) (1 + n_1(z,t) + \ldots),
\]

and, defining for each \( z \ y = (x - \mu_0(z))/\sigma_0(z) \),

\[
P = \frac{2\tau \nu_0(z)}{\sigma_0(z)} (Q_0(y, z) + Q_1(y, z, t) + \ldots)
\]

The moments of the spatial distribution of frequencies can be expanded in the same way,

\[
\begin{align*}
\bar{\nu} &= \bar{\nu}_0 (1 + \bar{n}_1(t) + \ldots), \\
\bar{\nu}^2 &= \bar{\nu}_0^2 (1 + \bar{n}_1^2(t) + \ldots),
\end{align*}
\]
where
\[ \bar{n}_1(t) = \frac{1}{\nu_0} \int dz \rho(z) \nu_0(z)n_1(z, t) \]
\[ \hat{n}_1(t) = \frac{2}{\nu_0^2} \int dz \rho(z) \nu_0^2(z)n_1(z, t) \]

The Fokker-Planck equation at first order is
\[
\tau \frac{\partial Q_1}{\partial t} = \mathcal{L}[Q_1] + \frac{\left( H_1(z) \bar{n}_1(t - \delta) + H_2(z) \hat{n}_1(t - \delta) \right) \partial^2 Q_1}{2} \\
+ \left( G_1(z) \bar{n}_1(t - \delta) + G_2(z) \hat{n}_1(t - \delta) \right) \frac{\partial Q_1}{\partial y}
\]
\[ (102) \]

where
\[ G_1(z) = \frac{JC\nu_0 \tau - \epsilon J \tau z \sqrt{C (\nu_0^2 - \epsilon \sigma_0^2)} \nu_0^2}{\sigma_0(z)} \]
\[ G_2(z) = \frac{J \tau z \sqrt{C (\nu_0^2 - \epsilon \sigma_0^2)} \nu_0}{2\sigma_0(z)} \]
\[ H_1(z) = \frac{J^2 C \nu_0 \tau - \epsilon J^2 \tau z \sqrt{C (\nu_0^2 - \epsilon \sigma_0^2)} \nu_0^2}{\sigma_0^2(z)} \]
\[ H_2(z) = \frac{J^2 \tau z \sqrt{C (\nu_0^2 - \epsilon \sigma_0^2)} \nu_0}{2\sigma_0^2(z)} \]

The eigenmodes of Eq. (102) can be written
\[ Q_1(y, z, t) = \hat{Q}_1(y, z) \exp(i\omega t/\tau) + \text{c.c.} \]
\[ n_1(z, t) = \hat{n}_1(z) \exp(i\omega t/\tau) + \text{c.c.} \]

leading to the solvability conditions, for each z
\[ \hat{n}_1(z) = I(z) \bar{n}_1 + J(z) \hat{n}_1 \]
where
\[ I(z) = \frac{\hat{W}_2 [R_1] (y_\theta) - \left[ \hat{W}_2 [R_1] (y) \right]_{y_\theta}^{y_r} + H_1(z) e^{-i\omega \delta/\tau} \left( \hat{\phi}_2(y_\theta) - \hat{\phi}_2(y_r) \right)}{\hat{\phi}_2(y_\theta) - \hat{\phi}_2(y_r)} \]
\[ J(z) = \frac{\hat{W}_2 [R_2] (y_\theta) - \left[ \hat{W}_2 [R_2] (y) \right]_{y_\theta}^{y_r} + H_2(z) e^{-i\omega \delta/\tau} \left( \hat{\phi}_2(y_\theta) - \hat{\phi}_2(y_r) \right)}{\hat{\phi}_2(y_\theta) - \hat{\phi}_2(y_r)} \]

with
\[ R_{1,2} = e^{-i\omega \delta/\tau} \left( \frac{G_{1,2}(z)}{1 + iw} \frac{dQ_0(y)}{dy} + \frac{H_{1,2}(z)}{2(2 + iw)} \frac{d^2Q_0(y)}{dy^2} \right) \]
\[ (103) \]
Multiplying the above equation by \(\rho \nu_0(2\rho \nu_0^2)\) and integrating with respect to \(z\) we obtain

\[
\bar{n}_1 = \frac{<\nu_0 I>}{\nu_0} \bar{n}_1 + \frac{<\nu_0 J>}{\nu_0} \bar{n}_1^2
\]

\[
\bar{n}_1^2 = 2\frac{<\nu_0^2 I>}{\nu_0^2} \bar{n}_1 + 2\frac{<\nu_0^2 J>}{\nu_0^2} \bar{n}_1^2
\]

where we use the notation \(<\ldots> = \int dz \rho(z)\ldots\). The instability point together with the associated frequency are given by the condition that the associated determinant vanishes, i.e.

\[
1 = \frac{<\nu_0 I>}{\nu_0} + 2\frac{<\nu_0^2 J>}{\nu_0^2} + 2\frac{<\nu_0^2 I> <\nu_0 J> - <\nu_0^2 J> <\nu_0 I>}{\nu_0^2 \nu_0^2}
\]

The relative degree of synchrony of population \(z\) with the collective oscillation is given by

\[
\hat{n}_1(z) = \bar{n}_1 \left( I(z) + J(z) \frac{2<\nu_0^2 I>}{\nu_0^2} \frac{1}{1 - 2<\nu_0^2 J> / \nu_0^2} \right)
\]
