(Dated: December 18, 2019)

One of the hallmarks of quantum statistics, tightly entwined with the concept of topological phases of matter, is the prediction of anyons. Although anyons are predicted to be realized in certain fractional quantum Hall systems, they have not yet been unambiguously detected in experiment. Here we introduce a quantum impurity model, where bosonic (or fermionic) impurities turn into anyons as a consequence of their interaction with the surrounding many-particle bath. A cloud of phonons dresses each impurity in such a way that it effectively attaches fluxes/vortices to it and thereby converts it into an Abelian anyon. The corresponding quantum impurity model, first, provides a new approach to the numerical solution of the many-anyon problem, along with a new concrete perspective of anyons as emergent quasiparticles built from composite bosons or fermions. More importantly, the model paves the way towards realizing anyons using impurities in crystal lattices as well as ultracold gases. In particular, we consider two heavy electrons interacting with a two-dimensional lattice crystal in a magnetic field, and show that they behave as anyons when the impurity-bath system is rotated at the cyclotron frequency. A possible experimental realization is proposed by identifying the statistics parameter in terms of the mean square distance of the impurities and the magnetization of the impurity-bath system, both of which are accessible to experiment. Another proposed application are impurities immersed in a two-dimensional weakly interacting Bose gas.

I. INTRODUCTION

A topological classification of interacting quantum states is crucial in the context of current research on topological states of matter [1–4]. The discovery of such states in the fractional quantum Hall effect (FQHE) [5] has revolutionized our understanding of the quantum properties of matter, and hence they are becoming landmarks for the current as well as future research directions in physics. One of the most important characterizations of topological states of matter is in terms of the underlying fractionalized excitations. As proposed by Laughlin [6], the excitations in the FQHE are fractionally-charged quasiparticles, which were later demonstrated to be anyons with fractional statistics [7]. Since then, anyons have received a significant amount of attention, also because of their potential role in quantum computation [8–11].

Anyons are a type of quasiparticle whose quantum statistics interpolates between bosons and fermions. They occur only in lower-dimensional systems, i.e. mainly in two dimensions and to some extent in one dimension, although the latter will not be our focus here. The possibility of anyons in two dimensions may be traced to the algebraic triviality of the rotation group SO(2) and the topological non-triviality of a 2D configuration space with a point removed. Indeed, the symmetrization postulate which had been taken for granted during the first half of a century of quantum mechanics was called into question for such geometries in the 1960’s-80’s [12–21]. As elaborated for the first time by Leinaas and Myrheim [16], this leads to the possibility that when two identical particles are exchanged in two dimensions, the statistics parameter \( \alpha \) can assume any intermediate value between 0 (bosons) and 1 (fermions):

\[
\psi_A(r, \varphi + \pi) = e^{i\alpha\pi} \psi_A(r, \varphi),
\]

where \( \psi_A(r, \varphi) \) is the two-body wave function in relative coordinates, \( (r, \varphi) \). As a consequence, anyons have a peculiar property: when they are interchanged twice in the same way, the wave function does not return to the original. Namely, under a 2\( \pi \) rotation, the relative wave function is not single-valued, \( \psi_A(r, \varphi + 2\pi) = e^{2i\alpha\pi} \psi_A(r, \varphi) \). Nevertheless, if \( \psi_A(r, \varphi) \) is an eigenstate of some Hamiltonian \( \hat{H} \), one may introduce a single-valued wave function, \( \psi(r, \varphi) = \exp[-i\alpha\varphi] \psi_A(r, \varphi) \), which is governed by the Hamiltonian

\[
e^{-i\alpha\varphi} \hat{H} \frac{\partial}{\partial \varphi} \exp[i\alpha\varphi] = \hat{H} \left( \frac{\partial}{\partial \varphi} + i\alpha \right),
\]

where the statistics parameter now emerges as a gauge field. This establishes a connection between the statistics and gauge fields, and further implies that the orbital angular momentum of two particles in relative coordinates, which is given by \(-i\partial/\partial \varphi + \alpha\), is nonintegral [16] [18]. Such a configuration can be obtained with a magnetic field which substitutes the role of the statistics gauge field. This concept of anyons was discussed by Wilczek [18] [19], who realized them as a flux-tube-charged-particle composite – a charged particle “orbiting around” a magnetic flux \( \alpha \pi \).

The picture of flux-tube-charged-particle composites provides a formal description of anyons. From the practical point of view, however, it does not give much insight concerning a physical realization. Indeed there has been a recent upsurge in interest concerning the realization of anyons as emergent quasiparticles in experimentally feasible systems, in particular from the perspective of deriving robust, testable predictions such as density signatures [22][28]. Also the emergence of anyons in a FQHE setting by means of attachment of flux via Laughlin quasiholes was recently revisited and elaborated on...
in Ref. [29]. Here our main motivation is to define a physical Hamiltonian for a bipartite system such that the statistics gauge field emerges as a consequence of the interaction between the two subsystems [30, 31]. In particular, due to its experimental feasibility, we consider a quantum impurity model.

The presence of individual quantum particles, called impurities, is almost inevitable in many quantum settings. In several situations, ranging from crystals to helium nanodroplets to neutron stars, impurities are coupled to a complex many-body environment [32–34]. Their interaction with a surrounding quantum-mechanical medium is the focus of quantum impurity problems. Impurities do not only appear to be good descriptions of experimental reality, but also provide intricate examples of quantum critical phenomena [37, 38]. In general, quasiparticles formed by impurities are considered as an elementary building block of complex many-body systems. A well-known example is the polaron, which has been introduced as a quasiparticle consisting of an electron dressed by lattice excitations in a crystal [32–34]. Over the years, with the help of recent advances in ultracold atomic physics, which enable a high degree of control over experimental parameters such as interactions and impurity concentration, quantum impurities have been investigated in several different experimental and theoretical studies [35, 39, 48].

In this manuscript, we consider identical impurities immersed in a many-particle bath and show that they turn into anyons in the introduced model as a consequence of their interaction with the surrounding bath. Particularly, we treat the impurities as a slow/heavy and the surrounding bath as a fast/light system, and demonstrate that the latter manifests itself as a statistics gauge field with respect to the impurities. Excitations of the surrounding bath – a cloud of phonons – attach vortices to each impurity so that the quasiparticle formed from the impurity dressed by phonons becomes an anyon.

The paper is organized as follows. In Sec. II we present the basic machinery for anyons and give a brief review of the regular ideal anyon Hamiltonian. Afterwards, in Sec. III based on the emergent gauge picture, we derive the Hamiltonian of a quantum impurity model whose adiabatic limit corresponds to anyons. We present a transparent model where the impurities couple only to a single phonon mode. Then, we exemplify the model by investigating two- and three-impurity problems and their exact numerical spectra. In Sec. IV we present a new approach to the numerical solution of the many-anyon problem and provide a new perspective of anyons in terms of composite bosons or fermions. We discuss a possible experimental realization of the model in Sec. V by considering heavy impurities interacting with collective excitations of a bath within the Fröhlich-Bogoliubov model. We conclude the paper in Sec. VI with a discussion of our results and questions for future work. The Appendix provides some further technical details.

II. ANYON HAMILTONIAN

In general, one can derive the statistics gauge field within Chern-Simons theory [49–52]. The action of a system of non-relativistic charged particles with mass \( M \) coupled to the Abelian Chern-Simons gauge field \( \mathcal{A}_\mu \) is given by

\[
S = \frac{M}{2} \int dt \sum_{q=1}^N \dot{x}_q^2 + \int d^3y \mathcal{A}_\mu \dot{\gamma}^\mu + \frac{k}{2} \int d^3y e^{i\alpha p_{\text{imp}} \mathcal{A}_\mu \nabla_\mu} \mathcal{A}_\nu \partial_\nu \mathcal{A}_\rho.
\]

(3)

Here \( \dot{\gamma}^\mu(y) = \sum_{q=1}^N \dot{\gamma}^\mu(2\pi y - x_q) \) is a point-like source, \( k = 1/(2\pi \alpha) \) the level parameter, which assumes any number \([53]\), and \( e^{i\alpha p_{\text{imp}} \mathcal{A}_\mu \nabla_\mu} \mathcal{A}_\nu \partial_\nu \mathcal{A}_\rho \) the 2+1 dimensional Levi-Civita symbol. The letters \( \mu, \nu, \rho \) indicate the 2-dimensional Lorentz indices, i.e., \( \mu = 0 \) denotes the time component, whereas \( \mu = 1, 2 \) are the space components. By solving the zeroth component of the equations of motion, \( \delta S / \delta \mathcal{A}_0 = 0 \) and defining \( \mathcal{A} = \alpha \mathcal{A} \), one obtains the statistics gauge field:

\[
A_q^\mu = \frac{\partial}{\partial x_q^\mu} \sum_{q' > p} \Theta_{q'p} = \sum_{p(q) = 1} \epsilon^\mu_j \left( x_q^j - x_p^j \right) / \left| x_p - x_q \right|^2.
\]

(4)

where \( \sum_{q'p} \) denotes the summation over both of the particle indices \( q \) and \( p \) with the condition \( q > p \), \( \Theta_{qp} = \tan^{-1}\left[ y_{qp} / x_{qp} \right] \) is the relative polar angle between particles \( q \) and \( p \), \( x_{qp} = x_q^j - x_p^j \), and \( e_{12} = 1 \). The Hamiltonian for \( N \) ideal non-interacting anyons with statistics parameter \( \alpha \) can be written as

\[
\hat{H}_{N-\text{anyon}} = -\frac{1}{2} \sum_{q=1}^N \left[ \nabla_q + i\alpha A_q \right]^2,
\]

(5)

where we use natural units (\( \hbar = M = 1 \)), unless otherwise stated. Without loss of generality, we consider the Hamiltonian \( \hat{H}_{N-\text{anyon}} \) to act on bosonic states, i.e. the Hilbert space \( \mathcal{H} = L^2_{\text{sym}}(\mathbb{R}^{2N}) \) of square-integrable functions on \( \mathbb{R}^{2N} \), which are symmetric w.r.t. exchange. One can also consider fermionic states by changing \( \alpha \) to \( \alpha - 1 \).

A. Regular anyon Hamiltonian

The eigenvalue problem for the Hamiltonian [5] has been solved analytically only for the two-anyon case [16, 19, 53] (see also Refs. [55, 56] for a system of two anyons in the presence of the Coulomb potential), while for three or more particles only part of the spectrum is known exactly. The three- and four-anyon spectra have been investigated by means of numerical diagonalization techniques [57, 60], and a subspace of exact eigenstates is also known analytically for arbitrary \( N \) [61–65]. Rigorous upper and lower bounds on the exact ground-state energy were established in Refs. [66, 71]. Another approach has been to first regularize the Hamiltonian [5] by making the fluxes extended [72, 75], and in this situation an exact average-field theory and a corresponding Thomas-Fermi theory may be derived in the almost-bosonic limit \( \alpha \sim N^{-1} \rightarrow 0 \) [28, 76–79]. Also singular or point-interacting anyons may be considered [80, 84], as well as anyons regularized by a strong magnetic field [85]. See Refs. [21, 50, 64, 65] for reviews.

For ideal point-like anyons, however, the form of the Hamiltonian [5] leads to some singularity problems when the anyon spectrum is investigated from the bosonic end. For example,
let us consider two anyons confined additionally in a harmonic-oscillator potential. The Hamiltonian in relative coordinates is given by

$$\hat{H}_{2\text{-anyon}} = -\frac{1}{2r^2} \left( \frac{\partial}{\partial \varphi} + i\alpha \right)^2 - \frac{1}{2r} \frac{\partial}{\partial r} \left( \frac{\partial}{\partial r} \right) + \frac{\alpha^2}{2r^2} .$$

(6)

We observe that this form of the Hamiltonian allows neither a perturbative treatment of the problem nor the use of diagonalization techniques with respect to the free operator. Namely, the matrix element $\langle l, m|r^{-2}|l', m'\rangle$, where the state $|l, m\rangle$ is the eigenstate of the harmonic oscillator in polar coordinates with the principal and magnetic quantum numbers $l$ and $m$, respectively, is logarithmic divergent for the $m = 0$ states. For the three-anyon case, on the other hand, the problem occurs for all the zeroth-order bosonic eigenstates \[86\]. This is a well-known three-anyon case, on the other hand, the problem occurs for all the zeroth-order bosonic eigenstates \[86\].

This problem can be overcome with the similarity transformation $\hat{H}_{2\text{-anyon}} = r^{-a} \hat{H}_{2\text{-anyon}} r^a$, which is a self-adjoint Hamiltonian in the $L^2$ space weighted by the measure $r^{2n+1}dr$. In the transformed Hamiltonian the divergent term vanishes \[52\]. In fact, this transformation corresponds to a 'real gauge transformation' leading to an imaginary vector potential. In other words, it leads to the replacement of $\partial/\partial r \to \partial/\partial r + \alpha/r$ in the Hamiltonian \[6\]. If we further combine this transformation with the one given in Eq. \[2\], the regular (singular-free) two-anyon Hamiltonian can be obtained directly from the bosonic Hamiltonian via the transformation:

$$\hat{H}_{2\text{-anyon}} = \exp[-i\alpha(\varphi - 2\ln r)] \hat{H}_{2\text{-boson}} \exp[i\alpha(\varphi - 2\ln r)] .$$

(7)

We can generalize this and obtain the regular $N$-anyon Hamiltonian as

$$\hat{H}_{N\text{-anyon}} = \left( \prod_{q>p}^N \hat{z}_{qp}^{-a} \right) \hat{H}_{N\text{-boson}} \left( \prod_{q>p}^N \hat{z}_{qp}^a \right) = -\frac{1}{2} \sum_{q=1}^N \left\{ \nabla_q + i\alpha \hat{A}_q \right\}^2$$

(8)

with the gauge field

$$\hat{A}_q = \nabla_q \sum_{q > p}^N \left( \Theta_{qp} - i\ln r_{qp} \right) ,$$

(9)

where we define $\hat{H}_{N\text{-boson}} = -\sum_{q=1}^N \nabla_q^2/2$, $\hat{z}_{qp} = x_{qp} + iy_{qp} = e^{i\Theta_{qp} - i \ln r_{qp}}$, and $r_{qp} = |x_q - x_p|$. In the gauge field \[9\] the second term identifies the imaginary vector potential that eliminates the singularities arising due to the first term. This can be observed with the disappearance of the $\hat{A}_q^2$ term in the Hamiltonian, i.e., $\hat{A}_q^2 = 0$ because of the Cauchy-Riemann equations (note that the terms in \[9\] are each other’s harmonic conjugates). The $N$-anyon Hamiltonian in this gauge can be written as

$$\hat{H}_{N\text{-anyon}} = -\frac{1}{2} \sum_{q=1}^N \left( \nabla_q^2 + 2i\alpha \sum_{p \neq q=1}^N \frac{e^{i\Theta_{qp} + ilr_{qp}}}{r_{qp}^2} \frac{\partial}{\partial x_q} \right) .$$

(10)

The above Hamiltonian is again self-adjoint in a weighted space (with the weight $\prod_{p,q=1}^{2n} \exp[2i\alpha\ln r_{pq}]$ multiplying the usual measure), and it may serve as a model Hamiltonian for the calculation of the corresponding anyon spectra. Therefore, in the rest of the paper we will also consider this computationally convenient regular Hamiltonian $\hat{H}_{N\text{-anyon}}$, even though the main emphasis will be placed on the physical one $\hat{H}_{N\text{-anyon}}$.

### III. IMPURITY MODEL

We start by considering impurities immersed in a weakly interacting bath. Within the Fröhlich-Bogoliubov theory \[34\] \[90\] \[91\], a general Hamiltonian of an impurity problem is given by

$$\hat{H}_{\text{qim}} = -\sum_{q=1}^N \frac{\nabla_q^2}{2} + \sum_{l=1}^N \omega_l \hat{b}_l^\dagger \hat{b}_l$$

$$+ \sum_{l=1}^N \lambda_l(x) \left( e^{-i\phi_l(x)} \hat{b}_l^\dagger + e^{i\phi_l(x)} \hat{b}_l \right) .$$

(11)

Here the first term corresponds to the kinetic energy of the impurities, which are considered to be bosons. The formalism can be extended to fermionic impurities straightforwardly. The second term is the kinetic energy of the many-particle bath, whose collective excitations are given by phonons with the dispersion relation $\omega_l$, and $\Lambda$ is the total number of phonon modes. The creation and annihilation operators, $\hat{b}_l^\dagger$ and $\hat{b}_l$, obey the commutation relation $[\hat{b}_l, \hat{b}_l^\dagger] = \delta_{l\prime l}$. The final term describes the interaction between the bosonic impurities and the many-particle bath. While we assume that $\lambda_l(x)$ is a real function, $\beta_l(x)$ will at this stage be allowed to be complex for a later purpose. Both functions may depend on all the variables $x = \{x_1, \ldots, x_N\}$.

We treat the bosonic impurities as the slow system and the rest of the Hamiltonian as the fast one:

$$\hat{H}_{\text{fast}}(x) = \sum_l \omega_l \hat{b}_l^\dagger \hat{b}_l + \sum_l \lambda_l(x) \left( e^{-i\phi_l(x)} \hat{b}_l^\dagger + e^{i\phi_l(x)} \hat{b}_l \right) ,$$

(12)

where the coordinates of impurities, $x$, are regarded as parameters. We note that even if $\beta_l$ is complex, $\hat{H}_{\text{fast}}(x)$ is self-adjoint in the $\hat{\psi} = \exp\left[-\sum \text{Im} [\beta_l(\hat{b}_l^\dagger \hat{b}_l)]\right]$-weighted Fock space. The eigenstates and eigenvalues of the Hamiltonian \[12\] can be found by applying the following two transformations:

$$\hat{S} = \exp \left[-i \sum_l \beta_l(\hat{b}_l^\dagger - \hat{b}_l) \right] ,$$

$$\hat{U} = \exp \left[-\sum_l \frac{\lambda_l(x)}{\omega_l} \left( \hat{b}_l^\dagger - \hat{b}_l \right) \right] ,$$

(13)

where the transformation $\hat{S}$ is, in general, a similarity transformation, as $\beta_l$ might be complex, whereas $\hat{U}$ is unitary. Therefore, the eigenstates can be written as $\hat{S}\hat{\psi}_n$ with $|\hat{\psi}_n\rangle = \hat{U}|n\rangle$.
Here the states $|n\rangle$ symbolically represent normalized phonon states with the collective index $n$. Namely, $|0\rangle$ is the vacuum state of the bath, $|1\rangle \equiv \hat{b}_1^\dagger |0\rangle$ a one-phonon state, and so on. (Later, in simplified models, where we consider a single phonon mode, the states $|n\rangle$ correspond to the usual harmonic-oscillator eigenstates.) The eigenvalues, on the other hand, are given by $\epsilon_n = \sum_{i=1}^N \omega_i + \epsilon_0$ with the ground state energy $\epsilon_0 = -\sum_i A_i^2/\omega_i$.

Let us assume that there exists a large energy gap between the vacuum state $|0\rangle$ and the excited states $\hat{b}_1^\dagger |0\rangle$, i.e., we consider the limit $\omega_l \to \infty$. In this adiabatic limit the lowest energy spectrum of the Hamiltonian (11) is given by the Schrödinger equation

$$\left[-\frac{1}{2} \sum_{q=1}^N \left[ \nabla_q + i G_q \right]^2 + W(x) \right] \chi_{\epsilon}^F(x) = E \chi_{\epsilon}^F(x),$$

(14)

where

$$G_q = -i (\psi_0 | S^{-1} \nabla_q S | \psi_0) = -\sum_{l} (\lambda_l(x)/\omega_l)^2 \nabla_q \beta_l(x)$$

(15)

is the emergent gauge field and $W(x)$ the emergent scalar potential. The corresponding lowest energy eigenstates of the Hamiltonian (11) are, then, given by

$$|\Psi^F(x)\rangle = \chi_0^F \hat{S} \hat{U} |0\rangle;$$

(16)

see Appendix A for details. If we are able to match the emergent gauge field [13] with the statistics gauge field, the aforementioned adiabatic solution of the full problem described by the Hamiltonian (11) corresponds to the problem of $N$ anyons interacting with the potential $W(x)$. Although our essential focus is the statistics gauge field given by Eq. (4), i.e., the matching of $G_q = \alpha A_q$, we also consider the other choice (9) within a toy model for computational purposes. We emphasize that the condition $\omega_l \to \infty$ does not necessarily cancel out the emergent gauge field $G_q$, as we demonstrate in particular examples below.

At first sight, it looks like we have made the problem more complicated, as we consider bosons in a many-particle bath, instead of particles interacting with the statistics gauge field. However, the corresponding quantum impurity setup, first, lays the groundwork for realizing anyons in experiment (an experimental realization will be proposed in Sec. IV). Furthermore, this formulation reveals new insights into the structure of the anyon Hamiltonians (5) and (10), and on how anyons may emerge from composite bosons (fermions) – the topological bound state of a boson (fermion) and an even number of quantized vortices (cf. e.g. [22]). Finally, it introduces new techniques for numerical investigation of the $N$-anyon problem.

### A. Emergent interacting anyons

By using the definition of the gauge field (4) as well as imposing adiabaticity in the problem we can identify the parameters of the many-particle bath that turn the impurities into anyons. In order to present features of the introduced model in a transparent way, we consider for simplicity the following $l$-independent expressions:

$$\beta_l(x) = \beta(x) = -s \sum_{q=p}^N \Theta_{qp},$$

(17)

constant $\lambda_l = \lambda$, and $\omega_l = \omega$. Here $s$ is an integer such that $\beta(x_l)$ has the correct periodicity under the continuous exchange of particles and the Hamiltonian (11) commutes with the permutation operators. Without loss of generality it can be set to its lowest possible non-trivial value $s = 2$. The minus sign in (17) is chosen simply to eventually make our emergent anyons positively oriented.

We now introduce a unitary transformation $\hat{a}^\dagger_1 = \sum_{r} u_{r}^* \hat{b}_r^\dagger$, with $\sum_r u_{r}^* u_{r'}^* = \delta_{r, l}$, such that $\hat{a}^\dagger_1 = \sum_{r=1}^N \hat{b}_r^\dagger/\omega$. Particularly, we consider the choice of $\omega = \sqrt{\Lambda}$. Then, the impurity Hamiltonian (11) can be written as

$$\hat{H}_{\text{qim}} = -\frac{1}{2} \sum_{q=1}^N \nabla_q^2 + \omega \left( \hat{a}^\dagger \hat{a} + \Lambda^2 \right) + \lambda \omega \left( \hat{F} \hat{a}^\dagger + F^{-1} \hat{a} \right)$$

(18)

with

$$F = \prod_{q=p}^N \left( z_{qp}^2 \right).$$

(19)

For later convenience we use the notation $F^{-1}$, instead of $F^*$, even though they are equivalent in this particular case. In Eq. (18) we have neglected the term $\sum_{l=2}^N \omega \hat{a}^\dagger_1 \hat{a}_l$ as the impurities couple only to a single phonon mode, and omit the subindex, $\hat{a}^\dagger_1 \to \hat{a}^\dagger$. We further subtracted the ground state energy of the phonon part of the Hamiltonian, $-\omega_1 l^2$. Then, defining

$$\alpha = 2 \lambda^2,$$

(20)

and keeping the coupling $\lambda$ fixed in the limit of $\omega \to \infty$, the lowest energy spectrum of the quantum impurity problem (18) is governed by Eq. (17) with the gauge field $G_q = \alpha A_q$ and scalar potential $W = \alpha \sum_{q=1}^N A_q^2$.

The emergence of the anyon Hamiltonian can also be obtained without going to the gauge picture, by direct diagonalization of the Hamiltonian (18). Namely, if we apply the corresponding $\hat{S}$ and $\hat{U}$ transformations,

$$\hat{S} = F \hat{a}^\dagger, \quad \hat{U} = \exp \left[ -\sqrt{\alpha/2} (\hat{a}^\dagger - \hat{a}) \right],$$

(21)

the transformed Hamiltonian can be written as

$$\hat{H}_{\text{qim}}^* = \hat{U}^{-1} \hat{S}^{-1} \hat{H}_{\text{qim}} \hat{S} \hat{U} = \omega \hat{a}^\dagger \hat{a}$$

(22)

$$-\frac{1}{2} \sum_{q=1}^N \left[ \nabla_q + 2iA_q(x) \right] \left( \hat{a}^\dagger - \sqrt{\alpha} \left( \hat{a} - \sqrt{\alpha/2} \right) \right)^2.$$

If we diagonalize the Hamiltonian in the basis of the eigenstates of the free operators, the transition between different phonon
states for any bosonic (fermionic) eigenstate $|\Phi\rangle$ of the free $N$-particle Hamiltonian is quantified by the matrix element 
\[ \langle n| H'_{\text{qim}} | m \rangle / \langle n| H'_{\text{qim}} | n \rangle \] 
with $n \neq m$. In particular, the transition matrix element between the vacuum state and the one-phonon state is 
\[ \sqrt{\alpha/2} \frac{\langle \sum_{q=1}^{N} \left( 2i|\nabla_q, A_q|x_0 + (1 + \alpha) A_q^2 \right) \rangle_{\Phi}}{2\omega - \langle \sum_{q=1}^{N} \left( 2i|\nabla_q, A_q|x_0 + (1 + 2\alpha) A_q^2 \right) \rangle_{\Phi}}, \] 
(23)

where $[,]_+$ is the anti-commutator. Then, in the limit of $\omega \to \infty$ the transition matrix element becomes negligible (we refer to Appendix C for more details), and hence, the vacuum expectation value 
\[ \langle 0| H'_{\text{qim}} | 0 \rangle = -\frac{1}{2} \sum_{q=1}^{N} |\nabla_q + i\alpha A_q(x)|^2 + W(x), \] 
(24)
decouples from the rest of the spectrum. This is basically the statement of the adiabatic theorem. As a result, the energy levels belonging to the vacuum sector governed by Eq. (24) describes interacting anyons in the potential $W(x) = \alpha \sum_{q=1}^{N} A_q^2(x)$. We note, however, that for ideal point-like anyons the expectation values $\langle A_q^2 \rangle_\Phi$ in Eq. (23) are divergent for certain bosonic eigenstates of the free Hamiltonian, as we discussed in Sec. [IA] and therefore, the adiabatic theorem breaks down. In order to avoid these singularities the corresponding spectrum can be calculated instead from the fermionic end by changing $\alpha$ to $\alpha - 1$.

Let us investigate the form of the Hamiltonian (18) and the emergence of anyons in more detail. In this simplified model the interaction between the impurities and phonon field is described by the factor $F$. The $S$ transformation attaches two flux/vortex units to bosonic (fermionic) impurities to convert them into composite bosons (fermions). (In fact, in this particular case we call it a flux rather than vortex, as it is just a phase factor.) Then, a cloud of phonons, which manifests itself through a coherent state, dresses each impurity and forms a quasiparticle governed in the limit of $\omega \to \infty$ by the anyon Hamiltonian (24). The corresponding coherent state of phonons is given by 
\[ | \psi_0 \rangle = \hat{U}(0) = e^{-\alpha/4} \sum_{n=0}^{\infty} \left( -\frac{\sqrt{\alpha/2}}{\sqrt{n!}} \right)^n |n\rangle, \] 
(25)

which involves infinitely many phonons, weighted according to $\alpha$. In this adiabatic limit, the states in the Fock space decouple from each other, and each energy level is filled by anyons with the statistics parameter $2n + \alpha$, where $n$ corresponds to the energy levels of the Fock space sector. Specifically, if the impurities are initially bosons, in the vacuum state, $n = 0$, they turn into interacting anyons with statistics parameter $\alpha$ and spectrum described by Eq. (24). In the excited states, $n \neq 0$, on the other hand, the impurities become composite bosons with $2n$ units of flux and interacting with the statistics gauge field $\alpha A_q$ as well as the scalar potential $\alpha(1 + 2n) \sum A_q^2$. See Appendix C for more details concerning the diagonalization of Eq. (22).

Below we focus only on the vacuum state and present two simple examples. For an easier comparison with the results existing in the literature, we investigate impurities confined in a harmonic-oscillator potential and consider fermionic impurities with the coupling $\alpha - 1 = \lambda^2$ in order to deal with the singular interaction. Furthermore, since the interaction term depends only on relative coordinates, we factor out the center-of-mass problem, and make a transformation to relative coordinates. In general, the relative coordinates for an $N$-body problem are given by Jacobi coordinates: $R = \sum_{i=1}^{N} z_i/\sqrt{N}$ and $u_m = (\sum_{i=1}^{N} m - m_{n+1})/\sqrt{m(m+1)}$, where $m$ runs from 1 to $N - 1$.

### 1. Two anyons

As a first example, we consider the simplest case – the two-impurity problem. The Hamiltonian in Jacobi coordinates with the notation $u_1 = r \exp(i\psi)$, which is simply usual relative coordinates for a 2-body problem, becomes 
\[ \hat{H}_{\text{2-imp}} = -\frac{\nabla^2}{2} + \frac{r^2}{2} + \omega \left( \hat{a}^{\dagger} \hat{a} + \frac{\alpha}{2} \right) + \omega \sqrt{\frac{\alpha}{2}} \left[ e^{2i\psi} \hat{a}^{\dagger} + e^{-2i\psi} \hat{a} \right]. \] 
(26)

This two-impurity problem can be solved numerically by diagonalizing the Hamiltonian with the eigenstates of the free Hamiltonian – the first line of Eq. (26). These eigenstates are the phonon states $|n\rangle$ times the (anti-)symmetric impurity states. The latter are the usual harmonic oscillator wave functions:
\[ \Phi_{lm} = \sqrt{\frac{2(l+1)!}{(l + |m|) + 1}} e^{-\alpha/2} r^m L_{l}^m(r^2) \exp(i m \varphi)/\sqrt{2\pi}, \] 
(27)

where $L_{l}^m(r^2)$ are associated Laguerre polynomials. The corresponding eigenvalues are given by $2l + |m| + 1$. The symmetric impurity states in Jacobi coordinates follow from the parity of the angular quantum number of the impurities $m$: while even $m$ refers to bosons, the odd ones correspond to fermions. Due to the finite number of impurity states considered in numerics, there is an intricate relation between the number of impurity wave functions, maximum number of phonons, and actual value of $\omega$ in order to achieve convergence. It was found that the converged result of the anyonic spectra for the Hamiltonian (26) is obtained with $\omega \gtrsim 20$, up to 5 number of phonons, and several hundred impurity states. The result is demonstrated in Fig. [4](Top). In fact, this result can also be found exactly. It follows from Eq. (24) that the lowest levels are described by the Hamiltonian 
\[ \langle 0| \hat{H}_{\text{2-imp}} | 0 \rangle = -\frac{1}{2r} \left[ \frac{\partial}{\partial r} - i\varphi \right]^2 - \frac{1}{2r} \frac{\partial^2}{\partial r^2} - \frac{\alpha^2}{2} \] 
(28)

Then, the corresponding eigenvalues directly follow from the harmonic oscillator ones as $2l + \sqrt{(m + \alpha^2)/2 + 2\alpha} + 1$, which agrees with the numerical result shown in Fig. [4](Top).
with Jacobi coordinates, the notation $u$ for the impurity states in Jacobi coordinates is not trivial. Namely, the bosonic/fermionic wave functions are given by

$$\Phi^\pm_{n_{\nu\mu}} = \sqrt{\frac{2(n!)}{(m+n+1)!}} e^{-\frac{\eta}{\rho}} L_n^{m+1}(\rho^2) Y_{\nu\mu}^\pm(\theta, \phi, \psi),$$

where $Y_{\nu\mu}^\pm(\theta, \phi, \psi)$ are the hyperspherical harmonics; see Appendix B. The wave functions are normalized over the volume $dV = \rho^2 d\rho \cos(\theta) d\theta d\phi d\psi$ for $\rho \in [0, \infty), \theta \in [-\pi/4, \pi/4], \phi \in [-\pi/2, \pi/2], \psi \in [0, 2\pi]$. Here, $n = 0, 1, 2, \cdots$ is the radial quantum number and $m = 0, 1, 2, \cdots$ is one of the angular momentum numbers such that the corresponding spectrum reads $E_{nm} = (2n + m + 2)$. The other two angular quantum numbers $(\nu, \mu)$ have the same parity as $m$ and they are restricted by: $|\nu|, |\mu| \leq m$ and $\nu = 3q$ with a non-negative integer $q$; see also Ref. [94]. In Fig. 1 (Bottom), we show the corresponding spectra. In the diagonalization procedure over one thousand impurity states are considered and the maximum number of phonons is limited to 10 with $\omega \approx 50$.

B. A toy model for free anyons

Eq. (24), which describes the lowest levels of the impurity problem (18) in the limit of $\omega \to \infty$, can also serve as a new platform for studying the original $N$-anyon problem without the presence of the interaction potential $W$. Namely, instead of Eq. (17), if we define

$$\beta_i(x) = \beta(x) = -s \sum_{q \neq p}^N \left( \Theta_{qp} - i \ln r_{qp} \right)$$

with the same $\omega$ and $\lambda$ as in the previous case, the emergent gauge field is given by Eq. (9). In this case the corresponding impurity Hamiltonian analogous to Eq. (18) can be written as

$$\hat{H}_\text{imp} = -\frac{1}{2} \sum_{q=1}^N \nabla_q^2 + \omega \left( \alpha \hat{a}^\dagger \hat{a} + \alpha^2 \right) + \lambda \omega \left( \hat{F} \hat{a}^\dagger + \hat{F}^\dagger \hat{a} \right) + H.c. \quad (32)$$

with

$$\hat{F} = \prod_{q \neq p}^N z_{qp}. \quad (33)$$

We note that as $\hat{F}^\dagger \neq \hat{F}^*$, the Hamiltonian (32) is not Hermitian in this case. Nevertheless, its non-Hermiticity is harmless for our purposes, and indeed the fast part of the Hamiltonian is

![FIG. 1. Calculations resulting to the two-anyon (Top) and three-anyon (Bottom) spectra for the interacting anyon model in an external harmonic-oscillator potential (18). The spectra have been calculated from the fermionic end, i.e., the coupling is chosen as $\alpha = 1 = s \xi^2$ such that $\alpha = 1$ corresponds to free fermions. The applied parameters $l_{\text{max}} = 10$, $m_{\text{max}} = 21$, and $\omega = 23$ with up to 5 phonons for the two-anyon case. For the three-anyon case we consider all the antisymmetric impurity wave functions (30) restricted by the condition $E_{nm} \leq 26$ and limit the maximum number of phonons to 10 with $\omega = 54$. For clarity, we do not display all the curves in the second plot.](image)
self-adjoint in a Fock space weighted by $|\hat{F}|^{2\hat{a}}\hat{a}$. This allows us to rewrite the Hamiltonian in the gauge picture so that the lowest energy levels of the Hamiltonian (32) become real in the limit of $\omega \to \infty$. Namely, if we diagonalize the Hamiltonian, the energy levels belonging to the vacuum state in this limit are given by Eq. (24) with the replacement $A_q \to \hat{A}_q$. Moreover, as $\hat{A}_q \to 0$, the emergent scalar potential vanishes and hence Eq. (24) for this case simply corresponds to the free $N$-anyon Hamiltonian defined in the regular gauge (10):

$$\langle 0 | \hat{H}_{\text{qim}} | 0 \rangle = -\frac{1}{2} \sum_{q=1}^{N} \left[ \nabla_{q} + i \alpha \hat{A}_{q}(x) \right]^{2}.$$  \hfill (34)

Therefore, the Hamiltonian (32) describes free anyons in the limit of $\omega \to \infty$. The mechanism of how anyons emerge out of the impurity-bath coupling in this particular model is very similar to the previous interacting case. The only difference is the form of composite bosons/fermions. In contrast to the factor $F$, in the Hamiltonian (32) the attachment of flux/vortex is performed by $\hat{F}$. As the latter includes also a length, we will call the multiplication by $\hat{F}$ vortex attachment. Therefore, in this toy model, impurities are dressed by vortices by means of phonons.

Similar to the previous interacting anyon case, the corresponding two- and three-impurity problems in this toy model can be solved by diagonalizing the Hamiltonian (32) with the eigenstates of the free Hamiltonian by considering the impurities confined additionally in a harmonic-oscillator potential. Instead of following this approach, below we present new computational techniques for the numerical solution, along with a new concrete perspective of anyons in relation to composite bosons or fermions.

### IV. A NEW PERSPECTIVE ON ANYONS

The simplified impurity model given in Eq. (32) or (18) also provides some useful analytical insights for the $N$-anyon problem. Here we focus solely on the Hamiltonian (32). Nevertheless the interacting case follows straightforwardly. The Hamiltonian (32) can be written in terms of the impurity basis states, $|\Phi_{m}\rangle$, which are the (anti-)symmetric eigenstates of the free $N$-particle Hamiltonian $\hat{H}_{\text{boson}}$, as

$$\hat{H}_{\text{qim}} = E_{\text{N-boson}} + \omega \left( \hat{a}^{\dagger} \hat{a} + \frac{\alpha}{2} \right) + \omega \sqrt{\frac{\alpha}{2}} \left( \hat{Z} \hat{a}^{\dagger} + \hat{Z}^{-1} \hat{a} \right),$$  \hfill (35)

where we define the elements of the matrices $(\hat{H}_{\text{qim}})_{nm} = \langle \Phi_{n} | \hat{H}_{\text{qim}} | \Phi_{m} \rangle$, $(E_{\text{N-boson}})_{nm} = \langle \Phi_{n} | \hat{H}_{\text{boson}} | \Phi_{m} \rangle$, and

$$(\hat{Z})_{nm} = \langle \Phi_{n} | \hat{F} | \Phi_{m} \rangle, \quad (\hat{Z}^{-1})_{nm} = \langle \Phi_{n} | \hat{F}^{-1} | \Phi_{m} \rangle.$$  \hfill (36)

We note that the inverse matrix $\hat{Z}^{-1}$ is deduced from the relation $(\hat{Z}^{-1})_{nm} = \sum_{q=1}^{N} \langle \Phi_{n} | \hat{F} | \Phi_{q} \rangle \langle \Phi_{q} | \hat{F}^{-1} | \Phi_{m} \rangle = \delta_{nm}$, where we use the fact that the (anti-)symmetrizer, $\sum_{q} |\Phi_{q}\rangle \langle \Phi_{q}| = S$, commutes with the interaction term $\hat{F}$, and $S|\Phi_{q}\rangle = |\Phi_{q}\rangle$ for all (anti-)symmetric states. This matrix Hamiltonian can be diagonalized in the Fock space with the displacement operator $\hat{F} = \exp \left[ -\sqrt{\alpha} \left( \hat{Z} \hat{a}^{\dagger} - \hat{Z}^{-1} \hat{a} \right) / \sqrt{\alpha} \right]$. Then, the $N$-anyon spectrum, which emerges in the limit of $\omega \to \infty$, is given by the eigenvalues of the matrix

$$E_{\text{N-anyon}} = \sum_{n=0}^{\infty} e^{-n/2} \frac{(\alpha/2)^{n}}{n!} E_{\text{N-boson}} Z^{n},$$  \hfill (37)

where we made use of the coherent state (25). A similar expression can also be obtained for the interacting anyon model (18) by removing tildes from $\hat{Z}$ and $\hat{Z}^{-1}$, i.e., $\hat{Z} \to Z = \langle \Phi_{n} | \hat{F} | \Phi_{m} \rangle$ and similarly for $\hat{Z}^{-1}$. In this case the expression (37) corresponds to the interacting anyon energy.

First of all, Eq. (37) naturally simplifies to $E_{\text{N-boson}}$ for $\alpha \to 0$, and, in general, it can be given by a power series

$$E_{\text{N-anyon}} = \sum_{n=0}^{\infty} \frac{1}{n!} \left( \frac{\alpha}{2} \right)^{n} K_{n}$$  \hfill (38)

with the matrices

$$K_{n} = \sum_{i=0}^{n} \binom{n}{i} (-1)^{n-i} E_{\text{N-boson}} Z^{n}.$$

One can show that $K_{n} = 0$ for all $n \geq 3$. This follows from Eq. (38) that the entries of the matrix $(\hat{Z}^{-1})_{nm} E_{\text{N-boson}} Z^{n}$ can be written as

$$\langle \Phi_{n} | \hat{F} | \Phi_{m} \rangle = \langle \Phi_{n} | \hat{H}_{\text{N-comp}}^{(n)} | \Phi_{m} \rangle,$$  \hfill (40)

where the Hamiltonian $\hat{H}_{\text{N-comp}}^{(n)} = -\sum_{q=1}^{N} \left[ \nabla_{q} + i2n\hat{A}_{q} \right]^{2} / 2$ describes $N$ composite bosons (fermions). Furthermore, for the free anyon model $K_{n}$ also vanishes as a result of the fact that $\hat{A}_{q}^{2} = 0$. Therefore, the power series expansion (38) simply yields

$$E_{\text{N-anyon}} = E_{\text{N-boson}} + \frac{\alpha}{2} \left( \hat{Z}^{-1} E_{\text{N-boson}} \hat{Z} - E_{\text{N-boson}} \right),$$  \hfill (41)

or, in terms of composite bosons (fermions), it can be written as

$$\hat{H}_{\text{N-comp}}^{(n)} = \frac{1}{2} \left( \hat{H}_{\text{N-comp}}^{(2)} - \hat{H}_{\text{N-comp}}^{(0)} \right).$$  \hfill (42)

It is straightforward to show that the above simple expression is equivalent to the $N$-anyon Hamiltonian (10). As we discuss below, Eqs. (41) and (42) admit new numerical techniques for studying various many-anyon problems as well as a natural geometric interpretation in terms of vector bundles.

### A. New numerical techniques for free anyons

Although the resulting formula (41) looks almost trivial, we would like to emphasize that it is derived within the introduced
quantum impurity model by the non-trivial algebraic properties of the coherent state \(25\). This, first, shows the consistency of our approach, and further provides a new approach to the numerical solution of the \(N\)-anyon problem. Specifically, all the diagonalization techniques that we are aware of in the literature are based on the diagonalization of the matrix whose entries are given by the interaction term \(\langle \Phi_n \parallel \hat{A} \parallel \Phi_m \rangle\). However, Eq. \(41\) is based on the matrix \(Z\), which is much easier to construct in comparison to the former. This will be illustrated below in particular examples.

1. Examples

We again consider our impurities confined additionally in a harmonic-oscillator potential. Moreover, since in this toy model there are no singular terms in the corresponding transition matrix element \(23\), i.e., \(\hat{A}_q^2 = 0\), we consider bosonic impurities. We first consider the two-impurity problem. The Hamiltonian in relative coordinates is given by

\[
\hat{H}_{2\text{-imp}} = -\frac{\nabla^2}{2} + \frac{r^2}{2} + \omega \left(\hat{a}^\dagger \hat{a} + \frac{\alpha}{2}\right) + \omega \sqrt{\frac{\alpha}{2}} \left[\sqrt{\hat{a}^\dagger \hat{a} + (\sqrt{\hat{a}^\dagger \hat{a}})^2}\right]. \tag{43}
\]

The corresponding matrix \(Z\) can be constructed from the matrix elements \(\langle \Phi_{n_1} \parallel (\sqrt{\hat{a}^\dagger \hat{a} + (\sqrt{\hat{a}^\dagger \hat{a}})^2}) \parallel \Phi_{m_1} \rangle\) and the matrix \(Z^{-1}\) from the elements \(\langle \Phi_{n_1} \parallel (\sqrt{\hat{a}^\dagger \hat{a} + (\sqrt{\hat{a}^\dagger \hat{a}})^2}) \parallel \Phi_{m_2} \rangle\), where \(\Phi_{n_1}\) are the harmonic oscillator wave functions \(27\). We note that as the phase factor excludes the \(m = m' = 0\) states leading to singularities, the latter matrix elements are finite. The corresponding spectra are presented in Fig. 2 (Top), which agrees with the well-known result \(2l + |m + \alpha| + 1\). In the numerics the Hilbert space dimension is limited to several hundreds \((\approx 300)\) impurity basis states.

Next, we study the three-impurity problem, which reflects the full many-body character of anyons. In Jacobi coordinates the Hamiltonian for the three-impurity problem is given by

\[
\hat{H}_{3\text{-imp}} = \frac{1}{2} \left(P_a^2 + P_\xi^2\right) + \frac{1}{2} \left(\eta^2 + \xi^2\right) + \omega \left(\hat{a}^\dagger \hat{a} + \frac{\alpha}{2}\right) + \omega \sqrt{\frac{\alpha}{2}} \left[\frac{1}{2} (\eta^3 - 3n\eta^3) \hat{a}^\dagger \hat{a} + 2(\eta^3 - 3n\eta^3) \hat{a}\right]. \tag{44}
\]

In this particular example, instead of constructing the matrices \(Z\) and \(Z^{-1}\) separately, we first constructed the matrix \(Z^{-1}\) by using the symmetric impurity wave functions \(30\). Afterwards we take its pseudoinverse and define \(Z\). Although the other way around is also possible, we find the former way more convenient for numerical reasons as \(Z^{-1}\) is a more stable matrix. Similar to the two-impurity case, all the entries of \(Z^{-1}\) are finite due to the presence of the phase factor in the interaction term; see Appendix B for the calculation of the matrix elements in hyperspherical coordinates. In Fig. 2 (Bottom), we show the corresponding spectra, which agree with the known three-anyon spectra \(57\) \(58\). We found that one can access the spectrum for the interval \(0 \leq \alpha \leq 1\) by considering less than a thousand impurity wave functions. Moreover, in contrast to the diagonalization of the corresponding anyon Hamiltonian \(10\), the calculation of the matrix \(Z^{-1}\) is quite straightforward; see Appendix B. This appears to us as a very promising way for numerical investigation of various many-anyon problems.

B. Emergence of anyons from composite bosons

In addition to the new numerical approach, Eq. \(37\) provides a new perspective on anyons. It follows from Eq. \(40\) that the \(N\)-anyon Hamiltonian can be written as

\[
\hat{H}_{N\text{-anyon}} = \sum_{n=0}^{\infty} \frac{e^{-\alpha/2}}{n!} \left(\frac{\alpha}{2}\right)^n \hat{A}^{(n)}_{\text{comp}}, \tag{45}
\]
or, by Eqs. (8) and (42),

\[
\tilde{H}_{N\text{-anyon}} = \sum_{n=0}^{\infty} \frac{e^{-\pi n/2}}{n!} \left( \alpha \frac{1}{2} \begin{pmatrix} n \end{pmatrix} \prod_{p q} \hat{r}_{p q}^a \prod_{p q} \hat{r}_{p q}^a \right) \quad (46)
\]

\[
= \prod_{p q} \hat{r}_{p q}^a \left( \hat{F}^{(0)}_{\text{N-comp}} + \frac{\alpha}{2} \left( \hat{F}^{(2)}_{\text{N-comp}} - \hat{F}^{(0)}_{\text{N-comp}} \right) \right) \prod_{p q} \hat{r}_{p q}^a . \quad (47)
\]

This formula shows how anyons emerge from composite bosons or, put it differently, it depicts how a fractional vortex manifests itself through integer vortices.

In fact, this statistics transmutation admits a natural geometric interpretation in terms of vector bundles of wave functions over the \(N\)-body impurity configuration space. Note that in general we may consider the \(N\)-anyon Hamiltonian \( \tilde{H} \) and its domain of functions as defining a complex line bundle (i.e. a rank one hermitian vector bundle) over the configuration space of \(N\) identical particles in the plane. In the cases considered here there are no further magnetic interactions than the statistical one, and this is then a locally flat line bundle which is characterized solely by the statistics parameter \( \alpha \in \mathbb{R} \).

Using the trivial bosonic bundle \( \alpha = 0 \) as reference, the other possible bundles are geometrically defined by the holonomy of the connection along loops in the configuration space, i.e. the exchange phase which comes in units of \( e^{i\pi \alpha} \). We note that \( \alpha \) and \( \alpha + 2 \) are unitarily equivalent by a gauge transformation when the free Hamiltonian is considered, however, upon introducing interactions or further regularity conditions into the domain of the kinetic energy operator it makes sense to consider these as different bundles. A family of such bundles \( \alpha = 2n, n \in \mathbb{Z} \), may be characterized geometrically by the minimal winding number \( n \) of the phase as two particles are simply exchanged, or the winding number \( 2n \) as one particle continuously encircles another one. This is the same as the number of unit fluxes attached to each particle, and the permutation symmetry enforces the same number to each particle.

We may thus talk about an even-integer family of bosonic bundles having the physical interpretation as composite bosons with \( 2n \) quanta of flux attached to each boson. Note that multiplication by \( F \) of Eq. (19) resp. \( F^* \) changes these winding numbers, and indeed these are the gauge transformations that unitarily transform one such bundle into the other [95].

Thus, our starting point in the statistics transmutation was the geometrically trivial bundle \( \tilde{H} \) of regular bosonic states on the plane \( \mathbb{R}^2 \) on which the free Hamiltonian – \( \sum q \nabla_q^2 / 2 \) is acting (i.e. our considered states are all exchange-symmetric and have finite expectation values w.r.t. this Hamiltonian). However, by coupling this Hamiltonian to the phonon Fock space in the form (32), we are effectively considering a semi-infinite ladder \( \{\mathcal{H}F^a n\}, n = 0, 1, 2, \ldots \) of even-integer bundles of composite bosons. The factor \( F^a \) ensures that the winding number of the phase under simple exchange increases by \( n \), and equivalently that the vorticity attached to each particle is \( 2n \). In Eq. (32) we have introduced the possibility of hopping from one such bundle, winding number or vorticity, to the next higher one by means of the interaction term \( \tilde{F} \hat{a}^\dagger \) and hence the symmetric (thus staying within the family of bosonic bundles) attachment of a minimal number of vortices to each particle (cf. the arguments leading to (17)), as well as the corresponding hopping to the next lower bundle using the term \( \tilde{F}^{-1} \hat{a} \) and thus the detachment of a minimal number of vortices. We then have the interpretation of Eq. (32) that we are introducing an energy gap \( \omega \) between each level of the bundles (which in this context may be interpreted or defined as the energy cost of creating the corresponding number \( N(N - 1) \) of vortices), and enabling the hopping between consecutive bundles on the ladder by a non-zero amplitude \( \lambda \omega \). In the simultaneous limit of both large energy gap \( \omega \) and large hopping amplitude, while keeping their ratio \( \lambda \) fixed, what then emerges according to Eq. (34) or (46) is the fractional bundle labeled by the fraction of vorticity per particle \( \alpha = 2l^2 \). The phonon state (25) attaches a Poisson-distributed sequence of weights on each integer bundle on the ladder, resulting in the superposition (46) of bundles.

Furthermore, according to the alternative form (47), it may be equivalently understood as a linear (modulo weights) deformation between the two lowest bosonic bundles. When \( l = 1 \) or \( l = 2 \) one effectively achieves a complete transmutation into the next integer level by means of the unitary equivalence of \( (|\tilde{F}|/F\hat{H}(\tilde{F}^a/F)|) = F^* \hat{F} F \). We anticipate that this geometric perspective on the statistics transmutation could be extended, for instance to the setting of higher-rank vector bundles and non-Abelian anyons.

V. EXPERIMENTAL REALIZATION

We now investigate a possible experimental configuration of the quantum impurity model (11). Let us consider \( N \) identical impurities, say bosons, with mass \( M \), immersed into a weakly interacting many-particle bath, whose collective excitations are given by phonons with a gapped dispersion \( \omega(k) \). This creates the necessary energy gap between the phonon states in the limit of \( M \to \infty \), which allows us to consider the problem in the adiabatic limit. Furthermore, we consider impurities confined to two dimensions and leave out the direct interaction between impurities, as the latter is irrelevant for our discussion.

In analogy to the Fröhlich-Bogoliubov theory, the Hamiltonian of such a model is given by

\[
\hat{H}_{\text{exp}} = -\frac{1}{2M} \sum_{q=1}^{N} \hat{\nabla}_q^2 + \sum_k \omega(k) \hat{b}_k^\dagger \hat{b}_k \quad (48)
\]

\[+
\sum_k \left( \hat{V}(k, x) \hat{b}_k^\dagger + V^*(k, x) \hat{b}_k \right)
\]

with \( \sum_k = \{d^2 k/(2\pi)^2 \} \). Here \( \hat{b}_k^\dagger \) and \( \hat{b}_k \) are the creation and annihilation operators for a phonon with the wave vector \( k \) and frequency \( \omega(k) \). They obey the commutation relation \( [\hat{b}_k, \hat{b}_{k'}^\dagger] = (2\pi)^3 \delta(k - k') \). The last term in Eq. (48) describes the impurity-phonon interaction with the coupling \( \hat{V}(k, x) \), which depends on the coordinates of impurities \( x = [x_1, \ldots, x_N] \).

As a first step, we decompose the creation and annihilation operators in polar coordinates,

\[
\hat{b}_k^\dagger = \sqrt{\frac{2\pi}{k}} \sum_{\mu = -\infty}^{\infty} e^{i\mu q_{\mu}/q_{min}} \hat{b}_{k\mu}^\dagger ,
\]

\[
\hat{b}_k = \sqrt{\frac{2\pi}{k}} \sum_{\mu = -\infty}^{\infty} e^{-i\mu q_{\mu}/q_{min}} \hat{b}_{k\mu} ,
\]
with \([\hat{b}_{k\mu}, \hat{b}_{k'\mu}^\dagger] = \delta(k - k')\delta_{\mu\mu'}\). The Hamiltonian (48) is given by

\[
\hat{H}_\text{exp} = -\frac{1}{2M} \sum_{q=1}^{N} \nabla_q^2 + \sum_{k, \mu} \omega(k) \hat{b}_{k\mu}^\dagger \hat{b}_{k\mu} + \sum_{k, \mu} \lambda_{\mu}(k, x) \left[ e^{-i\varphi_\mu(k, x)/2} \hat{b}_{k\mu}^\dagger + e^{i\varphi_\mu(k, x)} \hat{b}_{k\mu} \right]
\]

(50)

where \(\sum_k = \int_0^\infty dk\), and

\[
V_{\mu}(k, x) = \frac{k}{(2\pi)^3} \int d\varphi_k V(k, x) e^{i\mu \varphi_k},
\]

(51)

which has been further decomposed into \(V_{\mu}(k, x) = \lambda_{\mu}(k, x) e^{-i\varphi_\mu(k, x)}\). The Hamiltonian (50) is of the form of the general model Hamiltonian (11). As a result, according to Eq. (15), the emergent gauge field can be written as

\[
G_q = -\sum_{k, \mu} \left( \lambda_{\mu}(k, x)/\omega(k) \right)^2 \nabla \beta_{\mu}(k, x).
\]

(52)

If the bosonic impurities interact with the phonons in such a way that the emergent gauge field matches with the statistics gauge field (4), they turn into anyons in the limit of \(M \to \infty\). The eventual rotational realization of the model, therefore, reduces to the feasibility of such an impurity-phonon interaction. In general, the gauge field is non-zero when the integral \(\sum_k \left( \lambda_{\mu}(k, x)/\omega(k) \right)^2 \nabla \beta_{\mu}(k, x)\) is not an odd function under \(\mu\), which is a manifestation of breaking time reversal symmetry. This can be achieved by applying a magnetic field or rotation to the system. In principle, such an interaction is feasible with the state-of-art techniques in ultracold atomic physics, for instance in a rotating Bose gas. Below we present a simple and intuitive realization within a well-known problem – the Fröhlich polaron.

A. Fröhlich Polarons As Anyons

Let us consider two electrons confined in a plane interacting with longitudinal optical phonons, \(\omega(k) = \omega_0\). The corresponding Fröhlich Hamiltonian for two impurities is given by Eq. (48) with the following coupling (49)

\[
\hat{H}_F = \left( \nabla_1 - ia_1 \right)^2 + \left( \nabla_2 - ia_2 \right)^2 - \frac{2M}{2M} \sum_k \omega_0 \hat{b}_k^\dagger \hat{b}_k + \sum_k V(k) \left( e^{-ik \cdot x_1} + e^{-ik \cdot x_2} \right) \hat{b}_k^\dagger + \text{H.c.}
\]

(54)

where \(a_1 = B(-y_1, x_1)/2\) is the gauge field generating the magnetic field. Moreover, we rotate the impurity-bath system in the \(x - y\) plane at the cyclotron frequency \(\Omega = B/(2M)\). The experimental setup is depicted in Fig. 3. The rotation of the system allows us to factor out the center-of-mass coordinates in the limit of \(M \to \infty\). The Hamiltonian (54) can be written in the rotating coordinate system as

\[
\hat{H}_F = e^{-i\Omega \hat{J}_z} \left( \hat{H}_F - i \frac{\partial}{\partial t} e^{i\Omega \hat{J}_z} + i \frac{\partial}{\partial t} \right) + \frac{1}{2M} \left( -\nabla^2 - M^2 \Omega^2 (x_1^2 + x_2^2) \right) \hat{b}_k + \hat{b}_k^\dagger + \text{H.c.}
\]

(55)

Here \(J_z = L_{1z} + L_{2z} + \hat{\lambda}_z\) is the total angular momentum of the impurity-bath system along the \(z\)-direction, with \(L_{1z}\) being the angular momentum of the \(i\)-th impurity and \(\hat{\lambda}_z\) the collective angular momentum operator of the bath. Next we introduce relative and center-of-mass coordinates, \(r\) and \(R\), respectively, and then apply the unitary Lee-Low-Pines (LLP) transformation [90].

\[
\hat{T}_{\text{LLP}} = \exp\left[ -i \frac{\hat{R} \cdot \sum_k k \hat{b}_k^\dagger \hat{b}_k}{\sqrt{2}} \right].
\]

We decompose the creation and annihilation operators in polar coordinates, where the angular momentum operator simply reads \(\hat{\lambda}_z = \sum_k \mu \mu' \hat{b}_{k\mu}^\dagger \hat{b}_{k\mu}\). The transformed Hamiltonian can be rewritten as

\[
\hat{H}'_F = -\frac{1}{2M} \nabla_r^2 + \frac{M \Omega^2}{2} r^2 + \sum_{k, \mu} \omega_\mu \hat{b}_{k\mu}^\dagger \hat{b}_{k\mu} + \sum_{k, \mu} \lambda_{\mu}(k, r) \left[ e^{-i \varphi_\mu(k, r)} \hat{b}_{k\mu}^\dagger + e^{i \varphi_\mu(k, r)} \hat{b}_{k\mu} \right] + \text{H.c.}
\]

(56)

Here \(\varphi_\mu(k, r) = \omega_\mu + \mu \Omega\) is the effective phonon dispersion relation, where the second term arises as a consequence of the rotation. The impurity-bath coupling strength is given by

\[
\lambda_{\mu}(k, r) = \sqrt{k/(2\pi)} V(k) J_{\mu}(k r/\sqrt{2}) \left[ 1 + (-1)^\mu \right].
\]

(57)

which follows from the Jacobi-Anger expansion, \(\exp[i k \cdot x] = \sum_\mu \hat{b}_{\mu}(k r) \exp[\mu \varphi_\mu]\), with \(J_\mu(k r)\) being the Bessel func-
tion of the first kind. The last term in Eq. (56),

$$\hat{h}_R = \frac{1}{2M} \left( \nabla_R - i \sum_k k \hat{b}_k \hat{b}_k^\dagger / \sqrt{2} \right)^2 + \frac{1}{2} M \Omega^2 R^2, \quad (58)$$

is the Hamiltonian for the center-of-mass motion that couples to the many-particle bath. We note that the coupling term, \(\sum_k \nabla_R \cdot k \hat{b}_k \hat{b}_k / M\), is negligible in the limit of \(M \to \infty\), as the momentum operator scales as \(\sqrt{M}\). Therefore, the center-of-mass coordinate decouples in the transformed Hamiltonian. In a similar way, the contribution of the term \((\sum_k k \hat{b}_k \hat{b}_k)^2 / M\) to the fast Hamiltonian is also negligible in the limit of \(M \to \infty\). Consequently, \(\hat{h}_R\) will be omitted hereafter.

In realistic situations the maximum number of phonons \(n_{\text{max}}\) interacting with impurities is finite. Furthermore, because of the finite size of the first Brillouin zone, we consider a natural cut-off for the phonon wave vector \(k_{\text{max}}\). This puts an upper limit for the \(\mu\)-summation as well as for the \(k\)-integral. The limitation on the \(k\)-integral can affect the small distance behavior of the impurities. Nevertheless, as the repulsive Coulomb interaction between two electrons prevents us from considering small distances, we will ignore this cut-off. The cut-off for the \(\mu\)-summation, on the other hand, is essential in order to have a spectrum bounded from below. Namely, the ground state energy of the fast Hamiltonian can be written as

$$\epsilon_{gs} = \min \{0, n_{\text{max}}(\omega_0 - \Omega \mu_{\text{max}}) - \int_0^\infty dk \sum_{\mu=\pi,\mu_{\text{max}}} \frac{\lambda_\mu(k, r)^2}{\omega_\mu},$$

and we consider the case \((\omega_0 - \Omega \mu_{\text{max}}) > 0\), where the ground state is given by the vacuum state \(\hat{S} U(0)\).

It follows from Eq. (52) that the corresponding emergent gauge field for the ground state of the Hamiltonian (56) is given by

$$G = \frac{\alpha(r)}{r} \epsilon_G$$

with

$$\alpha(r) = - \sum_{\mu=\pi,\mu_{\text{max}}} \frac{(1 + (-1)^\mu)^2 \mu}{(\omega_0 + \mu \Omega)^2} \int_0^\infty dk \frac{k}{2\pi} \left( V(k) J_\mu(kr) / \sqrt{2} \right)^2 . \quad (61)$$

In general, the emergent gauge field does not necessarily correspond to a statistics gauge field, as the \(r\)-dependence of \(\alpha(r)\) relies on the form of \(V(k)\). Now we will have a closer look at the derivation of the Fröhlich Hamiltonian, where \(V(k)\) emerges as the Fourier component of the interaction between the impurity and surrounding many-particle bath in real space.

In the regular Fröhlich polaron, impurities are considered to be confined to two dimensions, but interact with a three dimensional bath, and \(V(k)\) emerges as a consequence of the interaction between the electron and the polarization field [97], which leads to \(V(k) = \sqrt{2\pi \gamma_F} / k\) with \(\gamma_F\) being the Fröhlich coupling constant for the electron confined in two dimensions. This form of the coupling describes surface polarons [97,100]. In this case, the statistics parameter scales as \(1/r\). Nevertheless, if we apply a strong magnetic field, of the order of \(\Omega \sim \omega_0\), the relative wave function of the impurities is localized in \(r\)-space, and hence the relative motion of two impurities is described by only the relative angle. In this case, we can omit the \(r\)-dependency of the statistics parameter, or consider a limited range, where \(\alpha(r)\) is approximately constant. We note, however, that for such a strong magnetic field \((\omega_0 - \Omega \mu_{\text{max}}) < 0\), and hence the ground state will not be the vacuum state after the corresponding \(\hat{S}\) and \(\hat{U}\) transformations.

1. 2D phonon bath

Instead of a three-dimensional bath, we now consider a quasi-2D bath. Namely, we consider impurities confined to two dimensions, and also interacting with a 2D bath. The latter can be achieved by assuming that the confinement of a 3D bath in the \(z\) direction is so strong that we can ignore the excitations in that direction, or we can consider a bath in the form of a single layer of atoms in a two-dimensional lattice, such as graphene. In this case, the polarization field behaves like a \(1/r\) field, instead of the \(1/r^2\) behavior of a 3D bath. This follows from the fact that in two-dimensional materials the Coulomb law scales as \(\ln r\), which has already been observed and investigated in several experimental works [101,103]. Then, the Fourier component is given by \(V(k) = \sqrt{2\pi \gamma/k^2}\) with some constant \(\gamma\), which we call the 2D Fröhlich coupling constant. As a result of this, the emergent gauge field yields \(G = e_G \alpha/r\) with the statistics parameter

$$\alpha = 4\gamma \omega_0 \Omega \sum_{\mu=\text{even}}^{\mu_{\text{max}}} \mu (\omega_0^2 - \mu^2 \Omega^2)^{-2}, \quad (62)$$

where we use the relation \(\int_0^\infty dk J_\mu(kr)^2 / k = 1/(2\mu!)\) for \(\mu \neq 0\). In Fig. 4 we show the statistics parameter as a function of the applied magnetic field.

Thus, the impurities, say electrons, immersed in a 2D many-particle bath in a magnetic field behave like anyons in the limit of \(M \to \infty\), when the impurity-bath system is rotated at the
cylotron frequency. The statistics parameter \((62)\) minus one in the fermionic case emerges as a function of the dispersion, cyclotron frequency, and the 2D Fröhlich coupling constant.

The origin of the emergent anyons can be intuitively understood in terms of the relative angular momentum of impurities immersed in a bath. By using Eq. \((15)\) and bearing in mind that the \(\hat{S}\) transformation \((13)\) can be written as

\[
\hat{S} = \exp\left(-i\varphi \sum_{k\mu} \mu \hat{b}_{k\mu}^\dagger \hat{b}_{k\mu}\right) = \exp\left(-i\varphi \hat{\alpha}_z\right),
\]

the emergent gauge field is given by \(G = -\langle 0|\hat{U}^{-1}\hat{\alpha}_z\hat{U}|0\rangle e_y/r\). In other words, the statistics parameter is simply given by the expectation value of the angular momentum of the many-particle bath in the coherent state

\[
\alpha = -\langle \hat{\alpha}_z \rangle_{\text{coherent state}},
\]

which can assume any number, as the coherent state is not an eigenstate of the angular momentum operator. Therefore, the relative angular momentum of the impurities is shifted by \(\alpha\) and hence becomes noninteger. This is the manifestation of anyons analogous to the picture of Wilczek’s flux-tube-charged-particle composite, and thereby, anyons can here be interpreted as impurities ‘orbiting around’ a ‘magnetic flux’ created by the many-particle bath through the coherent state. Indeed, this result is consistent with the conservation of the angular momentum of the impurity-bath system. Namely, the expectation value of the total angular momentum can be written as

\[
\langle \hat{L}_{\text{tot}} \rangle_{\psi E} = \langle \hat{L}_z \rangle_{\psi E} + \langle \hat{\alpha}_z \rangle_{\psi E},
\]

where \(\psi E\) is the total eigenstate of the impurity-bath system and \(\hat{L}_z\) the relative angular momentum of the impurities. Then, it follows from Eq. \((16)\) that in the limit of \(M \rightarrow \infty\) the first term is given by \(\langle \hat{L}_z \rangle_{\psi E} = m - \langle \hat{\alpha}_z \rangle_{\text{coherent state}}\) with \(m\) being a (half-)integer. The second term in Eq. \((65)\), on the other hand, reads \(\langle \hat{\alpha}_z \rangle_{\psi E} = \langle \hat{\alpha}_z \rangle_{\text{coherent state}}\) so that the total angular momentum is (half-)integer at the end.

Moreover, the manifestation of the statistics parameter in terms of the angular momentum of the many-particle bath, i.e., Eq. \((64)\), implies that the statistics parameter can be measured in experiment by detecting the phonon angular momentum. Recent works show that this is feasible; see for instance Refs. \([104, 105]\). The relation \((64)\) allows us also to propose a novel method to measure the statistics parameter. Namely, if we take the derivative of the Hamiltonian \((56)\) with respect to the cyclotron frequency \(\Omega\), we obtain \(\partial \hat{H}_{FR}/\partial \Omega = B r^2 / 2 + \hat{\alpha}_z\). If we further use the Hellman-Feynman theorem in the limit of \(M \rightarrow \infty\), where the total state is separable, the statistics parameter is given by

\[
\alpha = B \left(\frac{r^2}{2} - \frac{\partial E'_{\text{FR}}}{\partial \Omega}\right).
\]

We note that there arises also the term \(\langle \partial \hat{H}_{FR}/\partial \Omega \rangle = B (R^2)/2\) in Eq. \((66)\). Nevertheless, as the center-of-mass coordinate decouples from the Hamiltonian \(\hat{H}_{FR}\), the expectation value simply assumes an integer number: \(\langle \partial \hat{H}_{FR}/\partial \Omega \rangle = n_{R_c} + n_{R_b} + 1\) with \(n_{R_c}\) being the energy level in the center-of-mass dimension \(x (y)\). Consequently, we neglect its contribution to the statistics parameter. In Eq. \((66)\) the second term defines the magnetization of the system \(M\), i.e., \(\partial E'_{\text{FR}}/\partial \Omega = -2MM\), which is routinely measured in torque magnetometry setups to probe the 3D and 2D Fermi surfaces of different types of materials \([106, 110]\). The first term, on the other hand, can be measured with a standard time-of-flight measurement \([111]\). We note that the relation \((66)\) is reminiscent of the recently proposed method to observe anyonic statistics in the FQHE \([26]\), where the statistics parameter is defined in terms of the mean square radius of the density distribution of atoms.

2. 2D weakly interacting Bose gas

The proposed setup can be extended to different many-particle environments such as a two-dimensional weakly interacting Bose gas or a film of liquid helium. The Fröhlich-Bogoliubov regime of these impurity problems is governed by the Hamiltonian \((48)\); see Refs. \([112, 114]\) for the details on the validity of the Fröhlich-Bogoliubov theory. In such environments, however, the dispersion of the corresponding excitations \(\omega (k)\) is, in general, gapless. Nevertheless, realistic circumstances impose a natural low-momentum cutoff \(k_{\text{min}}\) for the dispersion. This allows us to investigate these impurity problems within the adiabatic theorem as well. Furthermore, if the condition \(\omega(k_{\text{min}}) - \mu_{\text{max}} > 0\) holds true, then the ground state of the fast Hamiltonian is given by the vacuum state after the corresponding \(\hat{S}\) and \(\hat{U}\) transformations. Consequently, Eq. \((61)\) remains valid by replacing \(\omega_0\) with the dispersion \(\omega (k)\):

\[
\omega (r) = - \sum_{\mu = -\mu_{\text{max}}}^{\mu_{\text{max}}} (1 + (-1)^{\mu}) \mu \int_{k_{\text{min}}}^{\infty} dk k \left(\frac{V(k) k^2 / \sqrt{2}}{2\pi} (\omega (k) + \mu \Omega)^2\right).
\]

FIG. 5. The statistics parameter of Eq. \((67)\) as a function of the distance \(r\) for impurities immersed in a 2D Bose gas. The long distance behavior of the emergent gauge field corresponds to the statistics gauge field. The applied Bogoliubov parameters are \(\eta_B = 7\), \(\gamma_B = 0.1\), \(g_{BB} = 1.5\), and \(m_B = 5\) such that the gas parameter reads \(\eta_B a_B^2 = \exp[-4\pi/(5m_B g_{BB})] \approx 0.18\). The other parameters are \(M = 20m_B\), \(\Omega = 10\), \(\mu_{\text{max}} = 16\), and \(k_{\text{min}} = 0.2\).
For instance, let us consider the impurities inside a two-dimensional Bose gas. The latter can be considered a weakly interacting gas if the condition $n_0a_B^2 \ll 1$ is satisfied, where $n_0$ is the density of the Bose gas and $a_B$ the boson-boson scattering length parameterizing the contact boson-boson interaction. The Bogoliubov dispersion is given by

$$\omega(k) = ck \sqrt{1 + k^2 \xi^2/2}.$$  \hfill (68)

Here $c = \sqrt{g_{BB}n_0/m_B}$ and $\xi = (2m_Bg_{BB}n_0)^{-1/2}$ are the speed of sound and the healing length of a weakly interacting Bose gas, respectively. $m_B$ is the boson mass and $g_{BB}$ is the boson-boson coupling constant given by $g_{BB} = 4\pi/(m_B \ln(1/n_0a_B^2))$. The coupling, on the other hand, is

$$V(k) = \sqrt{n_0(2\pi)^{-1}g_{IB}} \left( \frac{\xi^2k^2}{2 + \xi^2k^2} \right)^{1/4}$$ \hfill (69)

with $g_{IB}$ being the impurity-boson coupling constant. We further define the dimensionless boson-boson coupling strength $\gamma_B = m_Bg_{BB}/n_0$ and the dimensionless impurity-boson strength $\eta_B = g_{IB}/g_{BB}$. These two parameters control different physical regimes of Bose polarons; see Ref. [112, 113] for details. In Fig. [5] we present $\alpha(r)$ as a function of the distance $r$ in a parameter regime where the Fröhlich-Bogoliubov theory is applicable. Apart from small distances, $\alpha(r)$ is approximately constant, and hence, the emergent gauge field behaves as the statistics gauge field. The constant behavior of $\alpha(r)$ is a consequence of the assumption $\sqrt{n_0\xi} \ll 1$. Under this condition a 2D Bose gas converts impurities into anyons.

VI. DISCUSSIONS

In this paper, we have introduced a quantum impurity model where the surrounding many-particle bath manifests itself as the statistics gauge field with respect to the impurities, and the lowest energy spectra correspond to the anyonic spectra. In terms of the quasiparticle picture, anyons can here be identified as impurities which are first converted into composite bosons (fermions) and then dressed by a coherent state of phonons. Such a context of impurity problems, this can potentially be achieved non-Abelian anyons in terms of quantum impurities. In the gauge field. This would allow us to extend the model to realize non-Abelian anyons in terms of quantum impurities. In the context of impurity problems, this can potentially be achieved by considering internal degrees of freedom of phonons. Such an approach could then allow us to use quantum impurities as a platform for topological quantum computation.

APPENDIX

A. Derivation of the emergent gauge field

In general, we consider a free $N$-boson system coupled to another system. The corresponding total Hamiltonian can be written as

$$\hat{H}_{\text{tot}} = -\frac{1}{2} \sum_{q=1}^{N} \nabla_q^2 + \hat{H}_{\text{fast}}(x),$$

(70)

with $x = \{x_1, \ldots, x_N\}$ being the coordinates of bosons. Here the first term is the kinetic energy of bosons. Since it is often more convenient to study anyons in curvilinear coordinates, like polar coordinates as we discuss, we give the Laplacian in curvilinear coordinates in terms of the inverse metric tensor $g^{ij}$, with $g_{ij} = \det g^{ij}$.

$$\nabla_q^2 = \frac{1}{\sqrt{g_q}} \sum_{i,j} \frac{\partial}{\partial x_{ij}} \left( \sqrt{g_q} g^{ij} \frac{\partial}{\partial x_{ij}} \right).$$

(71)

The second term in Eq. (70) describes the Hamiltonian of the system that couples to bosons, and we assume that in general it is self-adjoint in a weighted space. The coordinates of bosons, $x$, are regarded as parameters in the Hamiltonian $\hat{H}_{\text{fast}}(x)$, whose eigenvalue equation is given by

$$\hat{H}_{\text{fast}}(x)\hat{S}\langle \psi_n(x) \rangle = \varepsilon_n(x)\hat{S}\langle \psi_n(x) \rangle,$$

(72)

where $\hat{S} = \hat{S}(x)$ is a similarity transformation such that $\hat{S}^{-1}\hat{H}_{\text{fast}}\hat{S}$ is Hermitian, and $\langle \psi_n(x)\hat{S}\langle \psi_n(x) \rangle = \delta_{n,m}$. Note that the identity operator in the weighted Hilbert space, where the Hamiltonian $\hat{H}_{\text{fast}}$ is defined, is given by $\hat{S}\sum_n \langle \psi_n(x)\rangle\langle \psi_n(x) \rangle\hat{S}^{-1} = I$.

The total quantum state, which is defined via the eigenvalue equation $\hat{H}_{\text{tot}}|\psi^E(x)\rangle = E|\psi^E(x)\rangle$, can be expanded as

$$|\psi^E(x)\rangle = \sum_n \chi_n^E(x)\hat{S}|\psi_n(x)\rangle,$$

(73)

where $\chi_n^E(x) = \langle \psi_n(x)\hat{S}|\psi^E(x) \rangle$. Then, the eigenvalue equation can be written as

$$\sum_m H_{nm}^\text{eff} \chi_m^E(x) = E \chi_n^E(x),$$

(74)

with the effective Hamiltonian

$$H_{nm}^\text{eff} = -\frac{1}{2} \sum_{q=1}^{N} \sum_{i,j} \left[ \frac{\partial}{\partial x_{ij}} + \langle \psi_m|\hat{S}^{-1}\frac{\partial}{\partial x_{ij}}\hat{S}|\psi_n \rangle \right]$$

$$\times \sqrt{g_q} g^{ij} \left[ \frac{\partial}{\partial x_{ij}} + \langle \psi_l|\hat{S}^{-1}\frac{\partial}{\partial x_{ij}}\hat{S}|\psi_m \rangle + \varepsilon_n \delta_{nm}, \right.$$

(75)

where $\langle \psi_m|\hat{S}^{-1}\frac{\partial}{\partial x_{ij}}\hat{S}|\psi_n \rangle$ is the emergent gauge field. We note that Eq. (74) with the Hamiltonian (75) is still exact. Now we assume that the spectrum of the Hamiltonian $\hat{H}_{\text{fast}}(x)$ is discrete and non-degenerate at least in the $n$th level, and that the energy splittings between level $n$ and the other levels, $m \neq n$, are so large that

$$\frac{\langle H_{nm}^\text{eff} \rangle}{\langle H_{nm}^\text{eff} \rangle - \langle H_{nm}^\text{eff} \rangle} \ll 1.$$

(76)

Then, in this adiabatic limit the Schrödinger equation (72) simply reads

$$\left\{ -\frac{1}{2} \sum_{q=1}^{N} \frac{1}{\sqrt{g_q}} \frac{\partial}{\partial x_{ij}} + \langle \psi_n|\hat{S}^{-1}\frac{\partial}{\partial x_{ij}}\hat{S}|\psi_n \rangle \right\} \sqrt{g_q} g^{ij}$$

$$\times \left[ \frac{\partial}{\partial x_{ij}} + \langle \psi_n|\hat{S}^{-1}\frac{\partial}{\partial x_{ij}}\hat{S}|\psi_n \rangle \right] + W(x)\chi_n^E(x) = E \chi_n^E(x),$$

(77)

where

$$W(x) = \varepsilon_n(x)$$

(78)

is the emergent scalar potential.

B. The three-impurity matrix element in hyperspherical coordinates

For the three-impurity problem the matrix elements of $\tilde{W}$ in hyperspherical coordinates are given by

$$\langle \Phi^h_{\alpha\beta\gamma}|2\rho^6 e^{i\delta}\left[A(\theta) \cos(3\phi) + iB(\theta) \sin(3\phi)\right]|\Phi^h_{\mu'\nu'\gamma'} \rangle,$$

(79)

where $A(\theta) = \cos(\theta)/(2 - \cos(2\theta))$, $B(\theta) = \sin(\theta)/(2 + \cos(2\theta))$ with $-\pi/4 \leq \theta \leq \pi/4$. The $\rho$- and $\psi$-integrals can be evaluated analytically. The latter integral, similar to the two-impurity problem, excludes the diverging $\rho$-integrals. The $\phi$-integral, on the other hand, can be written as

$$I_\omega = \int_{-\pi/2}^{\pi/2} \frac{d\phi \ e^{i\omega\phi}}{\left[A(\theta) \cos(3\phi) + iB(\theta) \sin(3\phi)\right]^2},$$

(80)

with $w = 6 \times \text{integer}$. Here, we used the hyperspherical harmonics $Y_{\alpha\beta\gamma}(\theta, \phi, \psi)$, which are given by

$$Y_{\alpha\beta\gamma}(\theta, \phi, \psi) = \left( \frac{1}{\sqrt{2}} - 1 \right) \delta_{\alpha,0} + \left( \frac{1}{2\pi} \right) \left( (m, \nu, \mu) \pm (\rho^\pm \alpha, \nu, \mu) \right),$$

(81)

where

$$\langle m, \nu, \mu | \rho^\pm \alpha, \nu, \mu \rangle = \sqrt{\frac{1}{2} \delta_{\alpha,0}}\Theta_{\rho^\pm \alpha}(x)^{\nu \mu},$$

(82)

with

$$\Theta_{\rho^\pm \alpha}(x) = (1 - x)^{\alpha/2}(1 + x)^{\rho^\pm \alpha/2} P_{\rho^\pm \alpha}(x).$$

(83)
with the Jacobi polynomials $P^\gamma_\delta(x)$ and the following numbers

$$\tilde{m} = \frac{m - \max(|\mu|, |\nu|)}{2}, \quad \alpha = \frac{|\nu + \mu|}{2}, \quad \text{and} \quad \beta = \frac{|\nu - \mu|}{2}.$$ (84)

The integral (80) can be transformed into a rational function of a complex variable by the substitution of $z = \exp(2i\phi)$:

$$I_w = -\frac{2i}{(A + B)^2} \int_0^\pi dz \frac{e^{2i w/2}}{(3^3 + \kappa)^2},$$ (85)

where the contour $C$ is the unit circle, and $\kappa = (A - B)/(A + B)$. This contour integral can be further written as

$$I_w = \frac{2i}{(A + B)^2} \frac{\partial}{\partial \kappa} \int_0^\pi dz \frac{e^{2i w/2}}{(z^3 + \kappa)^2},$$ (86)

where the latter contour integral can be straightforwardly determined by using the residue theorem. For $w \geq 0$ the integral is given by

$$I_w = -\frac{4\pi e^{i w/2} + 2\cos(\pi w/6)}{3(A + B)^2} \frac{\partial}{\partial \kappa} \left( H(1 - \kappa)^{w/6} \right),$$ (87)

which yields

$$I_w = \frac{2\pi e^{i w/2}}{3} \left( \delta(\theta) - \frac{w H(\theta)}{(A + B)^2} \left( A - B \right) \hat{x}^{-1}, \right),$$ (88)

with $H(\theta)$ being the step function. The $w < 0$ case, on the other hand, can be easily obtained by changing $w \rightarrow -w$ and $\theta \rightarrow -\theta$ in Eq. (88). Finally, the remaining $\theta$-integral can be calculated numerically.

C. Diagonalization of the impurity Hamiltonian

In this appendix we elaborate on why we expect to see that the spectrum of the full Hamiltonian operator converges to that of the lowest sector of the Fock space. Namely, we find that any eigenstate with low energy will have vanishing components outside the lowest sector in the adiabatic limit $\omega \rightarrow \infty$. However, a few technical assumptions enter because the various components of the full operator depend on the particle number.

Starting with an impurity-bath coupled Hamiltonian of the form [18],

$$H_0 := H_0 + \omega \hat{a}^\dagger \hat{a} + \lambda \omega (F \hat{a}^\dagger + F^{-1} \hat{a}) + \lambda^2 \omega$$

where $\omega \geq 0$ and $\lambda \in \mathbb{R}$ are parameters, and

$$H_0 := \sum_{j=1}^N \left[ -\nabla^2_x + V(x) \right]$$

acts in some $N$-body Hilbert space $\mathcal{H}$, let us define for arbitrary coupling $\gamma \in \mathbb{R}$ a deformed $N$-body operator

$$H_0^\gamma := \sum_{j=1}^N \left[ -(\nabla_x + \gamma F_j)^2 + V(x) \right].$$ (89)

For generality we allow for a potential $V$ (which may depend on all the variables and thus also include interactions), and also for $F$ to be any function of $x_1, \ldots, x_N$ such that

$$F_j := \nabla_x \log F = F^{-1} \nabla_x F$$

in (89) is well defined, say smooth, at least for non-coincident $x_j$ (we may then take an appropriate dense domain in $\mathcal{H}$).

Using $\hat{S} = F^\dagger, \hat{n} = \hat{a}^\dagger \hat{a}$, and $\hat{U} = e^{-i \hat{a}^\dagger \hat{a}}$ in the expansion

$e^X Ye^{-X} = Y + [X, Y] + \frac{1}{2!} [X, [X, Y]] + \frac{1}{3!} [X, [X, [X, Y]]] + \ldots$

we obtain the transformations

$$\hat{S}^{-1} \nabla x \hat{S} = \nabla x + F \hat{n},$$
$$\hat{S}^{-1} \hat{a}^{(i)} \hat{S} = F^{(i)} \hat{a}^{(i)},$$
$$\hat{U}^{-1} \hat{a}^{(i)} \hat{U} = \hat{a}^{(i)} - \lambda,$$

and thus $H_\omega$ is similar to

$$H_\omega := \hat{U}^{-1} \hat{S}^{-1} H_\omega \hat{S} \hat{U} = H_0 + \omega \hat{n},$$

$$H_\omega = \sum_{j=1}^N \left[ -\nabla^2_x + V(x) - (\nabla_x \cdot F_j + 2 F_j \cdot \nabla_x) \hat{U}^{-1} \hat{n} \hat{U} - F_j^2 \hat{U}^{-1} \hat{n}^2 \hat{U} \right].$$

We compute for arbitrary $n = 0, 1, 2, \ldots$

$$\hat{U}^{-1} \hat{n} \hat{U} |\mu\rangle = (\hat{a}^\dagger - \lambda (\hat{a}^\dagger + \hat{a}) + \lambda^2) |\mu\rangle = (n + \lambda^2) |\mu\rangle - \lambda \sqrt{n+1} |n+1\rangle - \lambda \sqrt{n} |n-1\rangle,$$

$$\hat{U}^{-1} \hat{n}^2 \hat{U} |\mu\rangle = (\hat{a}^\dagger - \lambda (\hat{a}^\dagger + \hat{a}) + \lambda^2) n + 4 \lambda^2 \hat{n} + \lambda^2 (\hat{a}^\dagger^2 + \hat{a}^2) - 2 \lambda^2 (\hat{a}^\dagger + \hat{a}) + \lambda^2 + \lambda^4) |\mu\rangle = (n^2 + 4 \lambda^2 n + \lambda^2 + \lambda^4) |\mu\rangle - \lambda (2n + 1 + 2 \lambda^2) \sqrt{n+1} |n+1\rangle + \lambda^2 \sqrt{n+2} \sqrt{n+1} |n+2\rangle - \lambda (2n - 1 + 2 \lambda^2) \sqrt{n} |n-1\rangle + \mu^2 \sqrt{n} \sqrt{n-1} |n-2\rangle.$$
and thus obtain the non-trivial operator matrix elements

\[
\langle n | H'_\omega | n \rangle = \sum_{j=1}^{N} \left[ -\nabla^2_{x_j} + V(x) + \omega n - (\nabla_{x_j} \cdot F_j + 2F_j \cdot \nabla_{x_j})(n + \lambda^2) \sigma_j \right] = H_0^{(\omega + \lambda^2)\sigma} + \omega n - \lambda^2(1 + 2n)\sigma, \\
\langle n + 1 | H'_\omega | n \rangle = \sum_{j=1}^{N} \left[ - (\nabla_{x_j} \cdot F_j + 2F_j \cdot \nabla_{x_j})(-\lambda \sqrt{n + 1}) - F_j^2(-\lambda(2n + 1 + \lambda^2) \sqrt{n + 1}) \right] = \lambda \sqrt{n + 1}(H_0 - H_0^{F} + 2(n + \lambda^2)\sigma) \\
\langle n - 1 | H'_\omega | n \rangle = \sum_{j=1}^{N} \left[ - (\nabla_{x_j} \cdot F_j + 2F_j \cdot \nabla_{x_j})(\lambda \sqrt{n}) - F_j^2(\lambda(2n - 1 + \lambda^2) \sqrt{n}) \right] = \lambda \sqrt{n}(H_0 - H_0^{F} + 2(n - 1 + \lambda^2)\sigma) \\
\langle n + 2 | H'_\omega | n \rangle = \sum_{j=1}^{N} \left[ - F_j^2(\lambda^2 \sqrt{n + 2} \sqrt{n + 1}) = -\lambda^2 \sqrt{n + 2} \sqrt{n + 1} \sigma \\
\langle n - 2 | H'_\omega | n \rangle = \sum_{j=1}^{N} \left[ - F_j^2(\lambda^2 \sqrt{n - 2} \sqrt{n - 1}) = -\lambda^2 \sqrt{n - 2} \sqrt{n - 1} \sigma. \right]
\]

Hence, we have a symmetric pentadiagonal matrix of operators

\[
\begin{bmatrix}
H_0^{(\omega + \lambda^2)\sigma} - \lambda^2 F^2 \\
\lambda(H_0 - H_0^F + 2\lambda^2 F^2) \\
-\lambda^2 \sqrt{2F^2} \\
0 \\
\vdots
\end{bmatrix}
\begin{bmatrix}
H_0^{(\omega + \lambda^2)\sigma} - \lambda^2 F^2 \\
\lambda(H_0 - H_0^F + 2\lambda^2 F^2) \\
-\lambda^2 \sqrt{2F^2} \\
0 \\
\vdots
\end{bmatrix}
\]

Note that for the choice (33), \( F_j = 2i \lambda \), so \( F^2 = 0 \) and these expressions simplify significantly, while with the choice (19), \( F_j = 2i \lambda \), \( F^2 = 4\lambda^2 \geq 0 \), and \( H_0^F = H_0^A = H_0 \), \( H_0^F = H_0^A \) is unitary equivalent to \( H_0^F \). Furthermore, one has the unitary equivalence of \( H_0^{(\omega \lambda)A} \) to \( H_0^{(\omega + 2\lambda^2)A} \) for any integer \( n \) as well as the diamagnetic inequality \( \langle H_0^{(\omega \lambda)A} \rangle_\phi \geq \langle H_0 \rangle_\phi \) for any \( \sigma \in \mathbb{R} \) and \( \Phi \in \mathcal{H} \) [69]. while \( H_0^{(\omega \lambda)A} = [\Phi^\gamma F^2 H_0^A | F^2 \gamma^2] \), also implying isospectrality for \( H_0^{(\omega + 2\lambda^2)A} \). Hence, if \( H_0 \geq -C \) and we consider a truncated subspace of \( N \)-body states \( \Phi_n \in \mathcal{H} \) for which \( \text{Re} \langle \pm H_0^F | \Phi_n \rangle \leq C \) and \( 0 \leq \langle F^2 \rangle_{\Phi_n} \leq C \) independent of \( n \) and \( \omega \), then for any normalized \( |\Psi\rangle = \sum_{n=0}^{\infty} \Phi_n |n\rangle \) with finite expectation \( \langle \hat{n}^{3/2} \rangle_\Psi \) (in the case \( F^2 = 0 \) it is sufficient that \( \langle \hat{n} \rangle_\Psi \leq C \)),

\[
\text{Re} \langle \Psi | H'_\omega' | \Psi \rangle \geq \sum_{n=0}^{\infty} \left( (n + 1) |\Phi_n| \right)^2 - 2|\Psi| \lambda \sqrt{n + 1} |\Phi_n| (H_0 - H_0^F + 2(n + \lambda^2 F^2) |\Phi_{n+1}|) - 2\lambda^2 \sqrt{n + 1} \sqrt{n + 2} |\Phi_n| F^2 |\Phi_{n+2}| \right) \\
\geq -2C(1 + |\Psi| \lambda \sqrt{2F^2} |\Phi_0|^2 + \sum_{n=0}^{\infty} (n - C - 8) |\Psi| \lambda \sqrt{n + 1} (1 + n + \lambda^2 C - 4\lambda^2 \sqrt{n + 1} \sqrt{n + 2} C) |\Phi_n| F^2 |\Phi_{n+2}|)
\]

by the Cauchy-Schwarz inequality. Keeping \( N \) and \( \lambda \) fixed, and demanding that \( \langle H'_\omega' | \Psi \rangle \) stays bounded while \( \omega^{-1} \langle \hat{n}^{3/2} \rangle_\Psi \to 0 \) as \( \omega \to \infty \), thus requires that \( 1 - |\Phi_0| = \sum_{n=0}^{\infty} |\Phi_n| \leq \langle \hat{n} \rangle_\Psi \to 0 \) by the above inequality.

Therefore, in the limit as \( \omega \to \infty \), the lowest part (as quantified by \( C \)) of the spectrum of \( H'_\omega \), and equivalently \( H_\omega \), is described by that of

\[
H_0^{(\omega + \lambda^2)\sigma} - \lambda^2 F^2 = \langle 0 | H'_\omega | 0 \rangle = 0 \langle 0 | \hat{S}^{-1} H_0 \hat{S} \hat{U} | 0 \rangle = e^{-\lambda^2 \sum_{n=0}^{\infty} \frac{\lambda^n}{n!} F^{-n} H_0 F^n}, \tag{90}
\]
where in the last identity we used the coherent state (25).
