ABSTRACT

A 21-year-old male was admitted with severe right arm and hand tremors after a thalamic hemorrhage caused by a traffic accident. He was also suffering from agonizing pain in his right shoulder that manifested after the tremor. Neurologic examination revealed a disabling, severe, and irregular kinetic and postural tremor in the right arm during target-directed movements. There was also an irregular ipsilateral rest tremor and dystonic movements in the distal part of the right arm. The amplitude was moderate at rest and extremely high during kinetic and intentional movements. The patient underwent left globus pallidum internus and ventral intermediate thalamic nucleus deep brain stimulation. The patient improved by more than 80% as rated by the Fahn-Tolosa-Marin Tremor Rating Scale and Visual Analog Scale six months after surgery.

Key Words  Deep brain stimulation; globus pallidus internus; Holmes' tremor; shoulder pain; ventralis intermedius nucleus.

Holmes' tremor (HT) is a rare phenomenon characterized by the unique combination of resting, postural, and kinetic tremors. HT typically appears from a week to years after an injury to red nuclei or their connections, such as ischemia, hemorrhage, trauma or neoplasm, affecting both the nigro-striatal system and the cerebello-thalamic tractus. There are usually other symptoms accompanying the tremor, such as nystagmus, dysarthria, dystonia, motor and sensorial deficits, depending on the original cause.

HT is a disabling, relatively low frequency (< 4–5 Hz) and irregular tremor that usually affects the proximal part of the limb, but the distal part may also be affected. There are several medical treatment options for HT, but these are frequently insufficient to relieve the symptoms. For these patients, surgery is an alternative treatment. Until now, ablative procedures such as thalamotomy and pallidotomy, as well as deep brain stimulation (DBS) of the ventral intermediate nucleus of thalamus (Vim), globus pallidus internus (GPI), or the area between the zona incerta and ventralis oralis anterior have been reported to be effective. However, the efficacy of targeting two different nuclei unilaterally in the same patient is rarely reported.

In the present study, we report a case of HT due to thalamic hemorrhage successfully treated by DBS of the unilateral Vim and GPI.

CASE REPORT

A 21-year-old male was admitted with severe right arm and
hand tremors after a thalamic hemorrhage caused by a traffic accident. He was also suffering from agonizing pain in his right shoulder that manifested after tremor. He had no prior relevant medical history and there were no abnormalities in his general physical findings. No pathology was diagnosed during orthopedic surgery consultation. Neurologic examination revealed disabling, severe, and irregular kinetic and postural tremors in the right arm during target-directed movements. There was also an irregular ipsilateral rest tremor as well as dystonic movements in the distal part of the right arm. The amplitude was moderate at rest and extremely high in kinetic and intentional movements. His baseline severity of tremor was evaluated with Fahn-Tolosa-Marín Tremor Rating Scale (TRS), and the preoperative score was 20 for the proximal and 36 for the distal arm. He marked the intensity of his shoulder pain as 9/10 using the Visual Analog Scale (VAS). Brain MRI showed no abnormality except the thalamic hypointensity in T2-weighted sequences in the left side compatible with the sequelae of the former thalamic hemorrhage (Figure 1). Optimum dosages of levodopa, amantadine, benzodiazepine, and anticholinergic agents did not relieve his tremor.

The surgical procedure was performed under local anesthesia and sedation using the Leksell (Elekta, Stockholm, Sweden) stereotactic frame with ring system. The surgical targets were the left GPi and Vim. Their positions were localized anatomically by direct visualizing on T2-weighted and inversion recovery MRI. FrameLink 2.0 software (Medtronic, Inc., Minneapolis, MN, USA) was used for the application of the computed tomography (CT)-MR fusion technique, and the MR image was reformatted to the anterior commissure-posterior commissure plane to yield the calculated coordinates for the GPi and Vim with the aid of Schaltenbrand and Wahren stereotactic atlas. Quadripolar electrodes (Model KN 1063, Medtronic, Inc.) were implanted in the left GPi and Vim in a single session. Electrode targeting was confirmed for Vim and GPi using microelectrode recordings (MERs). MERs were performed in three canals (center, medial, and posterior) for Vim and two canals (lateral and center) for GPi. The posterior canal was selected for Vim, and the center canal was selected for GPi according to MERs. Macrostimulation was performed for both targets and demonstrated no side effects. Macroelectrode stimulation showed improvement of more than 60% in the tremors and amelioration of his dystonia.

The final stereotactic x, y, z, ring, and arc coordinates of the targeted left GPi were 114.1, 108.4, 95.5, 73.7, and 99.5, respectively. For the left Vim they were 116.2, 88.5, 94.2, 52.8, and 111.9, respectively. Following implantation of the DBS lead, he was placed under general anesthesia for implantation of the pulse generator (Medtronic Soletra, Model 7426; Medtronic Neuromodulation). His immediate postoperative TRS was 11 points, and his VAS score was decreased to 3 after the surgery.

A postoperative cranial CT scan was performed to confirm the position of the electrodes. The electrodes were activated seven days after the surgery. The stimulation parameters were 1 V, 130 Hz, and 90 μs, with monopolar stimulation on contact 0 for both targets. Six months after stimulation, the tremor showed improvement, especially the resting component. The effects of the Vim and GPi stimulation were evaluated separately by individual activation of the leads. Final stimulation adjustments were 3 V, 90 μs, and 100 Hz for the Vim and 3 V, 210 μs, and 130 Hz for the GPi. The final TRS score for his right upper extremity tremor was 3 for the proximal and 4 for the distal arm. His VAS score was 1 at six months after surgery. There were no side effects related to the stimulation.

**DISCUSSION**

HT is characterized by a low frequency (typically < 4.5 Hz) tremor with irregular rest, action, and postural components, sometimes with an element of
The pathophysiology of HT is complex and full of speculation. It has been shown that impairment of the nigrostriatal pathway is not necessary and damage of cerebello-thalamic pathway is sufficient for HT development. Our patient did not respond to levodopa treatment, proving there were no changes in the nigrostriatal area.

The outflow pathways from GPi provide a direct influence on not only the thalamus but also the brain-stem motor centers, such as the pedunculopontine nucleus, related to the mesencephalic tegmental field that controls the axial and proximal appendicular musculature via the descending reticulospinal tract. Therefore, unlike thalamic surgery, which interrupts the thalamocortical output that controls distal appendicular musculature via descending corticospinal and corticobulbar tracts, GPi pallidal DBS influences the control of otherwise inaccessible axial and proximal muscles. This may be the reason why GPi DBS provides satisfactory improvement of proximal tremors.

A rapid decrease in distal tremors (as expected by thalamic surgery) and a late (within 6 weeks) response of proximal tremors (as expected by GPi surgery both for tremor and dystonia) probably indicate that both targets are effective in our case. This is the third demonstration of GPi + Vim surgery being effective in the treatment of HT. Based on our experience, we propose implanting GPi DBS as well as Vim in patients who have a proximal tremor.

On the other hand, one of the major complaints made by our patient was pain in his right shoulder, which occurred secondary to his proximal tremor. To the best of our knowledge, this is the first HT patient with shoulder pain in the literature. GPi DBS was also important from this perspective as it aided the satisfactory recovery of his shoulder pain.

In conclusion, because of the limited efficacy of Vim DBS on proximal tremors, the use of other or additional targets with better effects should be considered for the treatment of HT. To this end, GPi could be considered as an additional target, especially for HT patients with a predominant proximal tremor component.
