Abstract. Ultracool subdwarfs are low luminosity, late-type M and L dwarfs that exhibit spectroscopic indications of subsolar metallicity and halo kinematics. Their recent discovery and ongoing investigation have led to new insights into the role of metallicity in the opacity structure, chemistry (e.g. dust formation) and evolution of low-temperature atmospheres; the long-term evolution of magnetic activity and angular momentum amongst the lowest-mass stars; the form of the halo luminosity and mass functions down to the hydrogen-burning mass limit; and even fundamental issues such as spectral classification and absolute brightness scales. This Splinter Session was devoted to bringing advances in observational and theoretical ultracool subdwarf research to the attention of the low-mass stellar and brown dwarf communities, as well as to share results among ultracool subdwarf enthusiasts.

1. INTRODUCTION

The late-type M and L dwarf classes of ultracool dwarf stars and brown dwarfs are now well-sampled, due in large part to wide-field red and infrared imaging surveys such as 2MASS, DENIS and SDSS. We are now beginning to uncover the metal-poor, halo counterparts to these disk dwarfs, the so-called ultracool subdwarfs [1]. These sources have been found primarily in wide-field imaging surveys and the first generations of red/near-infrared proper motion surveys. Discoveries include the first L-type—and possibly T-type—subdwarfs, extending our knowledge of the Galactic halo down to the substellar (brown dwarf) regime. As the low-mass ultracool subdwarfs, with their extremely long nuclear burning lifetimes, were presumably formed early in the Galaxy’s history, they are important tracers of Galactic structure and chemical enrichment history. In addition, detailed studies of their complex spectral energy distributions are facilitating new insights on the role of metallicity in the opacity structure, chemistry and evolution of cool atmospheres; the long-term evolution of magnetic activity and angular momentum; and fundamental issues of spectral classification and temperature/luminosity scales.
This Splinter was devoted to highlighting advances in ultracool subdwarf research, both observational and theoretical. It was organized into three subtopics: Discoveries, Classification and Fundamental Parameters. Individual presentations will be made available at [http://www.browndwarfs.org/cs15](http://www.browndwarfs.org/cs15).

### 2. DISCOVERIES

#### 2.1. An Extremely Wide and Very Low-Mass Common Proper Motion Pair - Representatives of a Nearby Halo Stream?

(R.-D. Scholz et al.)

A pair of faint stars sharing exactly the same very large proper motion of about 860 mas/yr and separated by about six degrees has been discovered in a high proper motion survey of the southern sky using multi-epoch positions and photometry from the SuperCOSMOS Sky Surveys. The two stars, SSSPM J2003−4433 and SSSPM J1930−4311, have been classified as a late-type (M7) dwarf and an ultracool subdwarf (sdM7) (Figure 1) with individually estimated spectroscopic distances of 38 pc and 72 pc, respectively. In view of the accurate agreement in their large proper motions a common distance of about 50 pc and a projected physical separation of about 5 pc has been assumed, ruling out a physical binary. The mean heliocentric space velocity of the pair \((U, V, W) = (-232, -170, +74)\) km s\(^{-1}\) is typical of the Galactic halo population. These values rely on a preliminary radial velocity measurement and on the assumption of a common distance and velocity vector. The large separation and the different metallicities of dwarf and subdwarf make a common formation scenario as a wide binary (later disrupted) improbable. It seems more likely that this wide pair is part of an old halo stream [2].

![Figure 1. Low-resolution classification spectra of SSSPM J2003−4433 (M7) and SSSPM J1930−4311 (sdM7) and some comparison sources (from [2]).](image)
2.2. A Metal-poor Mid-T dwarf from the CFBDS Survey (P. Delorme et al.)

We report the discovery of CFBDS J150000-182407, a T subdwarf candidate which we identified during the Canada France Brown Dwarf Survey (CFBDS). CFBDS [3] is an $i'-z'$ wide-field search for ultracool brown dwarfs which uses the MegaCam wide-field camera on the Canada-France-Hawaii Telescope (CFHT).

CFBDS1500 is a peculiar T4.5 dwarf, with strong spectroscopic evidence for a subsolar metallicity. Comparison of the overall shape of its spectrum with synthetic spectra from [4] suggests $[\text{M/H}] \sim -0.3$, while the complete absence of the $\sim 1.25 \mu\text{m}$ K I doublet (Figure 2) rather suggests that $[\text{M/H}] \leq -0.5$ when comparing with the same models. The kinematics of CFBDS1500 imply an 80% probability that it belongs to the thick disk, but leaves ~10% probability that it instead is an older member of the thin disk or a member of the halo. $[\text{M/H}] \sim -0.5$ is consistent with either thick disc membership or an older thin disk population, while $[\text{M/H}] \sim -0.3$ would lean slightly towards the older thin disk but remains easily compatible with thick disk membership.

Spectroscopy and kinematics together make CFBDS1500 a strong thick disk candidate, and as such the first incontrovertibly substellar object which would not belong to the thin disk. As one of the few low-metallicity brown dwarfs known, it is a major benchmark for synthetic spectra. The inconsistency between the metallicity determined from the strength of the K I doublet and from the general shape of the spectrum will need to be explained. We tend to trust the metallicity constrain from the K I doublet more, since it depends (besides, admittedly, the structure of the atmosphere) on a single line pair with very well understood atomic physics, rather than on millions of incompletely characterized molecular lines.

If the $[\text{M/H}] \sim -0.5$ metallicity holds, the observed spectrum would suggest that the models overestimate the sensitivity of the general shape of the spectrum to metallicity, especially in the $J$-band. That would hardly be a surprise, given the many poorly constrained physical inputs that need to be taken into account. Since the discovery of
brown dwarfs belonging to old Galactic populations is now possible, it becomes crucial to interpret their spectra with state-of-the-art evolutionary models. The only one for low metallicity brown dwarfs (to our knowledge) was calculated without taking into account clouds in the atmosphere [6]. New theoretical work on this topic (e.g., [7]) is now a critical point of T sub-dwarfs characterization.

3. CLASSIFICATION

3.1. A Spectral Sequence of K- and M-type Subdwarfs
(W.-C. Jao et al.)

Using new spectra of 88 K and M-type subdwarfs, we have considered novel methods for assigning spectral types and take steps toward developing a comprehensive spectral sequence for subdwarf types K3.0 to M6.0. The types are assigned based on the overall morphology of spectra covering 6000Å to 9000Å through the understanding of GAIA model grids. The types and sequence presented link the spectral types of cool subdwarfs to their main sequence counterparts, with emphasis on the relatively opacity-free region from 8200–9000Å. When available, supporting abundance, kinematic, and trigonometric parallax information is used to provide more complete portraits of the observed subdwarfs. We find that the CaHn (n= 1–3) and TiO5 indices often used for subdwarf spectral typing are affected in complicated ways by combinations of subdwarfs’ temperatures, metallicities, and gravities, and we use model grids to evaluate the trends in all three parameters. Because of the complex interplay of these three characteristics, it is not possible to identify a star as an “extreme” subdwarf simply based on very low metallicity, and we suggest that the modifiers “extreme” or “ultra” only outline locations on spectroscopic indices plots, and should not be used to imply low or very low metallicity stars. In addition, we propose that “VI” be used to identify a star as a subdwarf, rather than the confusing “sd” prefix, which is also used for hot O and B subdwarfs that are unrelated to the cool subdwarfs. These results have been published in [8].

3.2. Spectroscopic Sequences of Cool and Ultra-cool Subdwarfs
(sdM/esdM/usdM) from the Sloan Digital Sky Survey
(S. Lépine et al.)

We present new spectra of cool and ultra-cool subdwarfs, obtained from the Sloan Digital Sky Survey (SDSS). Thousands of these sources have now been observed in SDSS (see [9] and poster by Lépine, these proceedings). The stars were categorized in a new, recently expanded classification system [10] as subdwarfs (sdM), extreme subdwarfs (esdM), and ultrasubdwarfs (usdM), based on the ratio of the TiO to CaH molecular bands. It is argued that the M/sdM/esdM/usdM subclasses represent a metallicity sequence (cf. [11, 12]), with the usdM being the most metal-poor of the subdwarfs.

While it has been suggested by others that the morphology of the subdwarfs depends on both their metallicity and gravity, observational evidence supports the idea that metal-
licity is the dominant parameter, and that the current classification system effectively ranks the stars according to mass (subtype) and metallicity (subclass). As demonstrated in Figures 2 and 3 of [10], stars kinematically selected from the Galactic disk display only small variations in their TiO/CaH ratio, while stars kinematically selected from the Galactic halo display a very broad range of TiO/CaH values. The disk population has a broader range of stellar ages, and should also have a broader range of surface gravities than the halo stars, which are uniformly old. The fact that the disk stars have a much smaller range of TiO/CaH than the halo stars indicates than metallicity effects must dominate in the subdwarfs. Furthermore, atmospheric models indicate that gravity variations not only change the TiO/CaH ratio, but they also notably affect the strength of atomic spectral lines such as KI and NaI. However SDSS spectra show no clear variation in the equivalent widths of the KI, NaI, and CaII lines for stars of a given subclass and subtype, which again suggest that stars of similar subtypes have similar surface gravities. Gravity, in the nearby halo subdwarfs, is not a free parameter but is essentially set by the initial mass and metallicity of the subdwarf.

Ultra-cool subdwarfs are particularly useful for refining the current classification scheme, because their molecular bands and atomic lines are more prominent. Spectra of many cool and ultra-cool subdwarfs are now available in the SDSS database, and new ones should become available in the future as halo subdwarfs are now specifically targeted for follow-up spectroscopy. The new SDSS spectra also have a broad spectral coverage (4000Å-9000Å), and spectra from many late-type subdwarfs can be combined to obtain high signal-to-noise spectral templates. A fit to these templates yield a more reliable classification than the narrowly defined TiO5, CaH2, and CaH3 spectral indices. The use of the spectral indices in the classification is useful, but should be phased out in favor of the new SDSS classification templates (Lépine, in preparation).

3.3. L Subdwarfs: Classification, Distance Scale and Low-Metallicity Condensate Formation

(A. Burgasser et al.)

L subdwarfs are the metal-poor counterparts to the L dwarf class of low mass stars and brown dwarfs, effectively extending our sampling of halo stars to the (metallicity-dependent) hydrogen-burning mass limit. With strong metal hydride bands, weak metal oxides and red optical spectral energy distributions, the L subdwarfs share many of the same spectral characteristics as L dwarfs, but differ in their considerably bluer near-infrared colors ($J-K_s \approx 0$ vs $1.5-2.5$) and much stronger metal hydride, metal oxide and alkali line absorption in the red optical (Figure 3). The first L subdwarfs were identified in 2003; today there are at least three reported in the literature [13, 14, 15], not including the unusual source LSR 1610-0040 [16] discussed in detail below.

One of the recent advances in L subdwarf research is a formalized spectral classification scheme for these objects. While the classification of M subdwarfs is actively debated due to the large samples now available (see contributions from S. Lépine and W.-C. Jao), there are too few L subdwarfs to accurately define the class. [17] have proposed that L subdwarfs be classified according to the closest match to the L dwarf standards of [18]
in the 7300–9000 Å range (see Figure 3), a region in which peculiarities are minimized. This had provided preliminary types for 2MASS 0532+82 (sdL7 [13]), 2MASS 1626+39 (sdL4 [14]) and SDSS 1256-02 (sdL3.5 [15]).

As the first L subdwarf identified, 2MASS 0532+82 has been the best studied. It is the first L subdwarf to have its astrometric parallax measured \( \pi = 37.5 \pm 1.7 \text{ mas} \) [21], and combined with photometry from 2MASS and Spitzer [23] we have measured a luminosity of \( \log_{10} L_{\text{bol}}/L_{\odot} = -4.24 \pm 0.06 \) and estimate \( T_{\text{eff}} = 1730 \pm 90 \text{ K} \) for this source. These parameters are comparable to those of mid-type L field dwarfs, suggesting that L subdwarf classifications are “later” than corresponding L dwarf types. Interesting, these values make the hydrogen burning status of 2MASS 0532+82 somewhat ambiguous, since depending on its metallicity (which is largely unconstrained) this source may be a star, a brown dwarf, or a brown dwarf which will ultimately reach the main sequence and become a star! Examining absolute magnitude relations, it appears that the \( M_K/\text{spectral type} \) relation of L subdwarfs is roughly coincident with those of L dwarfs (Figure 3), although more astrometric work is needed (see also [20]). 2MASS 0532+82 is also the only L subdwarf with high resolution spectral observations [24], which indicate rapid rotation \( (v \sin i = 65 \pm 15 \text{ km s}^{-1}) \) suggesting the absence of angular momentum evolution for very low mass stars. The \( UVW \) velocities of this source unambiguously confirm it as a halo object, with a retrograde Galactic orbit relative to the Galactic disk.

We are currently examining theoretical spectral models for the sdL3.5 SDSS 1256-02 ([22]; also see next contribution by B. Swift). Using the Phoenix-Drift models [25], we have attempted to reproduce the observed optical and near-infrared colors and spectra of this source. Our results so far indicate a \( T_{\text{eff}} \approx 2100–2500 \text{ K} \) and \( [M/H] \approx -1.5 – -1.0 \text{ dex} \), although there remain strong discrepancies particularly in the red optical. Interestingly, we find that even with the most advanced treatment of (metallicity-dependent)
cloud formation, clouds in the models are too thick and condensation too efficient to match the observations of SDSS 1256-02, consistent with the “cloud suppression” in ultracool subdwarf atmospheres suggested in prior studies [13, 17, 24, 26].

4. FUNDAMENTAL PARAMETERS

4.1. Theoretical Modeling of L Subdwarf Spectra
(B. Swift et al.)

We present fits of atmospheric models of varying metallicity to the published optical and near-infrared spectrum and IRAC photometry of the sdL7 2MASS J05325346+8246465 [13]. This source is the best-observed member of a growing population of what are suspected to be metal-poor ultracool dwarfs, and the only one with a parallax distance. The model selection was made using a goodness-of-fit statistic in conjunction with Monte Carlo simulated data to account for uncertainties in the absolute flux; this statistic was then examined in various bands to study systematic issues in the models and to produce a concordance fit for the properties of this object in $T_{\text{eff}}$, log $g$ and [M/H] space.

4.2. Astrometric Observations of LSR 1610-0040
(M. Cushing et al.)

Since its discovery [16], LSR 1610-0040 has defied explanation. Its red optical spectrum and high proper motion suggest that LSR 1610-0040 is an early-type L subdwarf, yet its near-infrared spectrum indicates a mid-type dM or sdM, albeit with numerous peculiar spectral features [24, 27]. Based on a comparison of its near-infrared spectrum to that of field M dwarfs, [27] assign LSR 1610-0040 a spectral type of sd/dM6.

We present new astrometric observations of LSR 1610-0040 [20]. At a measured distance of $\sim$32 pc, its position in color/absolute magnitude diagrams ($M_V$ vs $V-I$, $M_K$ vs $I-K_s$, $M_J$ vs $J-K_s$) is consistent with mid-type M dwarfs. However, its $B-V$ color is 1.2 mags redder than both M subdwarfs and dwarfs of similar spectral types. We speculate that the $B$-band magnitude of LSR 1610-0040 is suppressed due to enhanced AlH absorption since Al appears over-abundant relative to solar based on the strength of the 1.313 $\mu$m Al I doublet.

Perhaps most interesting is that the astrometric observations indicate that LSR 1610-0040 is an unresolved binary with a period of 1.66 yr. The photocentric orbit has a moderate eccentricity of 0.44$\pm$0.02, a semi-major axis of 0.28$\pm$0.01 AU, and an inclination of 83$\pm$1$^\circ$. Under the assumption that the secondary contributes little to no light to the system, and using a near-infrared mass luminosity relation, we estimate the masses of the components to be $M_A = 0.095$ M$_{\odot}$ and $M_B = 0.059$ to 0.082 M$_{\odot}$. We speculate that LSR 1610-0040A was originally a 0.05 Msun star with [Fe/H] $\sim$ −2 which later accreted $<0.05$ M$_{\odot}$ of material from a massive AGB star that has undergone hot bottom burning. Pollution by such material, enhanced in Al and Na and depleted
in O, would then explain the peculiar spectrum of LSR 1610-0040A. LSR 1610-0040B has too little mass to be the remnant white dwarf of such a hypothetical AGB star so the AGB star in question must have been a more distant companion that has since been lost from the system.
