Multiply periodic states and isolated skyrmions in an anisotropic frustrated magnet

A.O. Leonov¹ & M. Mostovoy¹

Multiply periodic states appear in a wide variety of physical contexts, such as the Rayleigh–Bénard convection, Faraday waves, liquid crystals and skyrmion crystals recently observed in chiral magnets. Here we study the phase diagram of an anisotropic frustrated magnet which contains five different multiply periodic states including the skyrmion crystal. We clarify the mechanism for stabilization of these states and discuss how they can be observed in magnetic resonance and electric polarization measurements. We also find stable isolated skyrmions with topological charge 1 and 2. Their spin structure, interactions and dynamics are more complex than those in chiral magnets. In particular, magnetic resonance in the skyrmion crystal should be accompanied by oscillations of the electric polarization with a frequency depending on the amplitude of the a.c. magnetic field. These results show that skyrmion materials with rich physical properties can be found among frustrated magnets. We formulate rules to help the search.

The magnetic skyrmion is a topological defect with a complex non-coplanar spin structure\(^1\). Predicted over 20 years ago\(^2\), skyrmions have been recently observed in conducting and insulating helimagnets under an applied magnetic field\(^3,4\). Magnetic skyrmion provides a physical realization of the idea that quantization of physical observables, such as electric and baryon charge, is rooted in topology\(^5,6\). The realization of the idea that quantization of physical observables, skyrmion spin texture induces one flux quantum of an effective exchange constant, \(J_{\text{NN}}\), \(J_{\text{NNN}}\) exchange interactions, such as electric and baryon charge, is rooted in topology\(^5,6\). The critical magnetic field transforms into the SkX, in addition, a state with two coexisting spirals was found in applied magnetic fields. These multi-\(q\) states are induced by thermal fluctuations and appear at non-zero temperatures.

Here we discuss a mechanism that lends stability to multiply periodic states even at zero temperature. We show that a uniaxial magnetic anisotropy strongly affects spin ordering in the frustrated triangular magnet: tuning magnetic field and anisotropy at zero temperature, we find eight different phases, five of which are multi-\(q\) states. A large part of the phase diagram is occupied by the SkX. We clarify the nature of the phases found in numerical simulations and present results of analytical studies of instability of spiral states towards additional periodic modulations. We calculate magnetic resonance spectra and magnetically induced electric polarization, which show strong sensitivity to spin ordering and can be used for experimental identification of complex magnetic states. We explore rich physics of isolated skyrmions in frustrated magnets. Their monopole and toroidal moment densities oscillate with the distance from the skyrmion centre, which gives rise to alternation of attraction and repulsion between skyrmions, clustering of skyrmions in high magnetic fields and stability of skyrmions with topological charge 2. Dynamics of skyrmions in frustrated magnets is different from that of chiral magnets because of the additional collective degree of freedom—skyrmion helicity. The coupling between the helicity and the skyrmion centre-of-mass motion leads to a dynamical magnetoelectric effect.

**Results**

**The model.** We consider classical spins, \(S_i\), of unit length on a triangular lattice in the \(xy\)-plane with FM nearest-neighbour (NN) and anti-FM next-NN (NNN) exchange interactions:

\[
E = -J_1 \sum_{\langle ij \rangle} S_i \cdot S_j + J_2 \sum_{\langle \langle ij \rangle \rangle} S_i \cdot S_j - h \sum_i S_i^z - \frac{K}{2} \sum_i (S_i^+)^2. \tag{1}
\]

where \(\langle ij \rangle\) and \(\langle \langle ij \rangle \rangle\) denote pairs of NN and NNN spins, respectively, and \(J_1, J_2 > 0\). The third and the fourth terms describe, respectively, the interaction with the magnetic field parallel to the \(z\) axis and the single-ion magnetic anisotropy.

The critical ratio \(J_2/J_1\) for appearance of magnetic spirals and other modulated spin states is 1/3. This can be understood by considering a modulation with the wave vector along the \(y\) axis parallel to a NNN bond (see inset in Fig. 2b), in which case the model effectively reduces to a spin chain running in the \(y\) direction with the FM NN interaction, \(J_1' = 2(J_1 - J_2)\), and the anti-FM NNN interaction, \(J_2' = J_2\). A spiral state in a chain appears for \(J_2/J_1 > \frac{1}{3}\) which corresponds to \(J_2/J_1 > \frac{1}{2}\). In what follows, the value of \(J_1\) is set to 1.

**Phase diagram.** Figure 1 shows the zero-temperature phase diagram of the model in the \((K,h)\)-plane for \(J_2 = 0.5\), which counts eight phases. Their spin configurations can be described in terms of the Fourier series,

\[
S_i = A_0 + \sum_{q \neq 0} A_q e^{i q \cdot x_i} + c.c. + \text{higher harmonics}, \tag{2}
\]

where \(q_1 = q(0,1)\), \(q_2 = q(-\frac{2}{3}, \frac{2}{3})\) and \(q_3 = q(\frac{2}{3}, \frac{2}{3})\) are the wave vectors of the three fundamental modulations minimizing the exchange energy (inset in Fig. 2b), such that \(q_1 + q_2 + q_3 = 0\). In all states, except the flop state (FL), the uniform spin component \(A_0\) is parallel to the applied magnetic field: \(A_0 = (0, 0, A_0^z)\). The amplitudes of higher harmonics, that is, modulations with other wave vectors from the triangular lattice

---

**Figure 1 | Zero-temperature phase diagram of the frustrated triangular antiferromagnet.** The eight phases are as follows: fully polarized ferromagnetic state (FM), conical spiral (CS), \(2q\)-state, \(2q'\)-state, vertical spiral (VS), VS plus two in-plane sinusoidal modulations (M), flop state (FL) and skyrmion crystal (SkX). Dashed line is the upper critical field, above which isolated skyrmions are unstable. The NNN exchange constant, \(J_2 = 0.5\), magnetic anisotropy, \(K\), and magnetic field, \(h\), are measured in units of the NN exchange constant, \(J_1 = 1\).
in the reciprocal space spanned on \( q_1 \) and \( q_2 \), are relatively small. The eight ground states of the model are:

1. The fully polarized FM state with \( A_0^0 = 1 \) and \( A_s = 0 \).
2. The CS state, which occupies the region of \( K<0 \) (easy plane anisotropy) and \( h<h_c(K) = \left( \frac{\sqrt{3}}{\pi} \right) K \). This is a single-\( q \) state with only one non-zero \( A_s \), describing a circular spiral in the horizontal plane, for example, \( A_1^* = \pm i A_1^0 \) and \( A_2^* = 0, \pm \) sign corresponding to two opposite directions of spin rotation in the spiral.
3. The 2-\( q \)-state with \( |A_1| > |A_2| \geq |A_3| \) (Fig. 2a). For \( K>0 \) (easy axis anisotropy), the conical state acquires the second spiral modulation in the horizontal plane, for example, with the wave vector \( q_2 \) and the opposite sense of spin rotation compared with that in the first spiral: \( A_1^* = \pm i A_1^0, A_2^* = 0 \).

4. The 2-\( q' \)-state, which is the same as the 2-\( q \)-state but with \( |A_1| = |A_3| \) (Fig. 2b). As \( K \) increases, the amplitude of the second spiral grows until it becomes equal to that of the first spiral. This transition is marked by dotted line in Fig. 1.

5. The spiral in a vertical plane, for example, \( A_1 = (i \cos(\gamma) A_0, i \sin(\gamma) A_1, A_1) \approx A_1 \), where the angle \( \gamma \) describes the rotation of the spiral plane around the \( z \) axis. This is the ground state for low applied fields and \( K>0 \). The vertical spiral (VS) is not perfectly circular and has harmonics.

6. The spiral in a vertical plane with two sinusoidal modulations in the direction normal to the spiral plane, for example, the spiral in the \( yz \)-plane with the wave vector \( q_1 \) and \( A_1 \approx A_1(0, i, 1) \) and the sinusoidal modulations with the wave vectors \( q_2 \) and \( q_3 \) along the \( x \) direction: \( A_2 = (A_2^0, 0, 0) \) and \( A_3 = (- A_2^0, 0, 0) \). The sinusoidal modulations appear above a critical magnetic field, \( h_c(K) \), and the transition between the VS state and this mixed (M) is of second order.

7. The FL (Fig. 2c). As magnetic field increases further, the spiral plane changes from vertical to horizontal. This flop transition is not instantaneous, but occurs in a narrow field interval, \( h_c(K) < h < h_c(K) \), in which the spiral plane as well as the direction of the sinusoidal modulations rotate.

The orientation of the spiral plane changes abruptly at \( h_c(K) \) and at \( h_c(K) \) the system undergoes a first-order transition to the 2-\( q \)-state. The FL is the only state, in which the uniform magnetization \( A_0^0 \) has a non-zero component parallel to the \( xy \)-plane.

8. The triangular skyrmion (or antiskyrmion) crystal state (Fig. 2d) with equal amplitudes of the three fundamental modulations:

\[
A_2 = A e^{i \phi x} (-i \sin(x_2), i \cos(x_2), 1) .
\]

These modulations are spirals in three vertical planes rotated with respect to each other by \( \pm 120^\circ, x_2 = x + (x - 1) \frac{2\pi}{3} (x = 1, 2, 3) \), where \( v = \pm 1 \) is the skyrmion vorticity describing the sense of rotation of the in-plane components of spins along a contour encircling the skyrmion centre. The sign of the phases \( \phi_1 + \phi_2 + \phi_3 \) is either 0 or \( \pm \pi \) and the \( z \)-component of spin in the centre of each skyrmion is \( S^z = \cos(\phi_1 + \phi_2 + \phi_3) \). The topological charge, \( Q \), of skyrmions forming the crystal is given by \( Q = \frac{v}{2} \cos(\phi_1 + \phi_2 + \phi_3) = \pm 1 \). The spin direction in the skyrmion centre is opposite to that of the applied magnetic field. Because of the arbitrary sign of vorticity, the topological charge of skyrmions can be both +1 and -1 for any field direction.

This degree of freedom does not exist for skyrmions in chiral magnets and magnetic bubbles, for which \( v = +1 \) and \( Q = -\). The SkX occupies a significant part of the phase diagram and all its boundaries are lines of first-order transitions.
with \( A = \sqrt{\frac{2\Delta h}{K}} \) and an arbitrary phase \( z \). For \( K > 0 \), the CS state becomes unstable against formation of an additional spin modulation. A small deviation from the CS, \( k = m \cdot m_0 \), changes energy by \( \delta E \approx \frac{1}{2} \int d^2x \left| k \cdot D(k) \right|^2 \). An additional modulation satisfying

\[
\begin{align*}
Dk &= 0, \\
(D(k) \cdot m_0) &= 0,
\end{align*}
\]

changes energy by \( \delta E = -\frac{2\pi}{C_1} \int d^2x (k \cdot m_0)^2 < 0 \), for \( K > 0 \). The solution of equation (7) is the second xy-spiral with the wave vector \( q_2 \) (or \( q_3 \)) and the opposite direction of spin rotation: \( k = B(\cos(q_2 \cdot x + \beta) \mp \sin(q_2 \cdot x + \beta)) \). The two-spiral state has a lower energy because of the small sinusoidal modulation of the z-component of spin with the wave vector \( q_3 \), \( \delta S_z = -(k \cdot m_0) = AB \cos(q_3 \cdot x - \alpha - \beta) \), necessary to preserve the spin length. This sinusoidal also has the minimal exchange energy, but its anisotropy energy for \( K > 0 \) is lower than that of the xy-spirals, which makes the conical state unstable.

Next we discuss the instability of the VS state, \( S = \pm \frac{1}{2} \sin \phi + \frac{1}{2} z \cos \phi \), for \( h, K \ll 1 \). The magnetic field and easy axis parallel to the spiral plane deform the spiral: \( \phi \approx q_1 \cdot x - a \sin(q_1 \cdot x) - b \sin(2q_1 \cdot x) \) with \( a = \frac{2h}{D_0^3 + D_1^3} \) and \( b = \frac{D_0}{D_1} \), corresponding to

\[
S^z \approx \frac{a}{2} + \cos(q_1 \cdot x) - \frac{a}{2} \cos(2q_1 \cdot x) - \frac{b}{2} \cos(3q_1 \cdot x).
\]

Importantly, the uniform magnetization equals the amplitude of the energetically costly second harmonic. This makes the magnetic susceptibility of the xy-spiral low and leads to appearance of an \( x \)-component of spin above a critical magnetic field. Expanding the spin energy in powers of \( S^z \) around equation (8), we obtain \( \sin(\phi)DS^z - S^z D\sin(\phi) = 0 \), the solution of which is the sum of two sinusoidal spin modulations with the wave vectors \( q_1 \) and \( q_3 \) plus relatively smaller harmonics: \( S^z \approx C(\cos(q_1 \cdot x + \gamma) - \cos(q_3 \cdot x - \gamma)) \). The second-order transition to the non-coplanar \( 3q \)-state (M-state) occurs at \( h_1(K) \approx K \frac{D_0 + D_1}{2D_0^3} \), when the lowering of the Zeeman energy due to the larger magnetization of the \( 3q \)-state compensates the increase of the anisotropy energy.

Similarly, the SkX owns its stability partly to the low anisotropy energy (as it is composed of three VSs) and partly to its large magnetic moment. The latter is the consequence of the constraint \( S^z = 1 \), which is impossible to maintain without adding to the \( 3q \)-state a large uniform magnetization. The same argument explains the enhanced stability of SkX to thin films of cubic chiral magnets, where the term \( -K/2(S^z)^2 \) describes an effective surface anisotropy. The anisotropy lowers the SkX energy with respect to the CS, while the applied magnetic field makes the SkX energetically more favourable than the helical spiral state.

An interesting question is why the \( 2q \) and skyrmion crystal states are favoured by both the entropic mechanism in absence of anisotropy and the magnetic anisotropy at zero temperature? The common origin seems to be the soft magnetic excitation spectrum of multi-\( q \) states, which on the one hand lowers free energy of these states by increasing their entropy and, on the other hand, lowers their energy by enhancing susceptibility to magnetic field and anisotropy.

The discussion of instabilities of spiral states in the continuum model of the frustrated triangular magnet also shows that the phase diagram Fig. 1 is generic, a minor difference being that in the discrete model with \( J_2/J_1 = 1/2 \), the wave vectors of the three fundamental modulations are commensurate with the lattice and constant throughout the phase diagram, while in the continuum model \( q \) is a function of \( K \) and \( h \).

**Helicity reversals and interaction between skyrmions.** Next we discuss properties of isolated skyrmions. The asymptotic of the in-plane spin components at a large distance \( r \) from the skyrmion centre is given by

\[
\left( \begin{array}{c}
S_x \\
S_y 
\end{array} \right) \approx u(r) \left( \begin{array}{c}
\cos \varphi \\
\nu \sin \varphi \\
-\nu \sin \varphi \\
\cos \varphi \\
\sin \eta \\
\cos \eta
\end{array} \right),
\]

where \( \varphi \) is the azimuthal angle in the \( xy \)-plane and \( \nu \) and \( \chi \) are, respectively, the skyrmion vorticity and helicity angle introduced in equation (3) (for simplicity, we consider large skyrmions and replace the discrete rotational symmetry of the triangular lattice by the continuous one).

In absence of in-plane magnetic anisotropy, the helicity angle \( \chi \) is arbitrary, \( \chi = 0, \pi \) corresponding to skyrmions carrying a monopole moment, \( A \propto \sum_i x_i \cdot S_i \), and \( \chi = \pm \pi/2 \) corresponding to skyrmions with a toroidal moment, \( T^z \propto \sum_i [x_i \times S_i]^z \) (ref. 25). Arbitrary \( \chi \) is a zero mode, which skyrmions in chiral magnets and magnetic bubbles do not have.

In addition, the toroidal and monopole moment densities show periodic sign reversals as the distance \( r \) from the center increases (Fig. 3), similar to the helicity reversals observed in magnetic bubbles in a ferrimagnetic hexaferrite, where \( \gamma \) can be both \( \pi/2 \) and \( -\pi/2 \) (ref. 26). We find it more convenient to keep the helicity angle fixed and associate these oscillations with the sign changes of \( u(r) \) in equation (10),

\[
u(r) \sim \frac{A}{\sqrt{r}} e^{-\sqrt{\frac{2g^2 - \kappa^2}{2r}}} \cos \left( \sqrt{\frac{\kappa^2 + 2g^2}{2r}} + \psi \right),
\]

where \( q \approx \sqrt{\frac{2g^2}{2r}} \) is the length of the minimal-energy wave vector and \( \kappa^4 = \frac{h}{K} \). The sign reversals of \( u(r) \) correspond to fan-like oscillations of spins around the \( z \) axis, whose amplitude decreases.

**Figure 3** | **Helicity reversals.** (a) False colour plot of the toroidal moment density, \( t_z \), in the skyrmion with the helicity angle \( \chi = \pi/2 \). (b) Fan-like oscillations of the out-of-plane spin component, \( S^z \). The skyrmion centre is located at \( x = 0 \).
exponentially with \( r \) for \( r > q \) or, equivalently, \( h > h(K) \). This condition ensures that the skyrmion energy is finite, and, hence, the lower critical field for stability of isolated skyrmions coincides with the line separating the fully polarized state from the CS state, for \( K<0 \), and the 2q-state, for \( K>0 \). There is also an upper critical field (dashed line in Fig. 1), above which skyrmions collapse.

The fan oscillations of spins in skyrmion give rise to sign changes of the skyrmion–skyrmion interaction \( U(r_{12}) \) (Fig. 4a). This interaction depends on the topological charges of skyrmions. For brevity, we call a skyrmion with positive vorticity and \( q = 1 \) a skyrmion, while a skyrmion with \( v = -1 \) and \( Q = +1 \) is called an antiskyrmion. Skyrmions or two antiskyrmions attract each other at distances of the order of the skyrmion diameter, the maximal reduction of energy being \( \sim 10\% \) of the skyrmion energy. Because of the attraction, the skyrmion crystal phase extends to \( h > h(K) \), as the energy per skyrmion in the crystal can be negative even when the energy of an isolated skyrmion is positive. Isolated skyrmions tend to form clusters, and the crystal can be negative even when the energy of an isolated skyrmion is positive.

Interactions between skyrmions also depend on their helicities: \( U_{sa}(r) \approx V(r) + W(r) \cos(\xi_s - \xi_a) \) (Fig. 4a), which couples the helicity dynamics to the translational motion of skyrmions. Another difference from chiral magnets is the existence of the locally stable skyrmion with topological charge \( Q = \pm 2 \), shown in Fig. 4b, which can be considered as a tightly bound state of two skyrmions with opposite helicities, similar to the magnetic bubble in 1.5-type superconductors. The oscillating interactions between skyrmions in the frustrated magnet are in sharp contrast with skyrmion–skyrmion interactions in non-centrosymmetric magnets, which do not show fan-like oscillations and repel each other at all distances.

Interactions between skyrmions depend on their helicities: \( U_{sa}(r) \approx V(r) + W(r) \cos(\xi_s - \xi_a) \) (Fig. 4a), which couples the helicity dynamics to the translational motion of skyrmions. Another difference from chiral magnets is the existence of the locally stable skyrmion with topological charge \( Q = \pm 2 \), shown in Fig. 4b, which can be considered as a tightly bound state of two skyrmions with opposite helicities, similar to the magnetic bubble in 1.5-type superconductors. The oscillating interactions between skyrmions in the frustrated magnet are in sharp contrast with skyrmion–skyrmion interactions in non-centrosymmetric magnets, which do not show fan-like oscillations and repel each other at all distances.

The helicity dependence of the skyrmion–antiskyrmion interaction is more complex: it is approximately proportional to \( \cos(2\alpha + \xi_s - \xi_a) \), where \( \alpha \) is the angle between the line connecting skyrmion with antiskyrmion and the \( x \) axis, with respect to which the skyrmion and antiskyrmion helicity angles, \( \xi_s \) and \( \xi_a \), are defined. Figure 4a shows skyrmion–antiskyrmion interactions for \( \xi_s = \xi_a \) and \( \alpha = 0 \). The minimum of the skyrmion–antiskyrmion potential occurs at larger distances and is more shallow than that of the skyrmion–skyrmion potential. One can form a metastable rectangular crystal with alternating columns of skyrmions and antiskyrmions (Fig. 4c). Such a crystal with zero topological charge has a higher energy than a purely skyrmion (or purely antiskyrmion) crystal, which is important for observation of Topological Hall Effects in frustrated magnets.

**Magnetoelectric coupling.** All modulated states in the phase diagram Fig. 1 break inversion symmetry and can induce an electric polarization, \( \mathbf{P} \), in a magnetic insulator. The two possible directions of spin rotation in spirals correspond to two opposite directions of \( \mathbf{P} \) (ref. 29).

Consider, for example, a quasi-two-dimensional magnet with the triangular spin layers stacked directly on top of each other (the so-called eclipsed stacking) and the symmetries of the crystal lattice being inversion \( I \), threefold axis \( 3_2 \) and the twofold axis \( 2_3 \) (e.g. space groups \( P3m1 \), \( R3m \)). This allows for three independent Lifshitz invariants describing the magnetically induced electric polarization, which in momentum representation have the form:

\[
H_{\text{ME}} = -3m \sum_q \left[ g_1 q^x S^x_q \left( q^x S^x_q + q^y S^y_q \right) \right. \\
\left. + g_2 \left( q^x E^x - q^y E^y \right) S^y_q S^y_q \right. \\
\left. + g_3 \left( q^x E^x - q^y E^y \right) S^y_q + (q^x E^x + q^y E^y) S^x_q \right].
\]

The polarization, \( \mathbf{P} = -\partial H_{\text{ME}} / \partial \mathbf{M} \), described by the first two terms lies in the spiral plane and is orthogonal to the spiral wave vector, as is the case for \( \mathbf{P} \) induced by a cycloidal spiral through the inverse Dzyaloshinskii–Moriya mechanism. The third term describes other symmetry-allowed directions of polarization, in particular, \( \mathbf{P} \) parallel to the wave vector of a helical spiral. The magnitude of electric polarization induced by spiral magnetic orders varies widely: 2000 \( \mu \text{C} \cdot \text{m}^{-2} \) in DyMnO\(_3\) (ref. 35) and 2 \( \mu \text{C} \cdot \text{m}^{-2} \) in CoCr\(_2\)O\(_4\) (ref. 36).

Figure 5b shows magnetic field dependence of the electric polarization in arbitrary units, for \( K = 0.04 \), \( g_2 = g_1 \) and \( g_3 = 0 \). The states with spirals in a vertical plane, including the SkX, induce polarization in the \( z \) direction (black line), while the states with spirals in the horizontal plane (CS and the two-spiral states) induce an in-plane polarization (red line). In the flop phase the spiral plane rotates in an applied magnetic field and so does \( \mathbf{P} \). The spontaneous in-plane magnetization, present in this phase (Fig. 5a) allows for effective control of the polarization direction by magnetic field and vice versa.

The orientations of spiral planes and skyrmion helicity in realistic materials will be affected by the sixth-order in-plane magnetic anisotropy, which we neglected. The interplay between this weak anisotropy and the interaction of the electric polarization induced by the spiral with an applied electric field can lead to giant magnetoelectric effects, such as the electrically induced rotation of the skyrmion helicity.

**Magnetic resonance.** We also studied collective spin dynamics for the states in the phase diagram Fig. 1 induced by the a.c. magnetic field, \( h_{\text{ac}} \sin(\omega t) \), parallel to the \( xy \)-plane. Figure 5c shows the false colour plot of the imaginary part of the in-plane dynamical magnetic susceptibility calculated along the \( K = 0.04 \) line in the phase diagram (as in panels (a) and (b)) by solving
Landau–Lifshitz–Gilbert (LLG) equation (see Methods section). The phase transitions between different states are reflected in sudden changes in the magnetic resonance spectrum.

While the SkX in chiral magnets shows two resonances: one with the counterclockwise and another with the anti-clockwise rotation of the skyrmion centres, in the frustrated magnet we find only one mode, in which skyrmions rotate counterclockwise. Figure 6a shows circular trajectories traced by the skyrmion centres for various amplitudes of the a.c. field and the resonant frequency \( \omega \). The field-induced spin dynamics in frustrated magnets is, however, more complex than in chiral magnets, because of the additional zero mode—helicity. This can be seen from the fact that the time dependence of an in-plane component of spin at a chosen site (Fig. 6c) is a superposition of periodic oscillations with two different periods. The shorter period corresponds to the rotation of the skyrmion centre, whereas the longer one results from a monotonous increase of the helicity angle, as evidenced by the series of snapshots shown in Fig. 6d (Supplementary Movie 1). The helicity dynamics is induced by the rotation of skyrmion centres through a nonlinear coupling between the two modes, as can be seen from the nonlinear dependence of the frequency of helicity rotations, \( \omega_{\text{hel}} \), on the amplitude of the a.c. magnetic field (Fig. 6b). The coupling between the helicity and translational dynamics must have important consequences for the current-induced motion of skyrmions in confined nanostructures.

Another remarkable feature of the magnetic resonance spectrum is the presence of the zero-frequency peak in the flop phase (Fig. 5c) related to the non-zero spontaneous in-plane magnetization, which in absence of the in-plane magnetic anisotropy has an arbitrary direction. Surprisingly, a low-energy mode is also present in the \( q_2 \)-state near the first-order transition to the flop phase, as shown in the inset to Fig. 5c (this transition does not actually occur at \( K = 0.04 \) because of the intervening SkX phase, which was artificially removed to obtain the susceptibility shown in the inset).

**Discussion**

In conclusion, the simultaneous presence of competing exchange interactions, uniaxial magnetic anisotropy and an applied magnetic field results in a plethora of multi-\( q \) states, including the skyrmion crystal. These complex magnetic states induce electric polarization. Soft magnetic modes present in some of these states can be used to control them with an electric field. Physics of isolated skyrmions in frustrated magnets is very rich and more complex than that in chiral magnets due to the additional degrees of freedom—vorticity and helicity. Skyrmion vorticity equal \( \pm 1 \) or \( \pm 2 \) can be used to store information. Skyrmion helicity interacts with an applied electric field and the coupling between the helicity and centre-of-mass dynamics of skyrmions leads to a characteristic magnetoelectric effect.
These results show that frustrated magnets can host skyrmions with physical properties not found in conventional noncentrosymmetric chiral magnets, provided they satisfy the following requirements: (1) spiral spin ordering in zero magnetic field resulting from competing exchange interactions; (2) threefold or sixfold symmetry axis, which ensures that the spirals with the three wave vectors, \(q_1\), \(q_2\), and \(q_3\), forming the skyrmion crystal, have the same energy; (3) \(q_1 + q_2 + q_3 = 0\); and (4) easy axis magnetic anisotropy axis stabilizing multi-q states.

Incommensurate magnetic orders resulting from the competition between NN FM and longer-range anti-FM interactions have been observed in triangular magnets with transition metal ions in edge-sharing octahedra, such as NiGa3S4 with strong third-NN interaction\(^{39,40}\), \(\sigma\)-NeFeO\(_2\) with \(J/J_z \sim 1\) (ref. 41) and magnetically induced electric polarization \(P = 60 \mu\text{C} \cdot \text{m}^{-2}\) (ref. 42) as well as in some dihalides, for example, FeNi\(_2\)Br\(_2\) (refs 43–45). Magnetocrystalline anisotropy of dihalides can be tuned by chemical substitutions: NiBr\(_2\) has an easy plane anisotropy \(K/J_z = -0.1\) (ref. 46), FeNi\(_2\)Br\(_2\) is an easy magnet for \(x > 0.1\) and FeBr\(_3\) is an Ising antiferromagnet with \(K/J_z = 1.3\) (refs 45,47). In \(\sigma\)-NeFeO\(_2\) and dihalides, the wave vectors of three incommensurate modulations do not add to zero because they have an out-of-plane component. A combination of frustrated interactions in the basal plane with a FM coupling between spin layers would help to make \(q_1\), \(q_2\), and \(q_3\) coplanar.

**Methods**

**Energy minimization.** The energy (1) has been minimized using the iterative simulated annealing procedure and a single-step Monte-Carlo dynamics with the Metropolis algorithm (for details, see ref. 18). We imposed periodic boundary conditions and performed simulations for lattices of different sizes to check the stability of the numerical routine.

**Dynamical properties.** The dynamical magnetic susceptibility for all multi-\(q\) states and the time evolution of spins in the oscillating magnetic field have been obtained by solving the LLG equation using the fourth-order Runge–Kutta method. We used a rather small dimensionless damping parameter, \(\alpha = 0.01\), to make visible all peaks in the imaginary part of dynamical magnetic susceptibility in Fig. 5c. To obtain initial spin configurations, we used the annealing technique supplemented by a further LLG relaxation for \(h_z = 0\). When the convergence of the spin configurations was reached, we switched on a periodic magnetic field in the xy-plane to study the spin dynamics (Fig. 6) or applied a magnetic field pulse at \(t = 0\) and monitored the response to obtain the magnetic susceptibility (Fig. 5c).

**Interactions between topological defects.** The skyrmion–skyrmion and skyrmion–antiskyrmion interaction potentials shown in Fig. 4 were calculated by minimizing the spin energy with the constraint, \(S = -1\), imposed at the centres of the topological defects. To calculate the helicity dependence of the interactions, we constrained the helicity angle at six sites neighbouring to the skyrmion centre and imposed \(S' = -0.427\) at these sites, which holds for an isolated skyrmion.

3. Mu¨hlbauer, S. NiBr\(_2\) has an easy plane anisotropy following requirements: (1) spiral spin ordering in zero magnetic field resulting from competing exchange interactions; (2) threefold or sixfold symmetry axis, which ensures that the spirals with the three wave vectors, \(q_1\), \(q_2\), and \(q_3\), forming the skyrmion crystal, have the same energy; (3) \(q_1 + q_2 + q_3 = 0\); and (4) easy axis magnetic anisotropy axis stabilizing multi-q states.
