(March 23, 2022)

We present the results of a large scale molecular dynamics computer simulation study in which we investigate whether a supercooled Lennard-Jones liquid exhibits dynamical heterogeneities. We evaluate the non-Gaussian parameter for the self part of the van Hove correlation function and use it to identify “mobile” particles. We find that these particles form clusters whose size grows with decreasing temperature. We also find that the relaxation time of the mobile particles is significantly shorter than that of the bulk, and that this difference increases with decreasing temperature.

Recent NMR experiments have shown that the relaxation in supercooled liquids is not homogeneous, i.e. that there are regions in space in which the relaxation of the particles is significantly faster (or slower) than the average relaxation of the system \cite{1}. Subsequently, this result has been supported by optical spectroscopy, forced Rayleigh scattering and further NMR experiments \cite{2}. However, these types of experiments are unable to determine the nature of these “dynamical heterogeneities,” and consequently details such as size are
unknown. Extrapolations of probe size sensitivity to heterogeneous dynamics indicate a typical heterogeneity size on the order of 2 – 5 nm in the vicinity of \( T_g \) \[3\].

Dynamical heterogeneities have also been observed in computer simulations \[4\]. However, these simulations were restricted to two dimensions and since it is expected that the dynamics of particles in two and three dimensions is significantly different, it is not clear whether the dynamical heterogeneities observed in these simulations have a counterpart in three dimensions. By analyzing the trajectories of monomers in a Monte Carlo simulation of a dense \((d = 3)\) polymer melt, Heuer and Okun \[5\] showed that in this system dynamical heterogeneities occur on short length scales, but the nature of the heterogeneities was not explored in detail. Thus despite the experimental evidence for the existence of dynamical heterogeneities, their microscopic properties are unknown and thus phenomenological models are often used to interpret experimental results \[3\]. In this Letter, we study a simple, glass-forming liquid to investigate whether dynamical heterogeneities can be observed in a 3-d system and, if so, to determine their properties.

We investigate a binary \((80:20)\) mixture of 8000 Lennard-Jones particles consisting of two species of particles, \(A\) and \(B\). The interaction between two particles of type \(\alpha, \beta \in \{A, B\}\) is given by \(V_{\alpha\beta}(r) = 4\epsilon_{\alpha\beta}[(\sigma_{\alpha\beta}/r)^{12} - (\sigma_{\alpha\beta}/r)^6]\) with \(\epsilon_{AA} = 1.0, \sigma_{AA} = 1.0, \epsilon_{AB} = 1.5, \sigma_{AB} = 0.8, \epsilon_{BB} = 0.5,\) and \(\sigma_{BB} = 0.88,\) with a cutoff radius of \(2.5\sigma_{\alpha\beta}\). Note that the \(AB\) interaction is stronger than both the \(AA\) and \(BB\) interactions, a fact which will be important in the subsequent discussion of the results. We report all quantities in reduced units, i.e. length in units of \(\sigma_{AA}\), temperature \(T\) in units of \(\epsilon_{AA}/k_B\), and time \(t\) in units of \(\sqrt{\sigma_{AA}^2m/\epsilon_{AA}}\), where \(m\) is the mass of either an \(A\) or \(B\) particle. We study the system at 10 different values of \(T\) ranging between 0.550 and 0.451. At each \(T\), the system was equilibrated for a time longer than the \(\alpha\)-relaxation time before evaluating the quantities presented below. At the lowest \(T\), quantities were evaluated for over \(4 \times 10^6\) time steps. All simulations were carried out in the microcanonical ensemble. More details on the simulation can be found in Ref. \[7\].

The dynamics of this model has been characterized in detail in previous simulations.
performed at different temperatures and at constant density [8]. In particular, it was found that at low $T$ the dynamics is described well by mode-coupling theory [9] with a critical temperature $T_c \approx 0.435$ and a critical pressure $P_c \approx 3.03$. In the present work we approach the point $(T_c, P_c)$ via a different path than that used in Ref. [8], on a straight line in the $T-P$ plane along which density increases with decreasing $T$ [10]. It has been shown [7] that along this path of approach to the critical point, the behavior of the relaxation dynamics is very similar to that found along the constant-density path of the previous simulation [8], providing evidence that the thermodynamic path of approach to the critical point does not significantly change the nature of the divergence of the relaxation time, and hence how the system vitrifies. Hence, we expect the results presented here to be independent of the details of the approach to the glass transition, and so in the following we use $T$ alone to characterize the different state points.

To detect the presence of dynamical heterogeneities, we investigate the time dependence of the self part $G_s(r, t)$ of the van Hove correlation function [11] for the $A$ particles, where $r$ is the distance traveled by a particle in a time $t$. To a first approximation $G_s(r, t)$ has a Gaussian form but deviations from this form at intermediate times have been observed in simulations of glass forming liquids [8,12,13] and are thought to reflect the presence of dynamical heterogeneities [14]. Such deviations can be characterized by the non-Gaussian parameter of $G_s(r, t)$, $\alpha_2(t) = 3\langle r^4(t) \rangle / 5\langle r^2(t) \rangle^2 - 1$ [15]. Fig. 1 shows the time dependence of $\alpha_2$ for the $A$ particles at three different temperatures. We find that: (i) on the time scale at which the motion of the particles is ballistic, $\alpha_2$ is zero; (ii) upon entering the time scale of the $\beta$-relaxation $\alpha_2$ starts to increase; and (iii) on the time scale of the $\alpha$-relaxation, $\alpha_2$ decreases to its long time limit, zero. We observe that the maximum value of $\alpha_2$ increases with decreasing $T$, which is evidence that the dynamics of the liquid becomes more heterogeneous with decreasing $T$. Furthermore, we find that the time $t^*$ at which this maximum is attained also increases with decreasing $T$.

To determine the reason for the strong increase of $\alpha_2$ in the $\beta$-relaxation regime, we compare $G_s(r, t)$ with the distribution that is obtained from the Gaussian approximation,
i.e. by assuming that $G_s(r,t)$ is given by

$$G_g^s(r,t) = \left(\frac{3}{2\pi \langle r^2(t) \rangle}\right)^{3/2} \exp(-3r^2/2\langle r^2(t) \rangle),$$

where $\langle r^2(t) \rangle$ is the mean squared displacement of the particles. In Fig. 2 we show $(G_s(r,t) - G_g^s(r,t))/G_g^s(r,t)$ for $t = t^*$, where $t^*$ depends on $T$ (see Fig. 1). For small and intermediate values of $r$ ($r \leq 0.6$) the relative difference between $G_g^s$ and $G_s$ is less than a factor of three. However, for larger $r$, $G_g^s$ underestimates $G_s$ significantly. The discrepancy increases strongly with decreasing $T$ in that the normalized difference becomes as large as $10^8$ at the lowest $T$ (see inset of Fig. 2). Thus we find that in the supercooled liquid there is a significant number of particles that have moved farther than would be expected from the Gaussian approximation [12]. We define $r^*$ as the larger value of $r$ such that $G_s(r^*,t^*) = G_g^s(r^*,t^*)$, i.e. $r^*$ is the value of $r$ at which the normalized difference starts to become positive and very large (see Fig. 2). We thereby define “mobile particles” as $A$ particles that have moved farther than a distance $r^*$ within a time $t^*$. With this definition, the total number of mobile particles at any $T$ studied is a few hundred (out of 6400 $A$ particles), and thus constitute approximately 5% of the system. We note that we find the results presented below concerning the properties of the mobile particles to be relatively insensitive to the details of this definition.

Snapshots of the configuration of the mobile particles show that these particles tend to form clusters, i.e. they are not randomly distributed throughout the system. The spatial correlation between mobile particles is shown in Fig. 3, where we compare (cf. inset) $g_{AmAm}(r)$ and $g_{AA}(r)$, the radial distribution functions for the mobile particles and for the bulk, respectively. (In the following, “bulk” refers to all of the $A$ particles.) We find that at short and intermediate distances ($r \leq 4$) the mobile particles are more strongly correlated than the bulk. This is demonstrated more clearly by computing the ratio $g_{AmAm}(r)/g_{AA}(r)$, which is shown in Fig. 3 for three different $T$. From this figure we see that with decreasing $T$ the relative correlation between the mobile particles increases; i.e., the relative height of the first nearest neighbor peak ($r \approx 1$) increases quickly and the ratio decays more slowly as a function of $r$ if $T$ is decreased. At the lowest $T$, the size of the cluster is on the order
of $3 - 4\sigma_{AA}$ [16]. If we assume a molecule of diameter $0.4 - 0.5$ nm we find that the clusters have a size of about 1 nm, which is in rough agreement with experimental expectations [2,3]. We note that at small wave-vectors the partial structure factors for the bulk do not show any indication for the presence of these clusters. Thus it is perhaps not surprising that no evidence for the presence of such clusters was found from the structure factors measured in the neutron scattering experiments of Leheny, et al. [17].

What is the effect of these clusters of mobile particles on the bulk relaxation dynamics? To explore this question we compute the incoherent intermediate scattering function $F_s^{(Am)}(q, t)$ for the mobile particles and compare it with that for the bulk particles, $F_s^{(A)}$. These correlation functions, shown in Fig. 4 for three $T$, are calculated at a wave-vector $q = 7.2$, which coincides with the location of the main peak in the structure factor [8]. From this figure we see that $F_s^{(Am)}$ decays faster than $F_s^{(A)}$ and that the ratio between the relaxation time of the two correlation functions increases with decreasing temperature. (The relaxation time could, e.g., be defined as the time it takes a correlation function to decay to $e^{-1}$ of its initial value.) This ratio is approximately 3 for the highest $T$ and approximately 10 for the lowest $T$. It is not unreasonable to extrapolate that at temperatures close to $T_g$ the ratio between the relaxation times become as large as $10^2 - 10^4$, similar to values reported from experiments [1,2,6]. It is also interesting to note that the $\alpha$-relaxation time of $F_s^{(Am)}$ is on the order of the end of the $\beta$-relaxation of the bulk. This suggests that the relaxation of these clusters might be related to the $\beta$-relaxation of the bulk.

Also shown in Fig. 4 is the probability $P(t)$ that a particle which was mobile at time $t = 0$ is still mobile at time $t$, at the lowest $T$ investigated (bold dotted curve). We define $P(t)$ by $\langle (N(t) - N(0)^2/N_A)/(N(0) - N(0)^2/N_A) \rangle$, where $N_A$ is the total number of $A$ particles and $N(t)$ is the number of particles that were mobile at time $t = 0$ and still mobile at time $t$. A related correlation function for the least mobile particles has been measured in experiments [1,2]. We see that $P$ decays on the time scale of the intermediate scattering function of the mobile particles, demonstrating that the lifetime of a cluster is of the order of the relaxation time of the particles which constitute the cluster. However, the lifetime is
significantly shorter than the $\alpha$-relaxation time of the bulk. More details on the dynamics of the particles within the clusters will be given elsewhere [16].

We find that the existence of clusters of mobile particles is related to small, local equilibrium fluctuations in composition [15]. At all $T$, the pair correlation function $g_{AmB}(r)$ between the $B$ particles and the mobile particles is smaller than the bulk quantity $g_{AB}(r)$ for $r \leq 3$. Thus mobile particles have fewer $B$ particles in their vicinity than do generic $A$’s.

Because in this system the attractive interaction between $A$ and $B$ particles is stronger than either the $AA$ or $BB$ interaction, the presence of a $B$ between two $A$’s lowers the potential energy, giving rise to an effective attraction between the $A$’s. $A$ particles in a $B$-rich region can thus be expected to have a reduced mobility. $A$ particles in a $B$-poor region, however, will have a reduced effective attraction between them, resulting in a higher mobility [19].

Via this mechanism we expect that this sort of dynamical heterogeneity will occur in other fragile glass-forming systems, since local equilibrium fluctuations arising in the arrangements (packing) of the molecules will always be present [20]. Energetically favorable packings will reduce the local mobility, while less favorable packings will enhance the local mobility. Such correlations have been observed in recent spin glass simulations [21].

[19] Note that since a fluctuation in the concentration does not affect the distribution of the velocities of the individual particles, the mean kinetic energy of the $A$ particles in such a region is the same as the one in the bulk, thus the enhanced mobility is not due to a larger velocity of the mobile particles.

[20] This is supported by the fact that very recently Leheny, et al. have found evidence for the existence of such different packings in a computer simulation of propylene glycol [17].
