Abstract

The $\Lambda_b \to \Lambda_c$ semileptonic decay is analyzed in the framework of heavy quark effective theory to the order of $1/m_c$ and $1/m_b$. The QCD sum rule and large $N_c$ predictions to the decay form factors are applied. It argues that the subleading baryonic Isgur-Wise function in the large $N_c$ limit vanishes. The decay rates, distributions and asymmetry parameters are calculated numerically. Some of the nonleptonic decay modes are discussed in the end.
I. INTRODUCTION

The weak decays of heavy baryons provide testing ground for the Standard Model. They reveal some important features of the physics of heavy quarks. From the study of the heavy quark physics, some important parameters of the Standard Model, for instance, the Cabbibo-Kobayashi-Maskawa (CKM) matrix element $V_{cb}$ can be extracted by comparing experiments with theoretical calculations from the decay mode $\Lambda_b \rightarrow \Lambda_c l\bar{\nu}$. The main difficulties in the Standard Model calculations, however, are due to the poor understanding of the nonperturbative aspects of the strong interactions (QCD).

For the heavy hadrons containing a single heavy quark, an effective theory of QCD based on the heavy quark symmetry in the heavy quark limit [1], the so-called heavy quark effective theory (HQET), has been proposed [2]. The classification of the weak decay form factors of heavy baryons has been simplified greatly in HQET [3]. At the leading order of heavy quark expansion, only one universal form factor, the Isgur-Wise function, is required to describe the $\Lambda_b \rightarrow \Lambda_c$ semileptonic decay. To the order of $1/m_Q$ [4], one more universal function and one mass parameter are introduced [5]. However, the heavy quark symmetry itself has no power to give information about the details of the universal form factors and the mass parameter. For a complete analysis to the heavy baryons, we still need to employ some other nonperturbative methods. Interesting results about the heavy baryon weak decay form factors have been obtained by various nonperturbative methods. They are QCD sum rules [6], large $N_c$ limit [7], lattice simulation [8], dispersion relation and analyticity [9], and quark models [10].

In this paper, we apply the results of QCD sum rules and large $N_c$ limit to analyze in detail the weak decays of $\Lambda_b \rightarrow \Lambda_c$ to the order of $1/m_c$ and $1/m_b$. The analysis is useful to experiments in the near future. In Sec.2, $\Lambda_b \rightarrow \Lambda_c$ semileptonic decay form factors are discussed. While there is no large $N_c$ calculation for the universal form factor appeared in $1/m_Q$ corrections, we argue that it is zero in the large $N_c$ limit. In Sec.3, the numerical results for the decay rates, distributions and various angular asymmetry parameters are
calculated. In Sec.4, several non-leptonic decay modes of $\Lambda_b$ are discussed. We summarize the results in Sec.5.

II. FORM FACTORS

The hadronic matrix element of the weak current appeared in the effective Hamiltonian for $\Lambda_b \to \Lambda_c$ is parameterized generally by six form factors $F_i$ and $G_i$ ($i = 1, 2, 3$),

$$\langle \Lambda_c(v')|\bar{c}\gamma^\mu(1 - \gamma^5)b|\Lambda_b(v)\rangle = \bar{u}_{\Lambda_c}(v')(F_1\gamma^\mu + F_2v^\mu + F_3v'^\mu)u_{\Lambda_b}(v)$$
$$-\bar{u}_{\Lambda_c}(v')(G_1\gamma^\mu + G_2v^\mu + G_3v'^\mu)\gamma^5u_{\Lambda_b}(v) ,$$

where $v$ and $v'$ denote the four-velocities of $\Lambda_b$ and $\Lambda_c$ respectively. Within the framework of HQET, the classification of the form factors is simplified very much. To the order of both $1/m_c$ and $1/m_b$, they are expressed as

$$F_1 = C(\mu)\xi(y) + \left(\frac{\bar{\Lambda}}{2m_c} + \frac{\bar{\Lambda}}{2m_b}\right)[2\chi(y) + \xi(y)] ,$$
$$G_1 = C(\mu)\xi(y) + \left(\frac{\bar{\Lambda}}{2m_c} + \frac{\bar{\Lambda}}{2m_b}\right)[2\chi(y) + \frac{y - 1}{y + 1}\xi(y)] ,$$
$$F_2 = G_2 = -\frac{\bar{\Lambda}}{m_c(y + 1)}\xi(y) ,$$
$$F_3 = -G_3 = -\frac{\bar{\Lambda}}{m_b(y + 1)}\xi(y) ,$$

with the perturbative QCD coefficient in the leading logarithmic approximation

$$C(\mu) = \left[\frac{\alpha_s(m_b)}{\alpha_s(m_c)}\right]^{\frac{5}{27}} \left[\frac{\alpha_s(m_c)}{\alpha_s(\mu)}\right]^{a_L(y)} ,$$

where

$$a_L(y) = \frac{8}{27}[yr(y) - 1] , \quad r(y) = \frac{1}{\sqrt{y^2 - 1}}\ln(y + \sqrt{y^2 - 1}) .$$

$\xi$ and $\chi$ are the so-called leading and subleading Isgur-Wise function respectively. And the mass parameter $\bar{\Lambda}$ is defined as follows

$$\bar{\Lambda} = m_{\Lambda_Q} - m_Q .$$
By QCD sum rules, $\xi$, $\chi$ and $\bar{\Lambda}$ have been obtained [7]. QCD sum rule is regarded as a nonperturbative method rooted in QCD itself [12]. In a linear approximation, the leading Isgur-Wise function is fit as

$$\xi(y) = 1 - \rho^2(y - 1) , \quad \rho^2 = 0.55 \pm 0.15 . \quad (6)$$

On the other hand, the subleading Isgur-Wise function is negligibly small,

$$\chi(y) \simeq O(10^{-2}) . \quad (7)$$

And the parameter $\bar{\Lambda}$ is determined to be

$$\bar{\Lambda} = 0.79 \pm 0.05 \text{ GeV} . \quad (8)$$

It is interesting to compare above QCD sum rule results with that of large $N_c$. Large $N_c$ limit is one of the most important and model-independent method of nonperturbative QCD in spite of the realistic $N_c = 3$ [13]. HQET in this limit, for the heavy baryon case, is often believed to be the heavy quark Skyrme model [14]. The leading Isgur-Wise function is predicted as [8]

$$\xi(y) = 0.99 \exp[-1.3(y - 1)] . \quad (9)$$

The slope of this Isgur-Wise function is steeper than that of the sum rule. In the large $N_c$ limit, the parameter $\bar{\Lambda}$ equals to the proton mass [13]. In the following analysis, we take it as $\bar{\Lambda} \simeq 0.87 \text{ GeV}$ [13]. This result is in agreement with that obtained by QCD sum rules. However, there is no Skyrme model calculation for the subleading Isgur-Wise function.

We will assume that the subleading Isgur-Wise function is negligible in the Skyrme model analysis. In the following, we argue that this assumption is true in the large $N_c$ limit. The subleading Isgur-Wise function $\chi(y)$ is defined by

$$\langle \Lambda_c(v') | \Gamma h_{c}^{(c)} \Gamma h_{b}^{(b)} | i \int d^4x \frac{1}{2m_Q} \bar{h}_{v}^{(Q)}(x)(iD)^2h_{v}^{(Q)}(x)|\Lambda_b(v) \rangle$$

$$= \frac{\bar{\Lambda}}{m_Q} \chi(y) \bar{u}_{\Lambda_c}(v') \Gamma u_{\Lambda_b}(v) , \quad (10)$$

$$= \frac{\bar{\Lambda}}{m_Q} \chi(y) \bar{u}_{\Lambda_c}(v') \Gamma u_{\Lambda_b}(v) , \quad (11)$$
where $h_v^{(Q)}$ denotes the heavy quark field defined in the HQET with velocity $v$, and $\Gamma$ is some gamma matrix. $\chi(y)$ just measures the amplitude of the brown muck transfer through a strong interaction, described by above matrix element, from the heavy quark which has a velocity change from $v$ to $v'$ due to the weak decay. In the Hartree-Fock picture of large $N_c$ HQET, heavy baryon has $N_c - 1$ light quarks. Any $v \neq v'$ ($y \neq 1$) transition in fact is suppressed when $N_c$ is large, because that involves changing the momenta of all the light quarks inside the baryon. In the limit $N_c \to \infty$, we expect $\chi(y \neq 1) = 0$. Furthermore, it is well-known that $\chi(1) = 0$ due to Luke theorem [4]. Therefore, we get that $\chi(y)$ vanishes in the large $N_c$ limit. Although the above argument makes our assumption for $\chi(y)$ reasonable, it should be noted that there is still a subtle point which distinguishes the Skyrme model from the large $N_c$ limit. The point is that for heavy baryon weak decay form factors, the Skyrme model result is not exactly identical to that of large $N_c$. Consider the leading Isgur-Wise function, our large $N_c$ argument for $\chi(y)$ also applies to $\xi(y)$, that is $\xi(y \neq 1) = 0$. Because $\xi(1) = 1$, we expect that the leading Isgur-Wise function is $\delta$-function like, $\xi(y) \sim \delta(y - 1)$ in the large $N_c$ limit. However, this result in principle agrees with that of Skyrme model [8] $\xi(y) \sim \exp[-N_c^{3/2}(y - 1)]$, if $N_c$ is taken to be $\infty$. The so called Skyrme model result Eq.(9) can be obtained by taking $N_c = 3$. Therefore, $\chi(y) = 0$ can be understood as the result of large $N_c$ limit for the Skyrme model.

III. DECAY RATES, DISTRIBUTIONS AND ASYMMETRY PARAMETERS

With the knowledge of the form factors from QCD sum rule and large $N_c$ limit, we can calculate the rates, distributions and various asymmetry parameters for the $\Lambda_b \to \Lambda_c$ semileptonic decay. The standard expressions for these observables are given in Ref. [10] in terms of helicity amplitudes. The process $\Lambda_b \to \Lambda_c l\bar{\nu}$ is considered as a two-successive decay $\Lambda_b \to \Lambda_c + W_{\text{off-shell}}$, $W_{\text{off-shell}} \to l + \nu$. Let $\epsilon^\mu_{\lambda_W}$ be the polarization vector of $W_{\text{off-shell}}$, where $\lambda_W$ denotes the helicity state. Longitudinal state corresponds to $\lambda_W = 0$, whereas transverse state, $\lambda_W = \pm 1$. The helicity amplitudes are defined by
\[ H_{\pm \frac{1}{2} \lambda_W}^{V(A)} = \epsilon_\lambda^{\mu} \langle \Lambda_c(v'; \pm \frac{1}{2}) | J_{\mu}^{V(A)} | \Lambda_b(v) \rangle, \]  

where \( J^{V(A)} \) stands for the vector(axial vector) current, and \( \pm \frac{1}{2} \) in the subscript is the helicity of the daughter baryon \( \Lambda_c \). They can be expressed by the form factors,

\[ \sqrt{q^2} H_{\pm \frac{1}{2}}^{V,A} = \sqrt{2M_{\Lambda_b}M_{\Lambda_c}(y \mp 1)} \left\{(M_{\Lambda_b} \pm M_{\Lambda_c})(F_1, G_1) \right. \\
\left. \pm M_{\Lambda_c}(y \pm 1)(F_2, G_2) \pm M_{\Lambda_b}(y \pm 1)(F_3, G_3) \right\}, \]

\[ H_{\frac{1}{2} \pm}^{V,A} = -2\sqrt{M_{\Lambda_b}M_{\Lambda_c}(y \mp 1)}(F_1, G_1), \]  

where the upper(lower) sign is for the vector(axial vector) current. With the notation of \( J_{\pm 1}^{V,A} \), the differential decay rate can be expressed as

\[ \frac{d\Gamma}{dy \, d\cos \theta} = \frac{G_F^2}{(2\pi)^3} |V_{cb}|^2 q^2 \sqrt{y^2 - 1} \frac{M_{\Lambda_c}^2}{M_{12\Lambda_b}} \frac{3}{8} (1 + \cos \theta)^2 |H_{\frac{1}{2} 1}|^2 + \frac{3}{8} (1 - \cos \theta)^2 |H_{\frac{1}{2} -1}|^2 + \frac{3}{4} \sin^2 \theta |H_{\frac{1}{2} 0}|^2 + |H_{\frac{1}{2} -0}|^2, \]

where \( \theta \) is the angle between \( P_{\Lambda_c} \) and \( p_t \) measured in the \( W_{\text{off-shell}} \) rest frame. The \( y \) distribution of the decay rate is obtained by the integration over \( \cos \theta \),

\[ \frac{d\Gamma}{dy} = \frac{G_F^2}{(2\pi)^3} |V_{cb}|^2 q^2 \sqrt{y^2 - 1} \frac{M_{\Lambda_c}^2}{12M_{\Lambda_b}} \left[ |H_{\frac{1}{2} 1}|^2 + |H_{\frac{1}{2} -1}|^2 + |H_{\frac{1}{2} 0}|^2 + |H_{\frac{1}{2} -0}|^2 \right] \]

\[ = \frac{d\Gamma_{T+}}{dy} + \frac{d\Gamma_{T-}}{dy} + \frac{d\Gamma_{L+}}{dy} + \frac{d\Gamma_{L-}}{dy}, \]

where \( T_{\pm} \), \( L_{\pm} \) are defined as the transverse and longitudinal contribution to the decay rate with \( \pm \) final baryon helicity, respectively.

The numerical results are obtained by inputting the form factors discussed in last section. We have taken \( m_c = 1.44 \text{ GeV} \), \( m_b = 4.83 \text{ GeV} \), \( \mu = 0.47 \text{ GeV} \) and \( |V_{cb}| = 0.04 \). The partial decay distributions are plotted as a function of \( y \) in Fig.1 and Fig.2 for both QCD sum rule and large \( N_c \) predictions. It is easy to see the dominance of \( \frac{d\Gamma_{T+}}{dy} \) and \( \frac{d\Gamma_{T-}}{dy} \) over other plus helicity components. As discussed in Ref. [17], this is due to the left-handed V-A current. From Fig.2, we can see that the discrepancy of different model gets larger as \( y \) goes larger.
As a result of the fact that the slope of the Isgur-Wise function of large \( N_c \) is steeper than that of QCD sum rule, the decay distributions on \( y \) predicted by large \( N_c \) are smaller than that of QCD sum rule explicitly when \( y \gtrsim 1.1 \).

It is experimentally useful to calculate the lepton energy distribution. We obtain

\[
\frac{d\Gamma}{dE_l} = \frac{G_F^2}{8} |V_{cb}|^2 \frac{M_\Lambda}{8} \int_{y_{\min}(E_l)}^{y_{\max}} dy (y_{\max} - y) \left[ (1 + \cos \theta)^2 |H_{\pm 1}\rangle^2 + (1 - \cos \theta)^2 |H_{-\pm 1}\rangle^2 + 2 \sin^2 \theta (|H_{\mp 0}\rangle^2 + |H_{-\mp 0}\rangle^2) \right]
\]

\[
\equiv \frac{d\Gamma_{T+}}{dE_l} + \frac{d\Gamma_{T-}}{dE_l} + \frac{d\Gamma_{L+}}{dE_l} + \frac{d\Gamma_{L-}}{dE_l}
\]

(16)

where

\[
\cos \theta = \frac{E_l^{\max} - 2E_l + M_\Lambda (y_{\max} - y)}{M_\Lambda \sqrt{y^2 - 1}}
\]

\[
E_l^{\max} = \frac{M^2_{\Lambda_b} - M^2_{\Lambda_c}}{2M_\Lambda_b}
\]

\[
y_{\max} = \frac{M^2_{\Lambda_b} + M^2_{\Lambda_c}}{2M_\Lambda_b M_\Lambda_c}
\]

\[
y_{\min}(E_l) = y_{\max} - \frac{2E_l}{M_\Lambda_b M_\Lambda_c - 2E_l}
\]

(17)

The lepton energy spectrums of the decay rates are given in Fig.3 and Fig.4 for the QCD sum rule and large \( N_c \) Isgur-Wise function. As in the case of \( y \) distribution, the helicity minus components dominate the plus ones. And the decay distributions on \( E_l \) by large \( N_c \) are always smaller than that by QCD sum rule. The decay rates are obtained from Eq. (13) by integrating over \( y \), or from Eq. (16) by integrating over \( E_l \). The numerical results for the partial decay rates into given helicity states are listed in Table 1, where the quark model results [17] are also listed for comparison. The total decay rate is obtained by summing them up,

\[
\Gamma = 6.17 \times 10^{-14} \text{ GeV} \ , \ \text{Br.}(\Lambda_b \to \Lambda_c l\bar{\nu}) = 11.5\% \times \left( \frac{\tau(\Lambda_b)}{1.23 \times 10^{-12} \text{ sec}} \right)
\]

(18)

for QCD sum rule linear fitting, and

---

\footnote{Our results for \( \frac{d\Gamma_{T+}}{dE_l} \) are different from that given in Ref. [11].}
\[ \Gamma = 4.51 \times 10^{-14} \text{ GeV} \quad \text{Br.} (A_b \to \Lambda_c \ell \nu) = 8.43\% \times \left( \frac{\tau(A_b)}{1.23 \times 10^{-12} \text{ sec}} \right) \]  

(19)

for large \( N_c \) approximation. The quark model results given in Ref. [17] are \( \Gamma = 4.28 \times 10^{-14} \text{ GeV} \) and \( \text{Br.} = 7.99\% \) for \( \tau(A_b) = 1.23 \times 10^{-12} \text{ sec} \). The QCD sum rule predicts larger decay branching ratio than large \( N_c \) model, as we have expected. We also see that both QCD sum rule and large \( N_c \) predicts larger results for the decay than quark model of Ref. [17]. Up to the leading order, we have \( \Gamma = 5.52 \times 10^{-14} \text{ GeV} \) for QCD sum rule and \( \Gamma = 4.00 \times 10^{-14} \text{ GeV} \) for large \( N_c \) limit. It means that \( 1/m_c \) and \( 1/m_b \) corrections yield about 11\% enhancement for the total decay rate.

Now let’s turn to the various asymmetry parameters. The polarization effects in the process \( \Lambda_b \to \Lambda_c \) are revealed in various angular distributions. First, from Eq.(14), the polar angle distribution is

\[ \frac{d\Gamma}{dy \, d\cos \theta} \propto 1 + 2\alpha' \cos \theta + \alpha'' \cos^2 \theta, \]  

(20)

where \( \alpha' \) and \( \alpha'' \) are asymmetry parameters which can be expressed as

\[ \alpha' = \frac{|H_{1/2} 1|^2 - |H_{-1/2-1}|^2}{|H_{1/2} 1|^2 + |H_{-1/2-1}|^2 + 2(|H_{1/2 0}|^2 + |H_{-1/2 0}|^2)} \]  

(21)

\[ \alpha'' = \frac{|H_{1/2} 1|^2 + |H_{-1/2-1}|^2 - 2(|H_{1/2 0}|^2 + |H_{-1/2 0}|^2)}{|H_{1/2} 1|^2 + |H_{-1/2-1}|^2 + 2(|H_{1/2 0}|^2 + |H_{-1/2 0}|^2)}. \]  

(22)

There are other asymmetry parameters if the successive hadronic cascade decay \( \Lambda_c \to a + b \) where \( a \) and \( b \) are some hadrons, are considered. Two more angles are involved, \( \Theta_A \) and \( \chi \). \( \Theta_A \) is the angle between \( \Lambda_c \)’s momentum in \( \Lambda_b \) rest frame and \( a \)’s momentum in \( \Lambda_c \) rest frame assuming \( J_a = \frac{1}{2} \) and \( J_b = 0 \). \( \chi \) is the relative azimuthal angle between the decay planes defined by \( l, \nu \) and \( a, b \). \( \Theta_A \) and \( \chi \) distributions of the decay are

\[ \frac{d\Gamma}{dy \, d\cos \Theta_A} \propto 1 + \alpha \alpha_A \cos \Theta_A \quad \text{and} \quad \frac{d\Gamma}{dy \, d\chi} \propto 1 - \frac{3\pi^2}{32\sqrt{2}} \gamma \alpha_A \cos \chi, \]  

(23)

where \( \alpha_A \) is the asymmetry parameter in the \( \Lambda_c \) hadronic decay. In this case, the related asymmetry parameters, \( \alpha \) and \( \gamma \) are given by
\[ \alpha = \frac{|H_{1/2 \, 1}|^2 - |H_{-1/2 \, -1}|^2 + |H_{1/2 \, 0}|^2 - |H_{-1/2 \, 0}|^2}{|H_{1/2 \, 1}|^2 + |H_{-1/2 \, -1}|^2 + |H_{1/2 \, 0}|^2 + |H_{-1/2 \, 0}|^2}, \]  
(24)

\[ \gamma = \frac{2\text{Re}(H_{-1/2 \, 0}H_{1/2 \, 1}^* + H_{1/2 \, 0}H_{-1/2 \, -1}^*)}{|H_{1/2 \, 1}|^2 + |H_{-1/2 \, -1}|^2 + |H_{1/2 \, 0}|^2 + |H_{-1/2 \, 0}|^2}. \]  
(25)

When the \( \Lambda_b \) polarization is further considered, additional asymmetry parameters can be introduced. The new decay angles related are \( \Theta_P \) and \( \chi_P \). \( \Theta_P \) is the angle between \( \Lambda_b \) polarization and \( \Lambda_c \) momentum, and \( \chi_P \) is the azimuthal angle between the plane of \( \Lambda_b \) polarization, \( \Lambda_c \) momentum and that of \( a, b \)'s momenta. The decay distributions are

\[ \frac{d\Gamma_{pol}}{dy \, d\cos \Theta_P} \propto 1 - \alpha_P P \cos \Theta_P, \quad \text{and} \quad \frac{d\Gamma_{pol}}{dy \, d\chi_P} \propto 1 - \frac{\pi^2}{16} P \alpha_\Lambda \gamma_P \cos \chi_P, \]  
(26)

where \( P \) is the degree of polarization of \( \Lambda_b \). The asymmetry parameters \( \alpha_P \) and \( \gamma_P \) are

\[ \alpha_P = \frac{|H_{1/2 \, 1}|^2 - |H_{-1/2 \, -1}|^2 + |H_{1/2 \, 0}|^2 - |H_{-1/2 \, 0}|^2}{|H_{1/2 \, 1}|^2 + |H_{-1/2 \, -1}|^2 + |H_{1/2 \, 0}|^2 + |H_{-1/2 \, 0}|^2}, \]  
(27)

\[ \gamma_P = \frac{2\text{Re}(H_{1/2 \, 0}H_{-1/2 \, 0}^*)}{|H_{1/2 \, 1}|^2 + |H_{-1/2 \, -1}|^2 + |H_{1/2 \, 0}|^2 + |H_{-1/2 \, 0}|^2}. \]  
(28)

These asymmetry parameters are functions of \( y \). On averaging over \( y \), the numerators and denominators are integrated separately with proper weight, \( (y_{\text{max}} - y) \sqrt{y^2 - 1} \).

Our numerical results on the mean values of the asymmetry parameters are listed in Table 2 where both QCD sum rule and large \( N_c \) results are given. Note that these results include \( 1/m_c \) and \( 1/m_b \) corrections. The quark model results \[17\] are also listed for comparison. Note that all the results include \( 1/m_c \) and \( 1/m_b \) corrections.

**IV. NONLEPTONIC DECAYS**

In this section, we will consider the two-body nonleptonic decay modes \( \Lambda_b \to \Lambda_c \pi(\rho) \) and \( \Lambda_b \to \Lambda_c K^*(s) \). All these decays involve external \( W \)-emission diagrams which can be analyzed by using the factorization approximation \[18,19\]. \( \Lambda_b \to \Lambda_c \pi(\rho) \) also get contributions from internal \( W \)-emission which, however, is non-factorizable and is difficult to calculate reliably.
We will simply neglect this contribution in the analysis. Penguin diagrams do not contribute to these decays. There are contributions from W-exchange diagrams in both $\Lambda_b \to \Lambda_c \pi(\rho)$ and $\Lambda_b \to \Lambda_c K^{(*)}$ channels. Because such diagrams are suppressed by the possibility of the two valence quark lines meeting in the region of $1/M_W$, they are neglected. This is also justified by a detailed quark model analysis for $b$-baryon nonleptonic decays [20]. In short, the decays will be analyzed by using factorization assumption which is expected to be good except for the $\Lambda_c \pi(\rho)$ channels. In a recent study [21], the non-factorizable effect in decay $\Lambda_b \to \Lambda_c \pi$ has been estimated. The total non-factorizable contribution is about 30% of the factorizable one. Although it is indeed sizable, the factorizable effect is still dominant.

After factorization, the amplitude of the process can be expressed by the product of two matrix elements to which the form factors given in Sec.II can be applied just as in the case of the semileptonic decay. With the definition of the $\Lambda_b \to \Lambda_c$ matrix element Eq.(1), the widths of the decays into pseudoscalar meson(P) and vector meson(V) can be easily calculated:

$$\Gamma(P) = \frac{G_F^2}{2\pi} |V_{cb}|^2 f_P^2 a_1^2 M_{\Lambda_b}^3 \frac{r^2 \kappa_P}{(1 - \kappa_P^2)^2} [|A|^2 + \kappa_P^2 |B|^2]$$, \hspace{1cm} (29)

where

$$A = (1 - r) \left[F_1 + \frac{1 + r}{2} (F_2 + \frac{F_3}{r})\right]$$,

$$B = (1 + r) \left[G_1 - \frac{1 - r}{2} (G_2 + \frac{G_3}{r})\right]$$,

$$\kappa_{P(V)} = \sqrt{\frac{(1 - r)^2 - t_{P(V)}^2}{(1 + r)^2 - t_{P(V)}^2}}$$, \hspace{1cm} (30)

and

$$\Gamma(V) = \frac{G_F^2}{4\pi} |V_{cb}|^2 a_1 f_V^2 M_{\Lambda_b}^3 \frac{r^2 \kappa_V}{(1 - \kappa_V^2)^2} \left[2t_V^2 (\kappa_V^2 |F_1|^2 + |G_1|^2) + \kappa_V^2 |C|^2 + |D|^2\right]$$, \hspace{1cm} (31)

where

$$C = (1 + r) F_1 + \frac{2r}{1 - \kappa_V^2} (F_2 + \frac{F_3}{r})$$,

$$D = (1 - r) G_1 - \frac{2r \kappa_V^2}{1 - \kappa_V^2} (G_2 + \frac{G_3}{r})$$.

(32)
Here $V_{ij}$ denotes $V_{ud}$ for $\pi(\rho)$ and $V_{us}$ for $K(\star)$, and $r \equiv \frac{M_B}{M_{B_c}}$, $t_P(V) \equiv \frac{m_P(V)}{M_{B_c}}$ where $m_{P(V)}$ is the mass of the pseudoscalar (vector) meson. And $y = \frac{1+r^2-t^2_{P(V)}}{2r}$, $a_1$ is the QCD coefficient which is taken as a free parameter in the discussion of nonleptonic decays \[18,19\].

The above expressions are spin averaged results. If we take into account the spin effects, the spin up-down asymmetry of $\Lambda_b$ is a good parameter to analyze $\Lambda_b \to \Lambda_c$ nonleptonic decay. In this case, the decay rates are \[3,20\]

$$\Gamma(P) \propto 1 + \alpha(P)(S_{\Lambda_c} + S_{\Lambda_b}) \cdot \hat{p}_{\Lambda_c}, \quad (33)$$

where

$$\alpha(P) = -\frac{2\kappa_P \text{Re}(A^*B)}{|A|^2 + \kappa_P^2|B|^2}, \quad (34)$$

and

$$\Gamma(V) \propto 1 + \alpha(V)S_{\Lambda_b} \cdot \hat{p}_{\Lambda_c}, \quad (35)$$

where

$$\alpha(V) = \frac{\kappa_V \text{Re}(8t_V^2F_1G_1^* - CD^*)}{2[2t_V^2(\kappa_V^2|F_1|^2 + |G_1|^2) + \kappa_V^2|C|^2 + |D|^2]} \quad (36)$$

Here $S_{\Lambda_Q}$ is the spin vector of $\Lambda_Q$ and $\hat{p}_{\Lambda_c}$ is the unit vector of momentum of $\Lambda_c$. $\alpha_P(V)$ is the spin up-down asymmetry parameter of $\Lambda_b$.

The numerical results from QCD sum rule and large $N_c$ limit are given in Table 3. Because $y$ is near to 1.45, in the QCD sum rule case, we used the nonlinear fitting of the Isgur-Wise function $\xi(y) = (\frac{2}{y+1})^{0.5} \exp[-0.8\frac{y-1}{y+1}] \quad [8]$. The value of $a_1$ is taken to be 0.98 which is obtained from the decay $B \to D\pi \quad [19]$. Various decay constants are taken as follows; $f_{\rho} = 210$ MeV, $f_K = 158$ MeV and $f_{K^*} = 214$ MeV. The quark model results of Ref. \[20\] are also listed for comparison.

V. SUMMARY

We have analyzed the $\Lambda_b \to \Lambda_c$ semileptonic decay in the framework of HQET to the order of $1/m_c$ and $1/m_b$. The predictions for the Isgur-Wise functions and mass parameters
from QCD sum rule and large $N_c$ method are used. In the large $N_c$ limit, we argued that the subleading Isgur-Wise function vanishes. The decay rates, distributions and varuous asymmetry parameters are calculated numerically. Some of the $\Lambda_b$ nonleptonic decays are also calculated. The numerical results can be checked by the experiments in the near future.

**Acknowledgments**

We would like to thank Jungil Lee for helpful discussion. This work was supported in part by the KOSEF through SRC program, and in part by the Korean Ministry of Education, Project No. BSRI-97-2418. After finishing this work, we noticed a paper [22] which calculated the nonleptonic $\Lambda_b$ decays in the large $N_c$ and heavy quark limits.
