Abstract

We study the analytical solution of the Monte Carlo dynamics in the spherical Sherrington-Kirkpatrick model using the technique of the generating function. Explicit solutions for one-time observables (like the energy) and two-time observables (like the correlation and response function) are obtained. We show that the crucial quantity which governs the dynamics is the acceptance rate. At zero temperature, an adiabatic approximation reveals that the relaxational behavior of the model corresponds to that of a single harmonic oscillator with
an effective renormalized mass.

I. INTRODUCTION

The off-equilibrium features of glassy systems constitute a very interesting field of research. A great deal of attention has been paid to the study of the dynamics of exactly solvable models of disordered systems where much relevant information can be gathered even in the mean-field case. Numerical simulations of short-ranged and long-ranged models reveal a similar nature of the off-equilibrium dynamics [1–4]. The outstanding phenomenon which characterizes the off-equilibrium regime is the presence of aging, which has been experimentally observed in a large class of physical systems (for instance, in spin glasses [5] as well as in real glasses [6]). The distinctive feature of the aging phenomenon is that the response of the system to an external perturbation depends strongly on the time elapsed since the perturbation was applied. A phenomenological approach was proposed by Bouchaud [7] where the slow dynamics originates from the presence of large number of traps in phase space with a very broad distribution of lifetimes.

Much interest has been also devoted to the study of exactly solvable mean-field spin-glass models where information can be obtained from the solution of the dynamical equations. Of particular interest is the study of disordered models where replica symmetry is broken in the low-temperature phase. In this case, several results have been obtained in the study of $p$-spin models [8–10] as well as in the study of a particle in a random potential [11–13]. From these studies a very interesting connection [14] between mean-field glassy dynamical equations and the Mode Coupling Theory of glasses [15,16] has emerged. In this theoretical framework one derives a closed system of integrodifferential equations for the two-time correlation and response functions. Whereas all the information about the dynamics is contained in this system of equations, it is very difficult ascertain the long time evolution of one-time observables like the energy or the magnetization. Despite several advances in this direction (see for instance, the time series expansion carried out by Franz, Marinari and Parisi in case of the $p = 3$ spherical spin glass model [17]) this is still an open problem. Recently a completely different approach to the dynamics of glassy systems has been proposed by
Coolen and Sherrington [18]. They introduce a closure assumption (the equipartitioning hypothesis) which yields evolution equations for the one-time observables. In comparison with the results of simulations they obtain fairly good results in the short time regime. However it is still unclear whether the equipartitioning approximation is applicable for long times and how to proceed in case it this is the case [19,20].

On the issue of spin-glass dynamics, most of the existing works study Langevin equations. Meanwhile Monte Carlo dynamics has received less attention notwithstanding its great importance in numerical simulations, [22]. In particular, given that a major part of the numerical work in spin-glasses uses the Monte Carlo algorithm, we think that it is important to study the Monte Carlo dynamics in itself. Notice that Monte Carlo dynamics introduces the concept of acceptance rate which has no meaning for the Langevin dynamics. Interestingly, we shall see that the nature of the off-equilibrium regime strongly depends on the behavior of the acceptance rate. To shed some light on these issues we have considered the spherical Sherrington-Kirkpatrick (SK) model [21]. While this model lacks replica symmetry breaking in the low temperature phase, it can be analytically solved.

In a letter (hereafter referred as I) we introduced a method to solve the Monte Carlo dynamics of the spherical SK model [23]. We derived generalized dynamical equations for one-time quantities and a closed integrodifferential problem for their generating function. The same method can be successfully applied to models with Langevin dynamics. The purpose of this work is to present the method of the generating function, give a detailed account of the computations announced in I, and discuss some other topics such as the properties of two-time correlation and response functions and the long time behavior of dynamical quantities.

The paper is organized as follows. In the second section we introduce the spherical SK model and explain how to solve its Langevin dynamics by the method of the generating function. While the results of this section are well known [24,25], their derivation by means of the generating function serves as a clear introduction of this method. Section three contains the main result of this paper, i.e. the solution of the corresponding equations for the Monte Carlo dynamics.
Carlo dynamics. Section four analyzes the long-time behavior of dynamical quantities at finite and zero temperature and the conditions under which the results of the Langevin dynamics are recovered. The last section contains our conclusions while the Appendices are devoted to different technical matters.

II. THE LANGEVIN APPROACH: A REMINDER

The spherical Sherrington-Kirkpatrick spin glass model is defined by the Hamiltonian,

\[ \mathcal{H}\{\sigma\} = -\sum_{i<j} J_{ij} \sigma_i \sigma_j \]  

(1)

where the indices \(i, j\) run from 1 to \(N\) (\(N\) is the number of sites) and the spins \(\sigma_i\) satisfy the spherical global constraint

\[ \sum_{i=1}^{N} \sigma_i^2 = N. \]  

(2)

The interactions \(J_{ij}\) are Gaussian distributed with zero mean and \(1/N\) variance. The statics of this model reveals the existence of a thermodynamic second-order phase transition at \(T = 1\) \[21\] with a replica symmetric low-temperature phase.

We will revisit the Langevin dynamics of the spherical SK model in order to introduce the technique of the generating function. The Langevin equation is

\[ \frac{\partial \sigma_i}{\partial t} = -\frac{\partial \mathcal{H}}{\partial \sigma_i} + \mu(t) \sigma_i + \eta_i(t) \]  

(3)

with \(\eta_i(t)\) a Gaussian white noise \(\overline{\eta_i(t)\eta_j(t')} = 2T \delta_{i,j}\delta(t - t')\), \(\overline{\cdots}\) stands for average over the noise); \(\mu(t)\) is a time dependent Lagrange multiplier which ensures that the spherical constraint eq.(2) is satisfied at all times and \(\mathcal{H}\) is the Hamiltonian defined by eq.(1). We can rewrite the previous equation as a single mode problem,

\[ \frac{\partial \sigma_\lambda}{\partial t} = \lambda \sigma_\lambda + \mu(t) \sigma_\lambda + \eta_\lambda(t) \]  

(4)

Here \(\sigma_\lambda\) and \(\eta_\lambda\) are the projections of the configuration \(\{\sigma_i\}\) and the original noise \(\{\eta_i\}\) on the basis of eigenvectors which diagonalize the interaction matrix \(J_{ij}\). The \(\{\sigma_\lambda\}\) satisfy
the spherical constraint \( \sum_{\lambda=1}^{N} \sigma_{\lambda}^2 = N \). The transformation matrix which diagonalizes the \( J_{ij} \) is an orthogonal matrix. Hence, the components \( \eta_{\lambda} \) generate a white noise of the type,

\[
\eta_{\lambda}(t)\eta_{\lambda'}(t') = 2T \delta_{\lambda,\lambda'} \delta(t - t').
\] (5)

The eigenvalues \( \lambda \) of a random Gaussian symmetric matrix are distributed according to the Wigner semicircular law \( w(\lambda) \)

\[
w(\lambda) = \frac{\sqrt{4 - \lambda^2}}{2\pi}.
\] (6)

**A. Generating function for the one-time quantities**

Our purpose is to describe the time-evolution of certain one-time functions of the solutions of eq.(4). We define the set of moments,

\[
h_k = \frac{1}{N} \sum_{(i,j)} \sigma_i (J^k)_{ij} \sigma_j = \frac{1}{N} \sum_\lambda \lambda^k \sigma_\lambda^2
\] (7)

Notice that \( h_0 = 1 \) (spherical constraint) and \( h_1 = -2E \) where \( E \) is the energy. Using the result \( \lim_{t \to t'} \eta_{\lambda}(t')\sigma_\lambda(t) = 2T \) we get the equation

\[
\frac{\partial h_k}{\partial t} = 2h_{k+1} + 2\mu h_k + 2T \ll \lambda^k \gg
\] (8)

where

\[
\ll f(\lambda) \gg = \int_{-2}^{2} f(\lambda) w(\lambda) d\lambda
\] (9)

and \( w(\lambda) \) is given by eq.(6). In particular, eq.(8) for \( k = 0 \) gives the Lagrange multiplier as a function of the energy and temperature \( \mu = 2E - T \). In order to close these equations we define the generating function,

\[
g(x, t) = \frac{1}{N} \sum_{(i,j)} \sigma_i (e^{xJ})_{ij} \sigma_j = \frac{1}{N} \sum_\lambda e^{\lambda x} \sigma_\lambda^2(t) = \sum_{k=0}^{\infty} \frac{x^k}{k!} h_k(t).
\] (10)

This function yields all the moments \( h_k = \left( \frac{\partial^k g(x, t)}{\partial x^k} \right)_{x=0} \).
We now want to formulate a problem for $g(x, t)$ (equation, initial, boundary and subsidiary conditions) which has a unique solution. Then we will either be able to solve it (and thus determine the $h_k$'s exactly) or to infer the long-time behavior of the moments. By using Equations (7), (8) and (10), we find that $g(x, t)$ satisfies the following differential equation

$$\frac{\partial g(x, t)}{\partial t} = 2 \frac{\partial g(x, t)}{\partial x} + 2 \mu(t) g(x, t) + 2T \ll \exp(x \lambda) \gg, \quad \mu(t) = -\frac{\partial g}{\partial x}(0, t) - T. \quad (11)$$

These equations have to be solved with the boundary condition $g(0, t) = 1$ (the spherical constraint) and an appropriate initial condition $g(x, 0) = g_0(x)$ (defined by the initial configuration $\{\sigma_\lambda(t = 0)\}$). Besides taking the continuum limit in the definition (10), we see that

$$g(x, t) = \int_{-2}^{2} d\lambda w(\lambda) e^{x\lambda} \hat{g}(\lambda, t), \quad (13)$$

where the spectral transform $\hat{g}(\lambda, t) \geq 0$. The latter condition is kept by the dynamics if it holds initially. However its use is crucial to distinguish the physically meaningful stationary solutions from spurious ones. We can solve (11) by the method of characteristics assuming that $\mu(t)$ is given. The result is

$$g(x, t) = g_0(x + 2t)e^{2\int_0^t \mu(t') dt'} + 2T \int_0^t dt' \ll e^{(x + 2(t-t'))\lambda} \gg \ll e^{2\int_0^t \mu(t') dt'} \gg, \quad (14)$$

Inserting (14) in the spherical constraint $g(0, t) = 1$, it is possible to derive an integral equation which can be solved by means of the Laplace transform [25].

It is easy to check that (15) is a stationary solution of eq.(11) for $T > T_c = 1$.

$$g^{eq}(x) = -\ll \frac{e^{x\lambda}}{\beta(\lambda + \mu^{eq})} \gg \quad (15)$$

In this case the moments $h_k$ can be easily computed [21]

$$h_k^{eq} = -\ll \frac{\lambda^k}{\beta(\lambda + \mu^{eq})} \gg, \quad (16)$$

and the Lagrange multiplier $\mu^{eq}$ is given by
\[
1 = - \frac{1}{\beta(\lambda + \mu^eq)}
\]  \hspace{1cm} (17)

For \( T \leq 1 \), \( \mu^eq = -2 \), the stationary solution is given by
\[
g^eq(x) = (1 - \frac{1}{\beta})e^{2x} - \frac{e^{x\lambda}}{\beta(\lambda - 2)}
\]  \hspace{1cm} (18)

and the moments \( h_k \) are
\[
h_k^eq = (1 - \frac{1}{\beta})2^k - \frac{\lambda^k}{\beta(\lambda - 2)}
\]  \hspace{1cm} (19)

Substituting eqs. (15 and 18) in eq. (11) one can easily check that the right hand side of eq. (11) is identically zero.

**B. The correlation and response function**

In order to find closed expressions for the correlation function we define the following set of two-times moments,
\[
C_k(t', t) = \frac{1}{N} \sum_{(i,j)} \sigma_i(t')(J^k)_{ij} \sigma_j(t) = \frac{1}{N} \sum_{\lambda} \lambda^k \overline{\sigma_{\lambda}(t') \sigma_{\lambda}(t)}
\]  \hspace{1cm} (20)

Note that in this notation the usual two-times correlation function is given by \( C_0(t', t) \).

The equation of motion for the \( C_k(t', t) \) reads,
\[
\frac{\partial C_k(t', t)}{\partial t} = C_{k+1}(t', t) + \mu(t) C_k(t', t)
\]  \hspace{1cm} (21)

where we have used the result \( \eta_{\lambda}(t')\sigma_{\lambda}(t) = 0 \) for \( t' < t \). Previous equation has to be solved with the initial condition \( C_k(t', t') = h_k(t') \) where the \( h_k(t) \) are the one-time moments previously obtained from the generating function \( g(x, t) \).

We define the following generating function,
\[
K(x, t', t) = \frac{1}{N} \sum_{(i,j)} \sigma_i(t')(e^{xJ})_{ij} \sigma_j(t) = \frac{1}{N} \sum_{\lambda} e^{\lambda x} \overline{\sigma_{\lambda}(t') \sigma_{\lambda}(t)} = \sum_{k=0}^{\infty} \frac{x^k}{k!} C_k(t', t).
\]  \hspace{1cm} (22)

The generating function \( K(x, t', t) \) yields the generalized two-times moments \( C_k(t', t) = \left( \frac{\partial^k K(x, t', t)}{\partial x^k} \right)_{x=0} \) and satisfies the following homogeneous partial differential equation,
\[ \frac{\partial K(x, t', t)}{\partial t} = \frac{\partial K(x, t', t)}{\partial x} + \mu(t)K(x, t', t) \quad (23) \]

with the initial condition \( K(x, t', t) = g(x, t') \) and \( g(x, t') \) is given in eq. (14).

A similar method is applied to the response function. We define the set of two-times moments,

\[ G_k(t', t) = \frac{1}{N} \sum_{(i,j)} (J^k)_{ij} \frac{\partial \sigma_j(t)}{\partial \eta_i(t')} = \frac{1}{N} \sum_{\lambda} \lambda^k \frac{\partial \sigma_{\lambda}(t)}{\partial \eta_{\lambda}(t')} \quad (24) \]

where \( t' < t \). In this notation the usual response function is given by \( G_0(t', t) \). We construct the generating function

\[ \Gamma(x, t', t) = \frac{1}{N} \sum_{(i,j)} (e^{xJ})_{ij} \frac{\partial \sigma_j(t)}{\partial \eta_i(t')} = \frac{1}{N} \sum_{\lambda} e^{\lambda x} \frac{\partial \sigma_{\lambda}(t)}{\partial \eta_{\lambda}(t')} = \sum_{k=0}^{\infty} \frac{x^k}{k!} G_k(t', t). \quad (25) \]

The generating function \( \Gamma(x, t', t) \) yields the generalized two-times moments \( G_k(t', t) = \left( \frac{\partial^k \Gamma(x, t, t')}{\partial x^k} \right)_{x=0} \). With the usual regularization of the response function at equal times the dynamical equation for the \( \Gamma(x, t', t) \) reads,

\[ \frac{\partial \Gamma(x, t', t)}{\partial t} = \frac{\partial \Gamma(x, t', t)}{\partial x} + \mu(t)\Gamma(x, t', t) + \delta(t - t') \ll \exp(x\lambda) \gg \quad (26) \]

To solve this equation we need to impose the causality condition \( \Gamma(x, t', t) = 0 \) if \( t < t' \). The solution to equations (23) and (26) can be easily found. One gets the results,

\[ K(x, t', t) = g(x + t - t', t') e^{\int_{t'}^{t} \mu(t') dt'} \]
\[ \Gamma(x, t', t) = \ll e^{(x+t-t')\lambda} \gg e^{\int_{t'}^{t} \mu(t') dt'} \theta(t - t') \quad (27) \]

From these generating functions we can extract the usual two-time correlation and response function, \( C_0(t', t) = K(0, t', t) \) and \( G_0(t', t) = \Gamma(0, t', t) \). At equilibrium we can substitute the solution (13) in (26) obtaining,

\[ K(x, t', t) = K^{eq}(x, t - t') = g^{eq}(x + t - t') e^{\mu^{eq}(t-t')} \]
\[ \Gamma(x, t', t) = \Gamma^{eq}(x, t - t') = \ll e^{(x+t-t')\lambda} \gg e^{\mu^{eq}(t-t')} \theta(t - t') \quad (28) \]
Both functions are translationally invariant (i.e. depend only on the difference of times) and the fluctuation dissipation theorem for the generating functions also holds,

\[ \Gamma^{eq}(x,t-t') = \beta \frac{\partial K^{eq}(x,t-t')}{\partial t'} \]  

(29)

The off-equilibrium behavior of the quantities \( C_0(t',t), G_0(t',t) \) has been already studied in the literature (see [24,25]).

### III. THE MONTE CARLO APPROACH

We consider the Monte Carlo (MC) dynamics with the Metropolis algorithm. The idea behind the MC approach is to postulate a dynamics in which a new configuration is proposed and accepted with a certain probability. The dynamics is ergodic at finite temperature and satisfies detailed balance. Following (I) we will consider a particularly simple motion which makes the dynamics exactly soluble: take the configuration \( \{\sigma_i\} \) at time \( t \) and perform a small random rotation from that configuration to a new one \( \{\tau_i\} \) where

\[ \tau_i = \sigma_i + \frac{r_i}{\sqrt{N}} \]  

(30)

and the \( r_i \) are random numbers extracted from a Gaussian distribution \( p(r) \) of finite variance \( \rho \),

\[ p(r_i) = \frac{1}{\sqrt{2\pi \rho^2}} \exp\left(-\frac{r_i^2}{2\rho^2}\right) . \]  

(31)

Let us denote by \( \Delta E \) the change of energy \( \Delta E = E\{\tau\} - E\{\sigma\} \). According to the Metropolis algorithm we accept the new configuration with probability 1 if \( \Delta E < 0 \) and with probability \( \exp(-\beta \Delta E) \) if \( \Delta E > 0 \) where \( \beta = \frac{1}{T} \) is the inverse of the temperature \( T \).

**A. The probability distribution \( P(\Delta E) \)**

As before in the Langevin formulation, we want to obtain one and two time moments. It is useful to work in the basis for which the interaction matrix \( J_{ij} \) is diagonal. The energy then reads,
\( E\{\sigma_{\lambda}\} = -\frac{1}{2} \sum_{\lambda} \lambda \sigma_{\lambda}^2 \)  

(32)

where the \( \sigma_{\lambda} \) are distributed according to eq.(3). In this basis, the spin configuration still corresponds to a small random rotation, hence \( \sigma_{\lambda} \to \sigma_{\lambda} + r_{\lambda}/\sqrt{N} \) where the new random numbers \( r_{\lambda} \) are extracted from the same Gaussian distribution eq.(31).

The basic object we want to compute is the probability \( P(\Delta E) \) of having a given variation \( \Delta E \) of the energy \( E \). This is a quantity which gives the average number of accepted changes.

The variation \( \Delta E^* \) of the energy \( E \) in a Monte Carlo (MC) step is

\[
\Delta E^* = -\frac{1}{\sqrt{N}} \sum_{\lambda} \lambda \sigma_{\lambda} r_{\lambda} - \frac{1}{2N} \sum_{\lambda} \lambda r_{\lambda}^2
\]

(33)

while the quantity \( h_0 = \frac{1}{N} \sum_{\lambda} \sigma_{\lambda}^2 \) is changed by the following amount,

\[
\Delta h_0^* = \frac{2}{\sqrt{N}} \sum_{\lambda} \sigma_{\lambda} r_{\lambda} + \frac{1}{N} \sum_{\lambda} r_{\lambda}^2.
\]

(34)

The probability \( P(\Delta E) \) of having a change of energy is

\[
P(\Delta E) = \int \delta(\Delta E - \Delta E^*) \delta(\Delta h_0^*) \prod_{\lambda} (p(r_{\lambda}) dr_{\lambda})
\]

(35)

where the last delta function in the integrand accounts for the spherical constraint and the variation \( \Delta E^* \) is given in eq.(33).

Using the integral representation for the delta function

\[
\delta(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{i\alpha x} d\alpha
\]

(36)

and substituting in (35) we get

\[
P(\Delta E) = \int d\mu d\eta \exp\left(i\mu \Delta E - \frac{\rho^2}{2N} \sum_{\lambda} \frac{\sigma_{\lambda}^2 \gamma_{\lambda}^2}{(1 - i\gamma_{\lambda}^2 \rho^2/N)} - \frac{1}{2} \sum_{\lambda} \log(1 - i\gamma_{\lambda}^2 \rho^2/N)\right)
\]

(37)

where \( \gamma_{\lambda} = \mu \lambda + 2\eta \). After expanding the logarithm and retaining the first \( 1/N \) correction we get (after some manipulations)
\[ P(\Delta E) = \frac{1}{\sqrt{2\pi\rho^2B_1}} \exp\left(-\frac{(\Delta E + \rho^2E)^2}{2\rho^2B_1}\right) \]  

(38)

with

\[ B_1 = h_2 - 4E^2; \quad (h_0 = 1); \quad h_2 = \frac{1}{N} \sum_{\lambda} \lambda^2 \sigma_{\lambda}^2; \]  

(39)

The equation for the energy is obtained by considering the average variation of energy in an MC step. In this case one MC step corresponds to \( N \) elementary moves. In the thermodynamic limit we can write the continuous equations,

\[ \frac{\partial E}{\partial t} = \Delta E = \int_{-\infty}^{0} (\Delta) E P(\Delta E) d(\Delta E) + \int_{0}^{\infty} (\Delta E) \exp(-\beta \Delta E) P(\Delta E) d(\Delta E). \]  

(40)

We can check that equilibrium is a stationary solution of the Monte Carlo dynamics. Using standard static calculations \[28,21\] one can show that in equilibrium \( B_1 = h_2 - 4E^2 = -2ET \). In this case a straightforward computation shows that detailed balance is fulfilled. This means that, for a given value of \( \Delta E \), the first integral appearing in the r.h.s of eq.(40) cancels the contribution of the second integral in the r.h.s of eq.(40) for the same value of \( \Delta E \). In other words,

\[ P(-\Delta E) = \exp(-\beta \Delta E)P(\Delta E) \]  

(41)

The equation for the energy reads,

\[ \frac{\partial E}{\partial t} = -\frac{a(t)}{2} h_2(t) + b(t) E(t) \]  

(42)

where the coefficients \( a(t) \) and \( b(t) \) are given by

\[ a(t) = \rho^2 \beta \frac{e^{2\beta(\beta B_1 + 2E)}}{\sqrt{2 \pi}} \text{Erf}\left(\sqrt{\frac{2}{B_1}} \alpha\right) \]  

\[ b(t) = -\frac{1}{2}(\rho^2 \text{Erf}(\alpha) + (4E - T)a(t)) \]  

(43)

and \( \text{Erf}(x) \) is the complementary error function defined as \( \text{Erf}(x) = \frac{2}{\sqrt{\pi}} \int_{x}^{\infty} dx \exp(-x^2) \) and the parameter \( \alpha \) is given by,

\[ \alpha = -\frac{\rho E}{\sqrt{2B_1}} \]  

(44)
Note that the quantities $E$, $B_1$, and $\alpha$ depend on time. Also one can compute the acceptance rate as a function of time, which is the probability of accepting a certain change of the configuration,

$$A(t) = \int_{-\infty}^{0} P(\Delta E) d(\Delta E) + \int_{0}^{\infty} \exp(-\beta \Delta E) P(\Delta E) d(\Delta E). \quad (45)$$

A straightforward computation shows,

$$A(t) = \frac{Erf(\alpha)}{2} + \frac{1}{2} e^{\frac{\alpha^2}{2}(\beta B_1 + 2E)} \exp\left(\frac{\sqrt{2}}{B_1} - \alpha\right) \quad (46)$$

In order to obtain the time evolution of the acceptance rate and to solve the eq.(42) of the time evolution of the energy we need to know the energy $E$ and $h_2$ at time $t$. Unfortunately, one can see that the time evolution equation for $h_2(t)$ involves $h_3(t)$ and so on. This hierarchy of moments can be closed introducing a generating function like has been done in the Langevin dynamics. This is the purpose of the next section.

### B. Generating function for the one-time quantities

To close the equations of motion we consider the set of moments defined in eq.(7). The basic object to compute is the joint probability distribution $P(\Delta h_k, \Delta E)$. This quantity can be written as,

$$P(\Delta h_k, \Delta E) = \int \delta(\Delta h_k - \Delta h^*_k) \delta(\Delta E - \Delta E^*) \delta(\Delta h_0) \prod_{\lambda} (p(r_\lambda) dr_\lambda) \quad (47)$$

where the last delta function in the integrand accounts for the spherical constraint and the variation $\Delta E^*$ is given in eq.(33) while the variation $\Delta h^*_k$ is given by,

$$\Delta h^*_k = \frac{2}{\sqrt{N}} \sum_{\lambda} \lambda \sigma_\lambda r_\lambda + \frac{1}{N} \sum_{\lambda} \lambda^2 r_\lambda. \quad (48)$$

Following the same technical steps as in the derivation of $P(\Delta E)$ we obtain the following result,

$$P(\Delta h_k, \Delta E) = P(\Delta E) P(\Delta h_k|\Delta E) \quad (49)$$
where $P(\Delta E)$ is the probability distribution eq(38) and $P(\Delta h_k | \Delta E)$ is the conditional probability of $\Delta h_k$ given $\Delta E$. The final expression for the conditional probability is,

$$P(\Delta h_k | \Delta E) = \frac{1}{\sqrt{8 \pi \rho^2 (C_k - (B_k^2 / B_1))}} \exp\left(- \frac{\left(\Delta h_k + \rho^2 (h_k - \langle \lambda^k \rangle) + 2 B_k (\Delta E + \rho^2 E)^2\right)^2}{8 \rho^2 (C_k - B_k^2 / B_1)}\right)$$

(50)

with $C_k = h_{2k} - h_k^2$; $B_k = h_{k+1} + 2 E h_k$; ($h_0 = 1$; $h_1 = -2E$); and the average $\langle ... \rangle$ has been previously defined in eq.(9).

In order to obtain the dynamical evolution of the moments $h_k$ we have to compute its average variation in a MC step over the accepted changes of configuration. In the thermodynamic limit we can write the continuous equations,

$$\frac{\partial h_k}{\partial t} = \langle \Delta h_k \rangle = \int_{-\infty}^{\infty} d(\Delta h_k) \Delta h_k

\left(\int_{-\infty}^{0} d(\Delta E) P(\Delta h_k, \Delta E) + \int_{0}^{\infty} d(\Delta E) \exp(-\beta \Delta E) P(\Delta h_k, \Delta E)\right)$$

(51)

The solution for a general integral of the previous type is shown in the Appendix A. The following result is obtained,

$$\frac{\partial h_k(t)}{\partial t} = a(t) h_{k+1}(t) + b(t) h_k(t) + c_k(t)$$

(52)

where the time dependent quantities $a(t)$ and $b(t)$ are given in eq.(43) and the coefficients $c_k(t)$ are defined by

$$c_k(t) = (2E(t)a(t) - b(t)) \langle \lambda^k \rangle = \rho^2 A(t) \langle \lambda^k \rangle.$$  

(53)

Here $A(t)$ is the acceptance rate defined in eq.(46). Note that the rate variation of the moment $h_k$ depends linearly on the moments $h_k$ and $h_{k+1}$, but the coefficients $a(t)$, $b(t)$ and $c(x, t)$ are nonlinear functions of $h_1 = -\frac{1}{2} E$ and $B_1 = h_2 - h_1^2$ (second cumulant). It is thus reasonable to expect that the Monte Carlo dynamics is determined by the evolution of the first two moments. By means of the moments generating function $g(x, t)$ of eq. (11), we obtain from eq. (51).
\[
\frac{\partial g(x, t)}{\partial t} = a(t) \frac{\partial g}{\partial x} + b(t)g + c(x, t). \tag{54}
\]

where the time dependent quantities \(a, b\) are functions of the two first moments \(E(t)\) and \(h_2(t)\) (whose relation to \(g\) is indicated below) defined in (43) and

\[
c(x, t) = (2E(t)a(t) - b(t)) \ll e^{x\lambda} \gg \rho^2 A(t) \ll e^{x\lambda} \gg . \tag{55}
\]

As in the case of Langevin dynamics, \(g(x, t)\) is a solution of eq. (54) plus the following initial, boundary and subsidiary conditions:

\[
\begin{align*}
g(x, 0) &= g_0(x) \\
g(0, t) &= 1 \\
\frac{\partial g}{\partial x} \bigg|_{x=0} &= -2E(t) \\
\frac{\partial^2 g}{\partial x^2} \bigg|_{x=0} &= h_2(t)
\end{align*}
\tag{56}
\]

The second condition is the spherical one and the third and fourth define the first and second moments of the set \(h_k\). This linear partial differential equation equation can be readily solved with the method of characteristics. The general solution for a partial differential equation of the previous type (54) is shown in the Appendix B.

C. The correlation and response function

In order to find the dynamical equation for the set of correlation functions eq.(20) we perform a similar computation as has been done for the moments \(h_k\).

The elementary move eq.(30) at time \(t\) induces a change \(\Delta E^*\) and \(\Delta C_k^*\) in the energy and the \(k\)-moment of the correlation function \(C_k(t', t)\) (in what follows we take \(t' < t\)) defined in eq.(20),

\[
\begin{align*}
\Delta E^* &= -\frac{1}{\sqrt{N}} \sum_\lambda \lambda \sigma_\lambda(t)r_\lambda(t) - \frac{1}{2N} \sum_\lambda \lambda r_\lambda(t)^2 \\
\Delta C_k^* &= \frac{1}{\sqrt{N}} \sum_\lambda \lambda^k \sigma_\lambda(t')r_\lambda(t)
\end{align*}
\tag{57}
\]
The probability of having a change of the energy $\Delta E$ and the correlation $\Delta C_k$ is given by the joint probability,

\[ P(\Delta E, \Delta C_k) = \int \delta(\Delta E - \Delta E^*) \delta(\Delta C_k - \Delta C_k^*) \delta(\Delta h_0) \prod_{\lambda} (p(r_\lambda) dr_\lambda) \]

Using the integral representation of the delta function, retaining only the terms of order $\frac{1}{N}$ and performing all the Gaussian integrals we find

\[ P(\Delta E, \Delta C_k) = P(\Delta E) P(\Delta E | \Delta C_k) \]

where

\[ P(\Delta E | \Delta C_k) = \frac{1}{\sqrt{2\pi \rho^2 (h_{2k} - C_k^2 - \frac{D_k}{B_1})}} \exp \left( -\frac{(\Delta C_k + \frac{\rho^2}{2} C_k + \frac{D_k}{B_1}(\Delta E - \frac{\rho^2}{2} h_1))^2}{2 \rho^2 (h_{2k} - C_k^2 - \frac{D_k}{B_1})} \right) \]

where $h_{2k} = h_{2k}(t')$; $D_k(t', t) = C_{k+1}(t', t) + 2E(t)C_k(t', t)$ and $P(\Delta E)$ is given by eq.(38).

To solve the equation of motion for the $C_k(t', t)$ we write its average variation at time $t$ over the accepted changes of configuration,

\[ \frac{\partial C_k(t', t)}{\partial t} = \frac{\Delta C_k(t', t)}{\Delta C_k} = \int_{-\infty}^{\infty} \Delta C_k \, d(\Delta C_k) \]

\[ \left( \int_{-\infty}^{0} d(\Delta E) \, P(\Delta C_k, \Delta E) + \int_{0}^{\infty} d(\Delta E) \, \exp(-\beta \Delta E) \, P(\Delta C_k, \Delta E) \right) \]

(58)

Using the formulae of Appendix A we get the result,

\[ \frac{\partial C_k(t', t)}{\partial t} = \frac{a(t)}{2} C_{k+1}(t', t) + \frac{b(t)}{2} C_k(t', t) \]

(59)

where $a(t), b(t)$ have been previously defined in eq.(38).

Equation (59) is solved with the initial condition $C_k(t', t) = h_k(t')$ (once the time evolution of the $h_k(t)$ has been obtained solving the preceding hierarchy corresponding to the set of moments $h_k$).

In order to close the previous hierarchy of equations we introduce the generating function $K(x, t', t)$ of eq.(22) which yields the generalized two-times moments $C_k(t', t) = \left( \frac{\partial^k K(x, t', t)}{\partial x^k} \right)_{x=0}$. The $K(x, t', t)$ satisfies the following partial differential equation,

\[ \frac{\partial K}{\partial t} = \frac{a(t)}{2} \frac{\partial K}{\partial x} + \frac{b(t)}{2} K \]

(60)
together with $K(x, t', t') = g(x, t')$. The solution can be found by the method of the characteristics. A similar procedure can be used to obtain the generating function for the moments of the response function eq. (24). In the Monte Carlo dynamics the equivalent quantity is given by the moments,

$$G_k(t', t) = \lim_{\Delta \to 0} \frac{1}{N\Delta} \sum_{\lambda} \lambda^k m_{\lambda}(t') \sigma_{\lambda}(t)$$

where $\Delta$ measures the intensity of an applied staggered field $m_{\lambda}$. This quantity measures the correlation between the spin configuration at time $t$ and a small staggered magnetic field $m_{\lambda}(t')$ applied at a previous time $t'$. Equation (61) is the analogous of the correlation between the spin configuration at time $t$ and the noise at time $t'$ in the Langevin approach.

The staggered magnetic field $m_{\lambda}$ is an uncorrelated annealed random field taken from a Gaussian distribution of variance $\Delta$,

$$P(m_{\lambda}) = \left(\frac{2}{\pi \Delta^2}\right)^{-\frac{1}{2}} \exp\left(-\frac{m_{\lambda}^2}{2 \Delta^2}\right)$$

at each elementary move in the MC dynamics. The calculation of the response function proceeds in the following way: we compute the probability distribution for the variation of the $G_k(t', t)$ when a small staggered magnetic field $m_{\lambda}(t')$ is applied at an earlier time $t'$ in an elementary move eq. (30) at time $t$. We compute the joint probability distribution of the variation $\Delta G_k(t', t)$ for an elementary move at time $t$,

$$P(\Delta E, \Delta G_k) = \int \delta(\Delta E - \Delta E^*) \delta(\Delta G_k - \Delta G_k^*) \delta(\Delta h_0)$$

$$\prod_{\lambda} \left(p(r_{\lambda}) P(m_{\lambda}(t')) dr_{\lambda} dm_{\lambda}(t')\right)$$

where $\Delta h_0$ is given in eq. (34) and the variations of energy and $G_k$ are given by,

$$\Delta E^* = -\frac{1}{\sqrt{N}} \sum_{\lambda} \lambda \sigma_{\lambda}(t) r_{\lambda}(t) - \frac{1}{2N} \sum_{\lambda} (\lambda r_{\lambda}(t)^2 - m_{\lambda}(t') r_{\lambda}(t))$$

$$\Delta G_k^* = \frac{1}{\sqrt{N}} \sum_{\lambda} \lambda^k m_{\lambda}(t') r_{\lambda}(t)$$

Finally, the perform the limit $\Delta$ tending to zero for the intensity of the staggered magnetic field. Performing similar computations as in the correlation function case we obtain for the
average variation $\frac{\partial G_k(t',t)}{\partial t}$ (in the region of times $t' < t$) the equation (59) substituting $C_k$ by $G_k$. Note that the difference between the hierarchy of equations associated to the correlation and the response function lies in the region of times $t' > t$ where $G_k(t',t) = 0$ while $C_k(t',t) = C_k(t,t')$.

The partial differential equation associated to the generating function eq.(25) is in this case

$$\frac{\partial \Gamma}{\partial t} = a(t)\frac{\partial \Gamma}{\partial x} + b(t)\Gamma + \ll \exp(x\lambda) \gg \delta(t-t')$$ (65)

The partial differential equations (60) and (65) can be also readily solved with the method of the characteristics (see Appendix B) as was done for in case of the one time quantities. Note that the equations for the generating functions $g, K, \Gamma$ (eqs.(54, 60, 65)) are formally the same as in the Langevin approach eqs.(11, 23, 26) with the time-dependent parameters $a(t), b(t), c(x,t)$ given by,

$$a_{LANG}(t) = 2; \quad b_{LANG}(t) = 2(2E-T); \quad c_{LANG}(x,t) = 2T \ll \exp(x\lambda) \gg;$$ (66)

The main difference between the MC dynamics and the Langevin dynamics relies on the simpler time dependence of the coefficients $a, b, c$ in the last case. This makes the large-time behavior of the Langevin dynamics exactly soluble (see [24,25]) while this is a very complicated task in the MC case.

IV. ANALYSIS OF THE MONTE CARLO DYNAMICAL EQUATIONS

In this section we proceed to solve the resulting dynamical equations for the MC dynamics. First we analyze the equilibrium dynamics showing that it coincides with the Langevin dynamics by an appropriate rescaling of time. Then we study the off-equilibrium behavior contained in the MC dynamics at finite and zero temperature. Since it is also our purpose to test the correctness of the solution of our equations we will compare the theory with real Monte Carlo numerical simulations. Moreover we will compare the resulting dynamics with that expected in the Langevin case.
A. Equilibrium Monte Carlo dynamics

Dynamical equations for one-time and two-time quantities can be readily solved at equilibrium. Now the observables $h_k$ are independent of time and the two-time functions $C_k(t',t)$, $G_k(t',t)$ only depend on the differences of time $t - t'$. It is easy to check that the coefficients $a(t), b(t), c(x,t)$ of eqs.(43,55) are time-independent and given by,

\begin{align*}
  a^{eq} &= \rho^2 \beta \text{Erf}(\alpha^{eq}) \\
  b^{eq} &= \rho^2 \beta (2E - T) \text{Erf}(\alpha^{eq}) \\
  c^{eq}(x) &= \rho^2 \ll \exp(x\lambda) \gg \text{Erf}(\alpha^{eq})
\end{align*}

with

\begin{equation}
  \alpha^{eq} = -\frac{\rho E^{eq}}{\sqrt{2B_1^{eq}}} = \rho \sqrt{\frac{(2\beta - 1)}{8}}
\end{equation}

This coefficients are the same as for the Langevin dynamics except for a rescaling of time $t \rightarrow t' = \frac{\rho^2 \text{Erf}(\alpha^{eq})}{2} t$. Also one can show (using eq.(46)) that the acceptance rate is given by,

\begin{equation}
  A^{eq} = \text{Erf}(\alpha^{eq})
\end{equation}

Using the previous rescaling of time the equilibrium MC dynamical equations coincide with the Langevin ones [19].

B. Monte Carlo simulations

In order to check our analytical results for the MC dynamics we have performed some MC simulations for finite sizes. To simulate enough large sizes we worked in the basis of eigenvectors $\sigma_\lambda$. In this way all the information about the quenched disorder is fully contained in the spectrum of eigenvalues $\lambda$, which occupies much less memory than the full interaction Gaussian matrix $J_{ij}$. The set eigenvalues $\lambda$ is chosen according to the semicircular law eq.(6). Typically we start from a random initial configuration $\sigma_\lambda = \pm 1$ which fulfills the
spherical constraint. Then we perform a small rotation of this configuration \( \{ \sigma_\lambda \} \rightarrow \{ \sigma_\lambda + \frac{r_\lambda}{\sqrt{N}} \} \) (eq.(30)) where the \( r_\lambda \) are random numbers extracted from the Gaussian distribution eq.(31). To keep invariant the spherical constraint we normalize the length of the vector \( \{ \sigma_\lambda \} \) in order to make it of length one. The resulting change of energy eq.(32) is computed and accepted with probability \( \text{Min}(1, \exp(-\beta \Delta E)) \). We repeat this process for the new configuration and so on. A MC step corresponds to \( N \) rotations. Because an elementary move involves a global change of the configuration \( \{ \sigma_\lambda \} \), this algorithm is \( N \) times slower than a usual MC algorithm with only local changes. We are able to simulate relatively large sizes in the range \( N = 500 - 2000 \) in a reasonable amount of computer time.

C. Finite-temperature dynamics

In case of finite temperature it is relatively easy to solve MC equations in the large-time limit. All the information on the dynamics is contained in the time evolution of the coefficients \( a(t), b(t), c(x, t) \) which monotonically converge to their equilibrium values. then we expect the dynamics converges to the Langevin dynamics in the large-time limit except by a rescaling of the time

\[
t \rightarrow t' = \frac{\rho^2 \beta \text{Erf}(\alpha_{eq})}{2} t
\]

At finite temperature and according to the magnitude of the parameter \( \rho \) we distinguish two different regimes depending if the acceptance rate is large or small. This two limits differ in the magnitude of the time scale above which Langevin behavior is recovered.

1. The case \( \rho < 1 \)

In this case \( \text{Erf}(\alpha) \sim O(1) \) since \( \alpha \) is small, i.e. the acceptance is always large.

Note that in the particular limit \( \rho \) tending to zero the Langevin dynamics is recovered with a rescaling of time
\[ t \rightarrow t' = \frac{\rho^2 \beta}{2} t \]  

(71)

In figure 1 we show the decay of the energy for different temperature for a given value of \( \rho = 0.1 \) by numerically solving the eq.(B3). The theoretical prediction is compared with real Monte Carlo simulation results for \( N = 500 \) spins. In the figure we also show the asymptotic large time-behavior in the Langevin case \( E(t) - E^{eq} \sim \frac{3}{8} t^{-1} \) (See [25]) with the rescaling of time eq.(70).

Results for the correlation function \( C_0(t_w, t_w + t) = K(0, t_w, t_w + t) \) are shown in figure 2 for different values of \( t_w = 1, 10, 100, 1000 \) at the temperature \( T = 0.4 \) with \( \rho = 0.1 \) obtained by numerically solving eq.(B4). Again we compare the solution with real MC simulations for \( N = 500 \) spins. In the figure we also show the asymptotic large-time behavior in the Langevin case \( C(t_w, t_w + t) \sim t^{-\frac{3}{4}} \) (See [25]).

Note that in the dynamical regime shown in figure 2 there is no evidence of plateau or \( \beta \)-relaxation process in the correlation function. This process is a signature of the existence of a short-time regime (FDT regime) where the system is locally in equilibrium and the fluctuation-dissipation theorem applies (i.e. the \( C_0(t_w, t_w + t) \simeq C_0(t) \)). The reason why the \( \beta \)-relaxation process is not seen in the figure 2 is that the values of \( t_w \) shown there are too small. In the Langevin dynamics this regime usually appears for large values of \( t_w \) which become much larger in the MC case since we have to rescale the time by the parameter eq.(70) (the constant we have to rescale the time in figures 2 is approximately 87, i.e. 87 MC steps correspond to one unit of time in the Langevin dynamics). In this regime \( \rho \ll 1 \), because \( Er f(\alpha) \) is finite, we expect the \( t_w \) necessary to observe the plateau to scale like \( \rho^{-2} \) times the needed time in the Langevin case which requires quite large values of \( t_w \) in the MC case. This off-equilibrium regime observed in the case \( \rho \ll 1 \) where the acceptance rate is large is very similar to that observed in models with a continuous breaking of the replica symmetry, like the SK model [4] or finite-dimensional spin-glasses [2,22] where no evidence of plateau is found in the region of values of \( t_w \) explored.
2. The case $\rho > 1$

In this case $Erf(\alpha) \sim \frac{e^{-\alpha^2}}{\alpha}$ since $\alpha$ is large, i.e. the acceptance is always very small. In this regime the rescaled time constant eq. (70) is again small because $Erf(\alpha)$ is small (it decreases with $\rho$ like $\rho e^{-\rho^2}$). For values of $t_w \ll \frac{\exp(\rho^2)}{\rho}$ the system is in the short-time regime where a plateau is present and aging is present (i.e. the $C_0(t_w, t_w + t)$ strongly depends on $t_w$). This is clearly appreciated in figure 3 where we show the $C_0(t_w, t_w + t)$ for different values of $t_w = 1, 10, 100, 1000$ at $T = 0.4$, $\rho = 5$ and the numerical solution of eq. (B4). In the regime $t_w \ll \frac{\exp(\rho^2)}{\rho}$ there is a plateau which increases with $t_w$ and eventually converges to the value $q_{EA} = 1 - T$ for times $t_w$ of order $\frac{\exp(\rho^2)}{\rho}$. This is transient regime where the decay to the plateau does not satisfy time-translational invariance. No equivalent regime is found in the Langevin dynamics of the spherical Sherrington-Kirkpatrick model.

The behavior shown in figure 3 is very similar to that found in systems with strong freezing in the low temperature regime where the acceptance rate is quite low. Generally these are systems with one step of replica symmetry breaking like the spherical or Ising $p$-spin model ($p > 2$) \cite{1,23}, the Potts Glass model with $p$-states ($p > 4$) \cite{30}, the ROM (random orthogonal model) \cite{31} and frustrated systems without quenched disorder like the Bernasconi model \cite{32} and other type of models \cite{33}. All these systems are characterized by the presence of a dynamics with very low acceptance rate and the existence of a dynamical transition different of the statical one. While the statics of the aforementioned class of models is much different to that of the spherical SK model the dynamics shows interesting similarities.

D. Zero-temperature dynamics

In this subsection we are interested in extracting the large-time behavior of the dynamical equations at zero temperature. There is no reason in the zero-temperature case to get the same large-time behavior as in the Langevin case, the time-rescaling eq. (70) being ill defined.
Because in the zero-temperature regime the acceptance rate goes monotonically to zero (i.e. the parameter $\alpha$ diverges) the coefficients $a(t), b(t), c(x, t)$ in eqs.(43),(53) have a non trivial large-time limit. Then we expect a dynamical regime much different from that predicted in the Langevin dynamics. In fact, we will see that there is no limiting case in which the Langevin dynamics is found.

At $T = 0$ the coefficients $a(t), b(t), c(x, t)$ of eqs.(43),(55) become

$$
a_{T=0}(t) = -\frac{2\alpha e^{-\alpha^2}}{E \sqrt{\pi}}
$$

$$
b_{T=0}(t) = -\left(\frac{\rho^2 E r f(\alpha)}{2} + \frac{4\alpha e^{-\alpha^2}}{\sqrt{\pi}}\right)
$$

$$
c_{T=0}(x, t) = \frac{1}{2}\rho^2 \ll e^{x\lambda} \gg E r f(\alpha)
$$

(72)

Also the equation (43) for the acceptance rate reads,

$$
A(t) = \frac{E r f(\alpha)}{2}
$$

(73)

Note that the large time dynamics is governed by the time-dependent parameter $\alpha$ which diverges in the infinite-time limit. Unfortunately the dependence of the coefficients on $\alpha$ is strongly non-linear, which makes the mathematical treatment of the dynamical equations highly non trivial. However we can derive a nonlinear equation for the energy alone by means of the adiabatic approximation explained in the next subsection. Although a rigorous derivation of the adiabatic approximation is not known to us, the resulting equation yields an excellent approximation to the large-time behavior as given by the numerical solutions of the exact dynamical equations.

We can analyze qualitatively how the system evolves at zero temperature. Suppose the system starts from a random initial configuration $\sigma_i = \pm 1$ such that $E(t = 0) = 0$ and $B_1(t = 0) = 1$. The energy monotonically decreases to the ground state energy $E = -\frac{J_{\text{max}}}{2} = -1$ while $B_1$ decreases also to zero. In the large time limit $\alpha$ diverges and the acceptance rate goes to zero. There are two different regimes in the dynamics. The first one is an initial regime where $\alpha$ is small and the acceptance rate is nearly $1/2$. This corresponds to a gaussian $P(\Delta E)$ (eq.(38)) with width $\rho \sqrt{B_1}$ larger than the position of its center ($\rho^2 E$). In this case, the changes of configuration which increase or decrease the energy have the
same probability. The energy decreases fast in this regime because the acceptance is large.

The second regime appears when $B_1$ is so small in order that $\alpha$ becomes large. In this case the acceptance is very small (it goes like $\frac{\exp(-\alpha^2)}{\alpha}$) and the dynamics is strongly slowed down. The system goes very slowly to the equilibrium. It is in this second regime where the adiabatic approximation developed in the next subsection applies.

The adiabatic approximation shows that the large-time behavior in the Monte Carlo case is quite different from the Langevin case. This is not a surprise. Even for the simple harmonic oscillator, one can show that at zero temperature the dynamics is different in the MC and in the Langevin case \cite{34}. This is related to the non-ergodic nature of the dynamics at zero-temperature in which only the changes which decrease the energy are accepted.

This is clearly shown in figures 4, 5, 6, 7. In figure 4 and 5 we show the acceptance rate and energy as a function of time for three different values of $\rho$ by numerically solving the off-equilibrium equations eq. (B3) with the coefficients (72).

We note two important results. First, as previously said, we observe that $\alpha$ is the parameter which governs the dynamics. More concretely figure 4 shows that the magnitude of $\alpha$ separates two different regimes. In the regime $\alpha \ll 1$ the acceptance rate is 0.5 while it falls down rapidly to zero in the regime $\alpha \gg 1$. Second, the large time behavior of the energy shown in figure 5 is strikingly different from that expected in the Langevin dynamics at zero temperature where $E(t) + 1 \simeq O(1/t)$ \cite{25}. The energy decays like $1/log(t)$ (plus corrections) as shown below.

Figure 6 shows the $C_0(t_w, t_w + t)$ as a function of $t$ for four different values of $t_w$ by numerically solving the off-equilibrium equations eq. (B4) with the coefficients (72). Note that the large $t$ behavior of the $C(t_w, t_w + t)$ is strikingly different in the MC and the Langevin case since no trace of the power law decay $t^{-\frac{3}{4}}$ is observed and the $\frac{1}{t_w}$ scaley behaviour is lost. The correlation function strongly freezes (i.e. remains very close to one) for values of $t_w$ such that the acceptance rate at that time has already jumped to zero (see figure 4). This is reasonable because a very low number of accepted changes implies a very small change of the correlation function.
E. The adiabatic approximation

We now discuss the adiabatic approximation which gives the correct asymptotic large time behavior of the energy and the acceptance rate at zero temperature.

The equation of the energy eq.(42) can be written as a function only of the parameter $\alpha$,

$$\frac{1}{E} \frac{\partial E}{\partial t} = -\frac{1}{2} \rho^2 E r f(\alpha) + \frac{\rho^2 e^{-\alpha^2}}{2\alpha \sqrt{\pi}} .$$

(74)

This is an exact equation for the energy. Unfortunately we cannot solve it because we do not know the time evolution of $\alpha$. Once $\alpha$ is known we also know the time evolution of the energy, hence also all the moments $h_k$. In this sense, the parameter $\alpha$, and consequently the acceptance rate, fully determine the dynamics. In the large-time regime, where $\alpha$ is very large, we can expand the error function $E r f(\alpha) \simeq \frac{e^{-\alpha^2}}{\sqrt{\pi} \alpha} (1 - \frac{1}{2\alpha^2})$ and we get the simple equation,

$$\frac{1}{E} \frac{\partial E}{\partial t} = \rho^2 e^{-\alpha^2}$$

(75)

We solve this equation using an adiabatic approximation which turns out to be the correct large-time solution as one can check numerically solving the equation (B3). We replace $\alpha$ by an effective parameter which depends on off-equilibrium quantities via a quasi-equilibrium relation. In our case we use the quasi-equilibrium relation eq.(68) with $\beta = \frac{1}{T} = \frac{1}{\mu^*(E+1)}$ where $\mu^*$ is a renormalized parameter which has the physical meaning of an effective temperature. Note that $\mu^* = 2$ in the previous equation yields the equilibrium relation $E = -1 + \frac{T}{2}$ in the low temperature phase. Substituting in (75) and using $B_1 = -2\mu^* E (E+1)$ we obtain, in the large-time limit (i.e. $E \simeq -1$) and neglecting higher orders in $E + 1$,

$$\frac{\partial E}{\partial t} = -\frac{2}{\rho \sqrt{\pi}} (\mu^*(E+1))^2 \exp\left(-\frac{\rho^2}{4\mu^*(E+1)}\right)$$

(76)

In principle, $\mu^*$ is an unknown parameter. In the simplest adiabatic approximation $\mu^* = 2$. This corresponds to equipartitioning in the surface of constant energy where the
equilibrium relation $B_1 = -4E(E+1)$ is fulfilled at all times. It is possible to show [34] that for $\mu^* = 2$ the equation (76) is the equation of the energy for a simple harmonic oscillator with Hamiltonian $\mathcal{H} = \frac{1}{2}m\omega^2 x^2$ where $m\omega^2 = \lambda^{\text{max}} = 2$. Physically this means that the system relaxes as a simple harmonic oscillator with a value of $m\omega^2$ determined by the maximum eigenvalue of the spectrum. Physically a value of $\mu^* < 2$ means that the system relaxes as an effective single harmonic oscillator with effective mass $m\omega^2 = \frac{4}{\mu^*}$ larger than the single oscillator mass $m\omega^2 = 2$ [34].

The large-time solution of eq.(76) can be easily worked out. One finds that the parameter $\alpha$ diverges like $(\log(t))^{\frac{1}{2}}$, the energy decays like $E(t) = -1 + O\left(\frac{1}{\log(t)}\right)$ and the acceptation rate goes like $A(t) \sim \frac{1}{t}$. All these quantities have non-trivial subdominant corrections. In figure 7 we show the effective parameter $\mu^* = -\frac{B_1}{2E(E+1)}$ as a function of time obtained by solving eq.(133) for different values of $\rho$. Note that the effective parameter $\mu^*$ converges to a time-independent value in the asymptotic large time limit. By numerically solving the adiabatic equation (76) we have checked that the relaxation of the energy is in excellent agreement with the numerical solution of eq.(133). This is a check of the adiabatic approximation which yields the values $\mu^* \simeq 0.087, 0.72, 1.65$ for $\rho = 0.1, 1, 5$ respectively. Note that these quoted values of $\mu^*$ are smaller than 2.

V. CONCLUSIONS

In this work we have presented the analytical solution of the Monte Carlo dynamics of the spherical Sherrington-Kirkpatrick model. This is a very simple spin-glass model where full computations can be carried out. In order to analytically solve the MC dynamics we have used the technique of the generating function. The generating function allows us to close the dynamical equations in a similar way to how it has been done in other glassy models without quenched disorder. The present work is a step towards the use of this powerful technique in the spin glass context. As an example, we have solved the Langevin dynamics of the spherical SK model. In the context of the MC dynamics, the generating function has
been used to derive closed expressions for one-time quantities, like the generalized moments $h_k$, and for two-time quantities such as the correlation or response functions. The formalism of the generating function may be used to compare the results obtained with both dynamics, MC and Langevin.

By solving such a simple model, we lose the subtleties of having a replica broken low-temperature phase where the presence of a large number of metastable states makes dynamics much more interesting \[35\]. Nevertheless our results for the MC dynamics make it clear how relevant for off-equilibrium dynamics is the acceptance rate, a quantity which is absent in Glauber or Langevin dynamics. Since a major part of the numerical work on glassy systems employs MC dynamics, its analytical study is of the outmost importance to be used as a guide when trying to extract conclusions from numerics.

One of the most important results which emerge from this work concerns the importance of the acceptance rate in the off-equilibrium dynamics. We have seen that the main differences between the Langevin and the MC dynamics appear whenever this rate is small and for times not too large. The Langevin dynamics is obtained in the limit $\rho \to 0$ with an effective rescaling of time $t \to t' = t \rho^2 / \beta$ and the acceptance ratio is always 1 (cf. equations (43) and (55)). For finite $\rho$ and finite temperatures we have seen that the Langevin regime is found for times $t \simeq \rho^{-2}$ when $\rho$ is small and for times $t \simeq \exp(\rho^2) / \rho$ when $\rho$ is large. In the intermediate regimes very many different behaviors are observed, specially for $\rho > 1$ where the acceptance is small. The dynamics observed in figure 3 reminds one a lot of what is observed in models with one step of breaking (see for instance \[36,37\]). Furthermore, at zero temperature, the MC dynamics yields a completely new behavior where the system rapidly freezes as soon as the acceptance goes to zero. No analogous regime is found in the case of Langevin dynamics where the transition from finite to zero temperature is smooth.

We would like to comment three different directions which we think it would be interesting to explore. The first concerns the adiabatic approximation which is used to obtain closed equations for one-time moments. As it has been shown, this approximation suggests that the system behaves as a system of uncoupled harmonic oscillators with a renormalized
mass larger than the maximum mass corresponding to the largest eigenvalue of the Wigner spectrum. Although this suggestive approximation works extremely well, it would be interesting to understand it better. Future research should deal with a systematic derivation of the adiabatic approximation for one-time quantities (for instance, understanding the dependence of the effective parameter $\mu^*$ as a function of $\rho$), and its extension to the study of the long-time behavior of correlation functions. We think that the adiabatic approximation is a consequence of the relevance of entropic effects for the dynamics of the system. In the low acceptance regime, the system spends a long time searching configurations of lower energy in a very inefficient way. In this regime (not present when the dynamics is Langevin’s) the adiabatic approximation works very well. More generally one would like to improve it in order to find a systematic way to close the dynamical equations without having to use the full generating function. The work done by Coolen, Sherrington and collaborators [18] and that on the Backgammon model [38] is a step in this direction. The second direction to explore is the study of models with one step of replica symmetry breaking (like the $p$-spin spherical spin-glass model [9]) using the technique of the generating function. This is an interesting problem whose solution would allow us to obtain closed equations for one-time quantities like the energy and probably a set of higher moments. At present it is not clear whether this is possible or whether we can only obtain equations which relate the correlation and the response function [9,10]. Finally we want to mention that the type of differential equations studied here, (i.e. semilinear evolution equations like Eq. (54) whose coefficients depend self-consistently on the first moments of the solution), appear often in the study of the dynamics of quite different models in statistical physics. Let us cite among others the problems of synchronization of populations of coupled oscillators [9], arrays of Josephson junctions [10], and plasmas or self-gravitating systems [11,12]. Often these problems can be described by non-linear causal equations where the time evolution of an observable at time $t$ depends on all its previous history plus self-consistent relations for functions appearing in the equations. A general mathematical study of these types of equations would be welcome.
VI. ACKNOWLEDGMENTS

The work of L.L.B., F.G.P and F.R. has been supported by the DGICYT of Spain under grant PB92-0248 and the EC Human Capital and Mobility Programme contract ER-BCHRXCT930413. We are grateful to Silvio Franz for a careful reading of the manuscript, and to Conrado Perez-Vicente and Alex Arenas for stimulating discussions on this and related subjects.

APPENDIX A: THE EQUATION OF MOTION

In this section we write the general equation of motion associated to the general joint probability distribution

\[ P(\Delta E, \Delta O) = K \exp\left(-\frac{(\Delta E - a)^2}{2b^2}\right) \exp\left(-\frac{(\Delta O - c)^2}{2d^2}\right) \]  \hspace{1cm} (A1)

where \( c = e + f(\Delta E - a) \) and \( a, b, c, d, e, f \) are in general time-dependent parameters, \( \Delta E \) stands for the energy change and \( \Delta O \) the change of any observable (generalized moment, correlation or response function). In the MC dynamics \( a = -\rho^2 E, \ b^2 = \rho^2 B_1 \) (with \( B_1 \) given in eq.(39)) and \( c, d, e, f \) depending on the particular observable. The constant \( K = (4\pi b^2 d^2)^{-\frac{1}{2}} \) normalizes the probability distribution.

The equation of motion for the observable \( O \) is,

\[ \frac{\partial O}{\partial t} = \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy y P(x, y) w(x) \]  \hspace{1cm} (A2)

where \( w(x) = \text{Min}(1, e^{-\beta x}) \) is the Boltzmann factor. Straightforward computations yield

\[ \frac{\partial O}{\partial t} = \frac{1}{2} \left( e \text{Erf}(\alpha) + (e - f \beta b^2) \exp(-a\beta + \frac{b^2 \beta^2}{2}) \text{Erf}(\sqrt{\frac{b^2 \beta^2}{2} - \alpha}) \right) \]  \hspace{1cm} (A3)

where \( \alpha = -\frac{a}{(2\beta b)^2} \) and coincides with eq.(44) with the previously quoted values of \( a, b \).

At zero temperature the equation of motion is,

\[ \frac{\partial O}{\partial t} = \frac{1}{2} \left( e \text{Erf}(\alpha) - f \sqrt{\frac{2b^2}{\pi}} \exp(-\alpha^2) \right) \]  \hspace{1cm} (A4)

with the same previous definition of the parameter \( \alpha \).
In this section we present the general solution to the generating function \( g(x, t) \) in eq. (54) using the method of characteristics,

\[
\frac{\partial g(x, t)}{\partial t} = a(t) \frac{\partial g}{\partial x} + b(t)g + c(x, t) \tag{B1}
\]

In order to solve this equation we make the following change of variables \( x \to u(t) = x + \int_0^t a(t')dt' \) and eq. (B1) becomes

\[
\frac{d\hat{g}(u, t)}{dt} = b(t)\hat{g}(u, t) + c(u, t) \tag{B2}
\]

which is a linear differential equation easily solvable. The final result is,

\[
g(x, t) = g_0(x + \int_0^t a(t')dt')B(t) + B(t) \int_0^t dt' c(x + \int_0^{t'} a(t'')dt'', t') \tag{B3}
\]

where \( B(t) = \exp(\int_0^t b(t')dt') \) and \( g_0(x) = g(x, t = 0) \) is the initial condition. Once the \( g(x, t) \) has been obtained one can also get the generating function of the two time quantities. For instance the \( K(x, t', t) \) associated to the correlation function in eq. (60) is given by,

\[
K(x, t', t) = g(x + \frac{1}{2} \int_{t'}^{t} a(t'')dt'', t') B(t) \frac{B(t)}{B(t')}^{\frac{1}{2}} \tag{B4}
\]
