Serial Amnioinfusion as Regenerative Therapy for Pulmonary Hypoplasia in Fetuses With Intrauterine Renal Failure or Severe Renal Anomalies: Systematic Review and Future Perspectives

Simrit K. Warring, MD, MS; Victoria Novoa, MD; Sherif Shazly, MB, BCh, MS; Mari Charisse Trinidad, MD; David J. Sas, DO; Brenda Schiltz, MD; Mikel Prieto, MD; Andre Terzic, MD, PhD; and Rodrigo Ruano, MD, PhD

Abstract

The aim of this study was to investigate the effect of serial amnioinfusion therapy (SAT) for pulmonary hypoplasia in lower urinary tract obstruction (LUTO) or congenital renal anomalies (CRAs), introduce patient selection criteria, and present a case of SAT in bilateral renal agenesis. We conducted a search of the MEDLINE, EMBASE, Web of Science, and Scopus databases for articles published from database inception to November 10, 2017. Eight studies with 17 patients (7 LUTO, 8 CRA, and 2 LUTO + CRA) were included in the study. The median age of the mothers was 31 years (N = 9; interquartile range [IQR], 29-33.5 years), the number of amnioinfusions was 7 (N = 17; IQR, 4.5-21), gestational age at first amnioinfusion was 23 weeks and 4 days (N = 17; IQR, 21-24.07), gestational age at delivery was 32 weeks and 2 days (N = 17; IQR, 30 weeks to 35 weeks and 6.5 days), birthweight of newborns was 3.7 kg (N = 9; IQR, 2.7-3.7 kg), Apgar score at 1 minute was 2.5 (N = 8; IQR, 1-6.5), and Apgar score at 5 minutes was 5.5 (N = 8; IQR, 0-7.75). In conclusion, SAT may provide fetal pulmonary palliation by reducing the risk of newborn pulmonary compromise secondary to oligohydramnios. Multidisciplinary research efforts are required to further inform treatment and counseling guidelines. We propose a multidisciplinary approach to prenatal classification of fetuses with LUTO to inform patient selection.

LUTO consists of a heterogeneous group of pathologies, which most commonly includes posterior urethral valves, and has an incidence of 1 in 10,000.4-7 Vesicoamniotic shunting and fetal cystoscopy are current fetal interventions available in LUTO.6,8-11 Functional renal impairment occurs in over 70% of LUTO. In 1986, even in cases of LUTO following vesicoamniotic shunting, the most common cause of death was pulmonary hypoplasia. Physicians during this time noted that with such disappointing results, therapeutic amnioinfusion should be considered in cases of LUTO with severe renal impairment.12-16

Congenital renal anomalies include a variety of pathologies and severities, including bilateral renal agenesis (BRA), dysplastic kidneys, or severe polycystic disease. BRA is rare, with an incidence of 1 in 3000 pregnancies.2 Typically, termination of pregnancy is recommended given the expected mortality resulting from severe oligohydramnios and fetal pulmonary hypoplasia.17

Without therapeutic amnioinfusion, a diagnosis of LUTO or CRA may be incompatible with newborn survival. The objective of this study was to utilize the available literature to investigate the effect of SAT as a method of temporarily correcting oligohydramnios associated with LUTO and CRA, and thereby reducing mortality secondary to pulmonary hypoplasia. We report neonatal survival outcomes that may inform future direction in research and the clinical application of SAT, as well as highlight the need for a prospective clinical trial. We propose a classification system stratified by disease severity in fetuses with LUTO that can be used for SAT patient selection and present an introductory case report of SAT for fetal BRA.

REPORT OF A CASE
A 26-year-old woman, gravida 1, para 0, with a pregnancy complicated by fetal BRA was admitted to the antepartum service at our institution for preterm premature rupture of membranes (PPROM) at a GA of 30 weeks and 6 days in the setting of anhydramnios. Before presenting to our institution, the patient had SAT initiated at 27 weeks’ GA at an outside institution to palliate pulmonary hypoplasia. All amnioinfusion procedures took place with ultrasound under color flow Doppler, sterile procedure technique, 1% lidocaine without epinephrine analgesic, 22-gauge 5-inch spinal needle, and warm saline. At the first amnioinfusion at 27 weeks and 5 days’ GA, the patient’s body mass index (calculated as weight in kilograms divided by height in meters squared) was 26.95 kg/m², and her only current medication was prenatal vitamins. The results of chorionic villus sampling were normal, with a male chromosome detected. After infusion of 550 mL, the postprocedure AF index (AFI) was 15.9 cm and the maximal vertical pocket (MVP) was 6.0 cm. No complications occurred, and 3 mL of fluid was withdrawn for Gram stain and culture, which produced negative results. At the second amnioinfusion at 29 weeks and 4 days’ GA with a 600-mL infusion, the postprocedure AFI was 13.1 cm, MVP was 6.4 cm, and there were no complications. At the third amnioinfusion at 30 weeks and 3 days’ GA with a 650-mL infusion, the postprocedure AFI was 18.1 cm, MVP was 5.0 cm, and fetal heart rate deceleration to 58 beats/min was detected, which resolved postprocedure to 158 beats/min. The fourth amnioinfusion at 30 weeks and 6 days consisted of 700 mL warm saline and 5 mL indigo carmine infusion, and 5 mL of AF was aspirated for Gram stain and culture. The postprocedure AFI was 17.7

ARTICLE HIGHLIGHTS

- Severe oligohydramnios secondary to fetal renal anomalies and lower urinary tract obstruction leads to poor neonatal outcomes.
- Available evidence suggests that fetal serial amnioinfusion is a regenerative therapy that may provide pulmonary palliation and reduce the risk of newborn mortality from pulmonary compromise.
- Multidisciplinary prenatal counseling and management is necessary prior to offering this fetal intervention as substantial resources are involved in serial amnioinfusion therapy with the newborn ultimately relying on peritoneal dialysis and requiring renal transplant in the future.
- Given the lack of strong evidence supporting this fetal intervention, a clinical trial would be necessary to further assess the long term outcomes of this intervention.
cm, MVP was 5.4 cm, and there were no complications. Approximately 71/2 hours after the fourth amnioinfusion, the patient presented to the outside institution with PPROM. The patient felt a gush of fluid with blue dye noted. At the time of presentation, ultrasonography revealed an AFI of 0.7 cm and MVP of 0.7 cm, classifying her as having severe oligohydramnios. The placenta was noted to be anterior, and the cervix was 3.1 cm in length and closed. During the hospitalization, the patient received epidural anesthesia before delivery, started with dinoprostone. Labor augmentation included misoprostol and oxytocin. The patient felt a gush of amniotic fluid with blue dye noted.

The patient was diagnosed as having gestational hypertension at 32 weeks and 4 days’ GA, and she remained asymptomatic. At 34 weeks and 6 days’ GA, the patient was admitted to the labor and delivery service for induction of labor in the setting of PPROM. Induction was started with dinoprostone. Labor augmentation included misoprostol and oxytocin. The patient received epidural anesthesia before delivery, and the labor progressed without complications. The patient had a normal spontaneous vaginal delivery of a liveborn male at 35 weeks’ GA. The estimated blood loss was 350 mL, and the placenta was delivered intact with a histologically normal 3-vessel umbilical cord. The mother remained normotensive and had an uncomplicated postpartum course.

The newborn male was intubated at birth and given surfactant because of signs of hypotonia and lack of adequate respiratory effort. Apgar scores at 1, 5, and 10 minutes were 2, 6, and 8. Initial chest radiography revealed right pneumothorax, but the team opted not to intervene because of reassuring oxygen status. The family was aware of the serious concerns for pulmonary hypoplasia and requested a chaplain at the bedside. The team briefly paused cares to allow for baptism by the chaplain per the mother’s request.

After transfer to the neonatal intensive care unit, the patient was extubated at 5 hours of life to low-flow nasal cannula at 50 mL/min. The neonatal intensive care unit team continued as the primary service for the child with consultation from multiple specialties during the hospital stay including pediatric surgery, pediatric nephrology, infectious diseases, respiratory therapy, pediatric palliative care team, and ethicists. Weight on day of life (DOL) 1 had increased by 20 g from newborn weight, and the infant became critically ill, requiring vasopressor support for hypotension. Blood cultures obtained returned negative. On DOL 2, he was taken to the operating room for placement of a peritoneal dialysis (PD) catheter and G (gastrostomy) tube, as well as repair of an incidentally found inguinal hernia. The operation was complicated by an accidental colotomy with minimal meconium spillage that was repaired.

Enteral feeding was initiated on DOL 3 with breast milk via the G tube. The absence of renal tissue was confirmed with Doppler ultrasonography and no bladder was visualized (Figure 1). On DOL 4, electrolyte abnormalities were detected, and PD was initiated. Initially, the infant was unable to tolerate PD because of catheter leakage. A purse-string suture was surgically placed, but because the infant had tolerable laboratory findings, he did not undergo PD for several days. Peritoneal dialysis was then reinitiated on DOL 10 at minimal volumes. The infant required vasopressor support during dialysis. Unfortunately, he continued to struggle during his hospitalization with leakage from the PD catheter site, and bacterial peritonitis developed. The final culture growth included Klebsiella, and placement of his
hemodialysis catheter was delayed during antibiotic treatment. Specimens from his central venous line grew coagulase-negative cocci. After culture results were negative for 24 hours, the team proceeded with hemodialysis catheter placement.

On DOL 43, multiple procedures were performed related to catheter and central line placement, laryngoscopy, and bronchoscopy. Continuous renal replacement therapy was initiated. The patient had periods of hemodynamic instability that required frequent replacement of electrolytes, multiple units of blood products, and vasopressors. He advanced to feeding goals via the G tube though remained intubated and sedated until DOL 55.

Continuous renal replacement therapy was continued until DOL 68, when it was switched to PD. The infant underwent low-volume PD that had to be titrated because of catheter leakage. Complications that ensued during the remainder of his hospital stay included infiltration of the peripherally inserted central catheter line used for dialysis resulting in right brachial plexus injury. The patient then exhibited symptoms of increased tone on the left side and decreased tone of the right arm prompting magnetic resonance imaging that revealed multiple small cerebellar infarcts and a deep venous thrombosis in his right arm. The patient continued to have labile blood pressure and had a bradycardic arrest requiring resuscitation at 3 months and 28 days of age, which was thought to be due to excessive vagal responses to light stimulation during nursing cares. The patient had tracheostomy placement at 6 months of age, and a completely thrombosed inferior vena cava was noted below the liver with only collateral supply to the lower limbs, for which he underwent recanalization with interventional radiology. At 7 months of age, he weighed 5.1 kg, which placed him at less than 1 percentile (z score, −4.34) based on the World Health Organization (WHO) weight for age data on males 0 to 2 years old. His length was 49 cm, which placed him at less than 1 percentile (z score, −9.29) based on WHO length for weight data on males 0 to 2 years old. His head circumference was 38.8 cm, which placed him at less than 1 percentile (z score, −8.10) based on WHO head circumference for age data. During his seventh month of age, he had had multiple periods of hemodynamic instability and required multiple units of blood products for blood dyscrasias. He was receiving vasopressors on and off for several days and experienced bradycardic arrests with several resuscitations. Given that the infant’s long-term goal was renal transplant, the family agreed to proceed with palliative care since transplant was no longer an option due to poor growth. Brain magnetic resonance imaging revealed global cerebral loss and encephalomalacia resulting in laminar necrosis in the left parieto-occipital region (Figure 2). Electroencephalography revealed no brain wave activity. A brain death examination by the pediatric neurology service revealed no brain stem function or any higher cortical function. A cerebral blood flow study detected no flow through his cerebral vessels. The infant was pronounced dead at 7 months, 2 weeks, and 4 days of age after withdrawal of ventilatory and medication support.

LITERATURE REVIEW

Literature Search
A search was conducted in collaboration with an expert librarian for studies with SAT indicated for fetal LUTO or CRA. Inclusion required clear data on the SAT procedure, features of each patient who underwent SAT, and outcomes of each fetus diagnosed with LUTO or CRA. A search on MEDLINE, EMBASE, Web of Science, and Scopus was completed.
for articles published since the date of database inception to November 10, 2017. Key search terms included serial amnioinfusion therapy and lower urinary tract obstruction or renal anomalies or renal agenesis. Language was a criterion for exclusion. Only articles in English or that could be translated to English in text were used. The detailed search strategy is provided in the Supplemental Appendix, available online at http://www.mcpiqojournal.org.

Eligibility Criteria and Study Selection

The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines created by the National Institutes of Health were utilized throughout the review process (Figure 3). After the identification phase, duplicate removal was performed. Two reviewers screened all abstracts for relevant studies and assessed full-text articles for eligibility before inclusion. Studies reporting on SAT for LUTO or CRA with clear procedure details and fetal outcomes were included in the review. Studies in which individual patient data could not be extracted from a larger heterogeneous cohort of procedures done for other indications, such as PPROM or diagnostics, were not included. Two reviewers screened articles based on title and abstract relevance.

Data Abstraction

A standardized form was used for data abstraction that included authors, year of publication, country of origin, type of study, fetal indication for amnioinfusion therapy, maternal age, number of amnioinfusion procedures, GA at time of amnioinfusion in weeks, procedure technique, GA at delivery in weeks, method of delivery, complications during pregnancy or delivery, infant sex, newborn respiratory status, birth weight, Apgar scores at 1 and 5 minutes, newborn complications, and postnatal survival including status of dialysis or renal transplant. The main text, abstract, tables, and figures were used for data extraction. Prognostic variables and outcomes were reported in a descriptive manner for each study. Authors made descriptive conclusions, and no statistical analyses were conducted.

Because the studies consisted mostly of case reports and observational studies, there was considerable study-to-study heterogeneity that could not to be assessed due to large variability in the details reported for each patient. Pooled analysis was not feasible because of the heterogeneity, and all studies presented descriptive conclusions rather than quantitative conclusions with statistical analyses.

Data Analysis

A descriptive statistical analysis was completed using data amalgamation. Risk of bias in individual or across studies was not assessed. The descriptive analysis of important features including maternal age, number of amnioinfusions, GA at first amnioinfusion, GA at delivery, birth weight, and Apgar scores at 1 and 5 minutes using sample size, median, interquartile range (IQR), and range are presented in Table 1. The number of LUTO cases, cesarean sections, male infants, intubation in first 24 hours of life, 1-week survival, 1-month survival that did not require intubation at birth, 1-month survival, PD, renal transplant, and lost to follow-up after successful PD at discharge are reported in Table 2 using numbers and percentages.

RESULTS

A total of 892 records were identified through the database search. There were 502 articles remaining after duplicate removal, and 44
articles remained after title and abstract screening. Articles were assessed in full text and eligibility criteria by 2 individuals. A total of 36 articles were excluded based on set criteria after full-text article assessment. Study publication dates ranged between 1991 and 2016. Eventually, 8 studies with data on 17 patients who underwent SAT for LUTO, CRA, or both were eligible.1,2,18-23 Eleven patients were from the United States, 3 were from Taiwan, and 1 each were from Canada, Germany, and the United Kingdom.

Among the 17 eligible studies, there were 7 cases diagnosed with LUTO, 8 with CRA, and 2 with LUTO + CRA. All of the studies provided information about the fetal diagnosis, number of amnioinfusions, procedure technique (serial percutaneous infusions vs transabdominal amnioport), GA at delivery, and postnatal survival. The studies differed
with respect to the degree of detail that was reported. There was variable reporting of maternal age, mode of delivery, neonatal birth weight, Apgar scores at 1 and 5 minutes, infant sex, pulmonary status at birth, and length of postnatal follow-up. The details reported for each patient are available in Table 3 and Table 4.

Descriptive analysis using sample size, median, IQR, and ranges of important features are available in Table 1. The median age of women who underwent SAT and had a fetal diagnosis of LUTO and/or CRA was 31 years (N=9; IQR, 29-33.5 years). The median number of amnioinfusions was 7 (N=17; IQR, 4.5-21). The median GA at first amnioinfusion was 23 weeks and 4 days (N=17; IQR, 21-24.07). The median GA of patients at delivery was 32 weeks and 2 days (N=17; IQR, 30 weeks to 35 weeks and 6.5 days). All of the patients who underwent SAT had preterm deliveries. The median birth weight of newborns was 3.7 kg (N= 9; IQR, 2.7-3.7 kg). The median Apgar score at 1 minute was 2.5 (N=8; IQR, 1-6.5). The median Apgar score at 5 minutes was 5.5 (N=8; IQR, 0-7.75).

The number of LUTO cases, cesarean deliveries, male infants, intubations in the first 24 hours of life, 1-week survivals, 1-month survivals, peritoneal dialyses, renal transplants, patients lost to follow-up after successful PD before discharge, and patients who did not require intubation at time of birth with 1-month postnatal survival are reported in Table 2 using sample size and numbers and percentages. There were 9 of 17 LUTO cases, 4 of 7 cesarean deliveries, 11 of 12 male infants, 6 of 11 intubations within the first 24

DISCUSSION
To our knowledge, this is the first systematic review on SAT for fetuses with intrauterine renal failure or severe renal anomalies. This study comprehensively reviewed the evidence of SAT outcomes in cases of LUTO and CRA. The current literature includes descriptive data and inconsistently reported on SAT technique, prenatal features, and postnatal outcomes. The amalgamation of outcomes indicates that SAT in cases of oligohydramnios diagnosed at early gestation secondary to fetal LUTO or CRA can mitigate the risk of pulmonary compromise in newborns.

After the inception of amnioinfusion, diagnostic amnioinfusion became widely accepted to improve fetal ultrasound visibility in the setting of oligohydramnios. The adequate visualization rate improved from 51% to 77% after diagnostic amnioinfusion was used in unexplained second-trimester oligohydramnios.24 Amnioinfusion as a therapeutic intervention was first described as active intrapartum management of pregnancies complicated by low AFV in 1983 by Miyazaki and Taylor.25 Intrapartum amnioinfusion led to suppression of variable decelerations during labor and improved newborn outcomes. SAT can also prevent pulmonary hypoplasia in patients with severe oligohydramnios attributable to PPROM.2,26-28 More recently, in animal models and humans with obstructive uropathy, fetal LUTO decompression and restoration of AFV by amnioinfusion has been reported to decrease the degree of pulmonary hypoplasia and renal dysplasia in newborns.7,29,30 Cases of fetal LUTO and CRA managed with SAT are rare, and therefore, minimal literature and research are available to thoroughly describe its effectiveness in improving fetal outcomes.

The studies reviewed for the purposes of this systematic review were conducted globally, including in the United States, Taiwan, Germany, United Kingdom, and Canada. Given the observational nature of these studies and inconsistent reporting on data features, a comparative and quantitative statistical analysis was not feasible. Of the 17 total patients who underwent SAT, there were 9 cases of newborns who successfully started PD (3 with renal agenesis, 4 with LUTO, 2 with LUTO with reported renal agenesis). Of these 9 patients who underwent PD, 1 renal agenesis and 3 LUTO cases had successful renal transplant between the ages of 19 months and 3 years from a related donor without rejection. All 4 of these successful renal transplant cases took place in the United States after 2014. These cases may reflect medical practice advances specific to the region and time the studies were conducted, which likely contributed to the successful outcomes. A limitation of this study was the lack of consistent patient selection criteria that hindered our ability to perform a statistical outcomes analysis given the widely varying severities of disease. The philosophy and criteria guiding which patients were selected for SAT were not fully described in the studies, and therefore, we could not account for selection bias or potential confounding factors when reviewing survival outcomes.

Evidence suggests that SAT provides clinically important pulmonary palliation and reduces the severity of pulmonary hypoplasia at birth in cases of oligohydramnios. When discussed with patients, SAT should be presented as one therapeutic option on a continuum of management choices for fetuses with LUTO or CRA.2 Selection criteria are imperative to direct how we counsel patients with varying degrees of abnormal fetal renal imaging, urinalyses, or oligohydramnios or in cases of other failed fetal interventions. Our team consisting of specialists from maternal and fetal medicine, neonatology, pediatric nephrology, pediatric surgery, and transplant surgery suggests the use of a classification system (Table 5) that defines patient groups by fetal renal disease severity. This multidisciplinary classification system, which is a modified version of the proposed classification of fetal LUTO according to severity by Ruano et al15 in 2016, is useful when considering which patients would be appropriate for SAT. Fetal urinary biochemistry after 18
weeks’ GA and ultrasound characteristics of fetal kidneys can be used to best estimate the fetal renal function. The primary imaging modality for prenatal diagnosis of the fetal urogenital tract is fetal ultrasonography. Additionally, magnetic resonance imaging can provide further information in the case of inconclusive findings by ultrasonography. Based on our observations, the postnatal outcomes of a fetal intervention are dependent on the severity of renal disease present prior to the intervention and can be categorized into 1 of 4 groups as described in Table 5.

Further clinical trials to evaluate feasibility, safety, and efficacy of SAT in mothers with fetuses diagnosed as having severe LUTO (stage III and IV) and CRA need to be completed in order to better determine the advantages and risks of SAT. Optimal procedure protocol, possible prognostic factors, and detailed quality-of-life outcomes should be published before SAT can be adopted as routine practice. To further evaluate SAT in fetuses with BRA, a multicenter study is under way at Mayo Clinic in Rochester, Minnesota, Stanford University in Pal Alto, California and Johns Hopkins Hospital in Baltimore, Maryland, supported by the North American Fetal Therapy Network (ClinicalTrials.gov Identifiers: NCT03101891). The study was designed after an extensive multidisciplinary national ethics conference, and the main goals are to assess the safety, feasibility, and efficacy of SAT to treat BRA diagnosed before 26 weeks’ GA.

Our data did not support a correlation between starting SAT at earlier GA and improved postnatal outcomes, likely because the earlier the onset of severe oligohydramnios, the greater the severity of renal disease and thus worse outcomes. Lung development occurs between 17 and 23 weeks’ GA, yet whether SAT should begin immediately after the diagnosis and cease after the canalicular phase of lung development ends has not been determined. There have been hypotheses reported in the past, such as Fisk et al suggesting 17 to 23 weeks as the appropriate GA, as supported by animal models. Fisk et al have also suggested that an increase in amniotic pressure may implicate complications such as PPROM and thus advocate for pressure monitoring during amnioinfusion. In 2005, Stefos et al noted that in hopes of necessitating fewer percutaneous procedures, physicians tend to overdistend the amnion with each therapy. Although there have been successful reports of AFV restoration with

### Table 5. Proposed Classification for Fetal Renal Disease in Lower Urinary Tract Obstruction According to Severity

| Variable                      | Stage I                                      | Stage II                                      | Stage III                                     | Stage IV                                      |
|-------------------------------|----------------------------------------------|-----------------------------------------------|-----------------------------------------------|-----------------------------------------------|
| Description                   | Mild lower urinary tract obstruction         | Severe lower urinary tract obstruction, with prenatal findings suggestive of preserved fetal renal function | Severe lower urinary tract obstruction, with prenatal findings suggestive of fetal abnormal renal function | Lower urinary tract obstruction with intrauterine fetal renal failure |
| Amount of amniotic fluid      | Normal                                       | Oligohydramnios or anhydramnios               | Oligohydramnios, but usually anhydramnios     | Anhydramnios                                  |
| Echogenicity of fetal kidneys | Normal                                       | Hyperechogenic                                | Hyperechogenic                                 | Hyperechogenic or absent                       |
| Renal cortical cysts          | Absent                                       | Absent                                        | Can be present                                 | Can be present                                 |
| Renal dysplasia               | Absent                                       | Absent                                        | Can be present                                 | Can be present                                 |
| Fetal urinary biochemistry    | Favorable within 3 consecutive evaluations    | Not favorable after 3 consecutive evaluations | Not favorable after 3 consecutive evaluations | Not favorable after 3 consecutive evaluations |
| Fetal intervention            | Not indicated                                | Indicated to prevent pulmonary hypoplasia and severe renal impairment | May be indicated to prevent pulmonary hypoplasia but not postnatal renal impairment; further studies are necessary | May be indicated to prevent pulmonary hypoplasia but not postnatal renal impairment; further studies are necessary |

Data from references 13 through 15.
serial percutaneous infusion, Hsu et al described an amnioport technique, similar to the Tchirikov modification published in 2010, that decreased the risk of PPROM overall. With an amnioport placement, the amnion is not punctured with each subsequent amnioinfusion procedure. This technique provides a more gradual increase in volume that could allow pregnancy to reach later GA and decrease PPROM risk. Hsu et al also determined that patients who cannot preserve AFV after the first amnioinfusion are not suitable for SAT. In 2000, Freedman et al reported that creatinine may be used as an appropriate marker of renal injury and possibly serve as a strong prognostic indicator. Fetuses with a creatinine nadir more than 1.0 mg/dL progressed to end-stage renal failure, while 75% of a creatinine level of less than 0.8 mg/dL maintained normal renal function for 54 months. Research efforts toward development of urinary markers to assist in proper selection of fetuses with salvageable renal function must be pursued.

SAT is generally accepted as a fetal intervention to improve short-term outcomes by palliating the most common cause of death in severe oligohydramnios, pulmonary compromise. However, before offering this short-term success of decreased pulmonary hypoplasia risk, it is necessary to assess the long-term outcomes in cases with complicated renal profiles so that informed counseling is possible. Beneficence should always remain a guiding principle for physicians. Even though scientific advancement requires stepping into experimental territory and pushing the envelope of current available therapies, it should never be done without thorough, evidence-based, informed counseling and research to support it. Even with the best of intentions, medicine remains imperfect, and newly designed therapies can harm patients. Patients may not fully understand the implications of caring for children with renal failure requiring PD and renal transplant, and this is especially difficult to fully grasp if evidence on long-term outcomes is unavailable.

Before the advent of SAT, there was no obligation to begin or continue a fetal intervention because the diagnosis of many cases of LUTO and CRA were incompatible with life. In other words, nontreatment did not pose an ethical dilemma. More recently, given the improved pulmonary outcomes in newborns of mothers who undergo SAT published in the literature and presented in the media, fetuses with LUTO or CRA and poor renal profiles have begun to be viewed similarly to newborns in whom terminal renal failure develops within the first few weeks of life. Some argue for the rights of an unborn child who will need lifelong management, such as renal transplant immunosuppression and high medical costs, as implicated by the choices of their parents to pursue SAT. Additionally, the US Food and Drug Administration approval for SAT is lacking, and there are risks associated with placement of a foreign body in a woman's abdomen with this technique. Extensive counseling by multidisciplinary teams should be required by institutions that choose to offer SAT. These teams should consist, at minimum, of specialists in maternal and fetal medicine, neonatal intensive care medicine, pediatric nephrology, transplant surgery, pediatric surgery, palliative care, social work, and ethical oversight.

The amnioinfusion procedure itself is associated with complications such as chorioamnionitis, placental abruption, and a predisposition to preterm delivery for the mother. Dialysis is notably challenging in newborns and therefore typically is only offered as a bridge to renal transplant. A number of investigators have reported success with long-term PD, although there are substantial hurdles including growth failure, developmental delay, and infections that complicate survival to renal transplant and offer a low quality of life for what may be the only few years of the infant's life. Other complications of PD can include poor drainage, leakage, or perforation of intra-abdominal organs. Case series have estimated short-term survival on PD for 1 to 5 years ranging from 52% to 89%. In a Canadian cohort of infants with renal replacement therapy initiated before age 2 years, 65.5% underwent successful renal transplant with a mean age of 2.7 years and 26.4% died; 95.7% of those deaths occurred in patients who did not survive on PD to renal transplant. In this 2012 study, mortality was highest in neonates with renal replacement initiated before 3 months of age, which may
be consistent with a higher degree of renal disease in this cohort.

Overall, this fetal intervention involves multiple invasive procedures to mothers and leads inevitably to newborns who will need PD and renal transplant in the future. Choosing to pursue SAT may be associated with pain, psychological trauma, and high costs with no guarantee of quality of life. This intervention presents a challenging course that may not be desired by many parents or families.

The inception of SAT and its association with short-term success has created hope that with less pulmonary morbidity overshadowing, care teams can focus on genitourinary problems and improve outcomes even further. There have been multiple cases of newborns without pulmonary hypoplasia who have been successfully placed on PD with an ultimate goal of renal transplant. In 1978, there was a 76% overall patient survival rate to 4 years of age in a cohort of 21 cases in which dialysis began in the neonatal period with transplantation occurring at a mean age of 3 years. Of note, caution should be utilized when extrapolating outcomes data of neonates with successful placement on PD. The majority of studies include full-term neonates rather than neonates born at a preterm gestation, as would be the more likely patient population in the setting of SAT. Children with successful renal transplants after PD are at risk of growth complications and immunosuppressant-related infections. Fetuses with other anomalies in addition to LUTO or CRA, such as ureteric agenesis or an underdeveloped bladder, present even more complex urologic problems for a transplanted kidney. In renal agenesis, the absence of a bladder or ureters necessitates an eventual nonbladder conduit for drainage of urine.

The patient case report in this article highlights the necessary multidisciplinary team and substantial resources required to care for an infant with BRA after antenatal SAT to palliate pulmonary hypoplasia. The infant in the case report unfortunately endured multiple complications during his 7-month hospital stay, and due to his insufficient growth during PD, he was unable to receive a kidney transplant. The possibility of such outcomes necessitates thorough and informed patient consent from the family choosing to undergo fetal SAT.

**CONCLUSION**

Evidence suggests that SAT may provide regenerative therapy resulting in pulmonary palliation and reduce the risk of newborn mortality due to pulmonary compromise. However, before SAT can be adopted into widespread practice, further research is needed, and SAT should only be undertaken in the context of a clinical trial to inform treatment and counseling guidelines. The present study proposes a multidisciplinary prenatal management classification system based on fetal disease severity that can be used as a guideline to inform patient selection in clinical trials evaluating SAT for mothers of fetuses with LUTO. With strong evidence lacking for this fetal intervention, a clinical trial is justified to further assess the long-term outcomes of this intervention in cases of severe fetal renal dysfunction.
