ABSTRACT
We present new observations of Lyman-α (Lyα) Blob 1 (LAB1) in the SSA22 protocluster region (z = 3.09) using the Keck Cosmic Web Imager (KCWI) and Keck Multi-object Spectrometer for Infrared Exploration (MOSFIRE). We have created a narrow-band Lyα image and identified several prominent features. By comparing the spatial distributions and intensities of Lyα and Hβ, we find that recombination of photo-ionized H I gas followed by resonant scattering is sufficient to explain all the observed Lyα/Hβ ratios. We further decode the spatially-resolved Lyα profiles using both moment maps and radiative transfer modeling. By fitting a set of multiphase, ‘clumpy’ models to the observed Lyα profiles, we manage to reasonably constrain many parameters, namely the H I number density in the inter-clump medium (ICM), the cloud volume filling factor, the random velocity and outflow velocity of the clumps, the H I outflow velocity of the ICM and the local systemic redshift. Our model has successfully reproduced the diverse Lyα morphologies, and the main results are: (1) The observed Lyα spectra require relatively few clumps per line-of-sight as they have significant fluxes at the line center; (2) The velocity dispersion of the clumps yields a significant broadening of the spectra as observed; (3) The clump bulk outflow can also cause additional broadening if the H I in the ICM is optically thick; (4) The H I in the ICM is responsible for the absorption feature close to the Lyα line center.

Key words: galaxies: kinematics and dynamics — intergalactic medium — galaxies: high-redshift — galaxies: evolution

1 INTRODUCTION
Lyα Blobs (LABs) – spatially extended (projected sizes ≥ 100 kpc) gaseous nebulae at high redshift (z ≥ 2) with immense Lyα luminosities (L Lyα ∼ 1043–46 erg s−1) – are among the most enigmatic and intriguing objects in the universe. To date, hundreds of LABs have been discovered (e.g., Francis et al. 1996; Fynbo et al. 1999; Keel et al. 1999; Steidel et al. 2000; Matsuda et al. 2004, 2011; Dey et al. 2005; Saito et al. 2006; Smith & Jarvis 2007; Hennawi et al. 2009; Ouchi et al. 2009; Prescott et al. 2009, 2012; Erb et al. 2011; Cai et al. 2017), yet their physical origin remains murky. Many of the LABs have been found in overdense regions associated with massive proto-clusters, which will presumably evolve into rich galaxy clusters observed today (e.g., Steidel et al. 1998; Prescott et al. 2008; Yang et al. 2009, 2010; Hine et al. 2016). Hence, the study of LABs may elucidate the formation process of massive galaxies and the mechanisms of concurrent feedback events.

What are the possible energy sources that power the observed Lyα emission of LABs? Thus far, numerous mechanisms have been made to answer this fundamental question, but a consensus is yet to be reached. Among many proposed scenarios, one of the most plausible Lyα production mechanisms is photo-ionization via embedded energetic sources (e.g., starburst galaxies or AGNs) followed by subsequent recombination (Haiman et al. 2000; Fardal et al. 2001; Furlanetto et al. 2005; Dijkstra et al. 2006a,b; Scarlata et al. 2009; Goerdt et al. 2010; Faucher-Giguère et al. 2010; Rosdahl & Blaizot 2012). This explanation is especially favored for LABs with no or only weak associated energy sources identified even with deep multi-wavelength observations (Nilsson et al. 2006; Smith & Jarvis 2007; Saito et al. 2008; Smith et al. 2008). In either case, a substantial fraction of the Lyα photons will be resonantly scattered multiple times before escape (Steidel et al. 2010, 2011), although the ‘cold accretion’ scenario is supposed to induce a lower degree of polarization due to a lower chance of scattering from the inside out (Dijkstra & Loeb 2009; Hayes et al. 2011; Trebitsch et al. 2016; Eide et al. 2018).

In this paper, we present new observations and analyses of one of the first LABs ever discovered, SSA22-Blob1 (LAB1, Steidel et al. 2000). LAB1 is one of the brightest and largest LABs discovered to date, with a Lyα luminosity of ∼ 1.1 × 1044 erg s−1 (Weijmans et al. 2010) and a spatial extent of ∼ 100 kpc (Matsuda et al. 2004). Since its discovery, LAB1 has been studied extensively, at wavelengths including X-ray (Geach et al. 2009), optical (Ohyama et al. 2003; Bower et al. 2004; Weijmans et al. 2010), infrared (IR, Uchimoto et al. 2008, 2012; Webb et al. 2009) and submillimeter (submm, Geach et al. 2005; Matsuda et al. 2007; Geach et al. 2014; Hine et al. 2016). Two Lyman-break galaxies (LBG), C11 and C15 (Steidel et al. 2000, 2003; Matsuda et al. 2004), and multiple dust-obscured star-forming galaxies (Geach et al. 2007, 2014, 2016) have been identified within LAB1. However, X-ray observations yield non-detections, indicating the absence of Compton-thin AGNs (Geach et al. 2009).

To determine the principle energy source(s) powering LAB1, three main approaches have been adopted: the first is to infer the gas kinematics (e.g., inflows v.s. outflows) from the observed properties of Lyα as well as other non-resonant emission lines (e.g., [O III], Hα, Hβ). For example, Bower et al. (2004) and Weijmans et al. (2010) measured a velocity shear of the Lyα emission from C11 and C15 using integral-field spectroscopy, which suggests the presence of outflows. On the other hand, McLinden et al. (2013) reported a nearly zero velocity offset between Lyα and [O III] in C11 and C15,
which they interpreted as an absence of strong outflows. An alternative approach is to compare the available energy budget of possible energy sources with the observed Lyα emission. For example, Geach et al. (2016) deduced the IR luminosities and corresponding star formation rate (SFR, \( \sim 150 M_{\odot} \text{yr}^{-1} \)) of the embedded sources from their 850\( \mu \text{m} \) flux density measured with ALMA, and found that this energy budget is sufficient to power the observed Lyα luminosity. However, as it is difficult to independently constrain the fraction of Lyα photons that escape from the galaxy and scatter into our line of sight, additional energy sources (e.g., cold accretion) cannot be ruled out entirely (Geach et al. 2014; Hine et al. 2016).

Thirdly, Hayes et al. (2011) and Beck et al. (2016) have measured polarized Lyα emission using polarimetric imaging. Although they claimed that this result should be strongly supportive of a ‘central powering + scattering’ model, Trebitsch et al. (2016) pointed out that the scattering inside the cold filaments in the ‘cold accretion’ scenario could still account for the degree of polarization observed.

In this paper, we use an advanced kinematic approach to further test the feasibility of the ‘central powering + scattering’ scenario. The traditional kinematic approach – inferring the underlying gas velocity field from the observed peak shifts and line widths (e.g., McLinden et al. 2013) – is worth scrutinizing, as resonant scattering may modify the line profiles in a very complex way. Instead, we model the Lyα profiles using Monte-Carlo radiative transfer (MCRT). Due to its computationally expensive nature, Lyα MCRT modeling normally assumes a simple, idealized geometry, e.g., a spherically symmetric expanding shell of H I gas surrounding a central Lyα emitting source (the ‘shell model’, Verhamme et al. 2006; Dijkstra et al. 2006b). This simple model has successfully reproduced many observed Lyα spectra (e.g., Schaefer & Verhamme 2008; Verhamme et al. 2008; Dessauges-Zavadsky et al. 2010; Vanzella et al. 2010; Gronke 2017), although it has also encountered some challenges for those with multiple peaks (Verhamme et al. 2008; Kulas et al. 2012; Rivera-Thorsen et al. 2017) or very large line widths (Hashimoto et al. 2015; Yang et al. 2016, 2017; Orlitová et al. 2018). Moreover, recent observations have shown increasing evidence that the circumgalactic medium (CGM), just like the interstellar medium (ISM), is multiphase and clumpy (e.g., the Lyα emission and metal absorption line observations of high-redshift quasars (Cantalupo et al. 2014; Hennawi et al. 2015)), which is further corroborated by simulations with increased spatial resolution (e.g., Hummels et al. 2019). Therefore, a more realistic model that accounts for the multiphase nature and clumpy geometry of H I gas is needed to properly characterize the radiative transfer processes of Lyα photons.

Up to now, this multiphase ‘clumpy’ model has been explored theoretically via both semi-analytical calculations (Neufeld 1991) and Monte-Carlo simulations (Hansen & Oh 2006; Dijkstra & Kramer 2012; Laursen et al. 2013; Gronke & Dijkstra 2016). However, due to its complex and multivariate nature, the multiphase ‘clumpy’ model has not been widely used in fitting real Lyα spectra (albeit the first attempt made in Forero-Romero et al. 2018). In this work, we use the framework proposed by Gronke & Dijkstra (2016) to model the spatially-resolved Lyα spectra in LAB1.

In addition to the Lyα observations in the optical (rest-frame UV) using the Keck Cosmic Web Imager (KCWI; Martin et al. 2010; Morrissey et al. 2012), we have carried out near-infrared (NIR, rest-frame optical) spectroscopic observations using the Keck Multi-object Spectrometer for Infrared Exploration (MOSFIRE; McLean et al. 2010, 2012). By comparing the spatial distribution of Lyα, O III and H β emission and fitting Lyα line profiles, we map the kinematic structure of H I in LAB1 and constrain its possible powering mechanisms(s).

The structure of this paper is as follows. In §2, we describe our KCWI and MOSFIRE observations and data reduction procedures. In §3, we present our new observational results and analyses. In §4, we detail the methodology and present our results of radiative transfer modeling using the multiphase, clumpyp model. In §5, we summarize and conclude. Throughout this paper we adopt a flat ΛCDM cosmology with \( \Omega_m = 0.315, \Omega_b = 0.685, \) and \( H_0 = 67.4 \text{ km s}^{-1} \text{Mpc}^{-1} \) (Planck Collaboration et al. 2018). We use the following vacuum wavelengths: 1215.67 Å for Lyα, 4862.683 Å for H β, and 4960.295/5008.240 Å for [O III] from the Atomic Line List v2.04.

2 OBSERVATIONS AND DATA REDUCTION

2.1 KCWI Observations

The KCWI observations of LAB1 were carried out on the night of 2018 June 16, with a seeing of \( \sim 1.0'' \) full width at half maximum (FWHM). We used the KCWI large slicer, which provides a contiguous field-of-view (FOV) of 20.4'' (slice length) \( \times 33'' \) (24 \( \times 1.35'' \) slice width). With the BM VPH grating set up for \( \lambda_c = 4800 \text{ Å} \), the wavelength coverage is \( \sim 4200 - 5330 \text{ Å} \), with spectral resolution \( R \sim 1800 - 2200 \). The data were obtained as 9 individual 1200 s exposures, with small telescope offsets in the direction perpendicular to slices applied between each, in an effort to recover some spatial resolution given the relatively large slice width. The total on-source exposure time was 3 hours.

Individual exposures were reduced using the KCWI Data Reduction Pipeline\(^1\), which includes wavelength calibration, atmospheric refraction correction, background subtraction, and flux calibration. The individual datacubes were then spatially re-sampled onto a uniform astrometric grid with 0.3'' by 0.3'' spaxels, with a sampling of 0.5 Å pix\(^{-1} \) (4.75 pixels per spectral resolution element) along the wavelength axis, using a variant of the ‘drizzle’ algorithm (with a drizzle factor of 0.9) in the MONTAGE\(^3\) package. The re-sampled cubes were then combined into a final stacked cube by averaging with exposure time weighting. Owing to the coarser spatial sampling in the long dimension of the spatial cube, the PSF in the final datacube is elongated along the N-S direction, with FWHM \( \sim 0.96'' \times 1.44'' \) (X-direction and Y-direction, respectively).

The resampled final datacube covers a scientifically useful solid angle of 18.9''\(^2\) \( \times 32.7'' \) on the sky, and a wavelength range (vacuum, heliocentric) of 4214 - 5243 Å. A variance image with the same dimensions was created by propagating errors based on a noise model throughout the data reduction.

2.2 MOSFIRE Observations

We observed selected regions of LAB1, chosen to include the highest Lyα surface brightness areas as determined from a very deep narrow-band Lyα image (see Steidel et al. 2011; Nestor et al. 2011) using MOSFIRE (McLean et al. 2010, 2012; Steidel et al. 2014) on the Keck I telescope. Spectra in the near-IR K band (1.95 - 2.40 μm) were obtained using four different slitmasks, each of which included a slit passing through part of LAB1 with a different RA, Dec, and position angle (PA). The four slits are labeled as ‘slit 1’ through ‘slit 4’ in Figure 1, and the observations are summarised in Table 1. Slits 1 - 3 were obtained using slits of width 0.7'', providing spectral resolving power of \( R \sim 3700 \); slit 4 observations used a 1.0'' wide slit, yielding \( R = 2600 \). The observations were obtained during four different observing runs between 2012 June and 2019 November, under clear skies with seeing in the range 0.43'' - 0.53'', as summarised in Table 1.

References. (1) This work; (2) McLinden et al. (2013); (2) Geach et al. (2016); (4) Kubo et al. (2015); (5) Unetitha et al. (2017).

The MOSFIRE K band observations (slit 1 was also observed in H band) were all obtained using an ABAB nod pattern along the slit direction with nod amplitude of 3″ between position A and position B for slits 1, 2, 3, and 15$^5$ for slit 4. Total integration times were 1.5 – 4.0 hours, as listed in Table 1, composed of 30 - 80 individual 180 s exposures. The data for each observation sequence were reduced using the MOSFIRE data reduction pipeline$^4$ to produce two-dimensional, rectified, background-subtracted vacuum wavelength calibrated spectrograms (see Steidel et al. 2014 for details). Observations obtained on different observing nights using the same slitmask were reduced independently; the 2-D spectrograms were shifted into the heliocentric rest frame and combined with inverse variance weighting using tasks in the MOSPEC (Strom et al. 2017) analysis package.

3 THE GAS KINEMATIC STRUCTURE OF LAB1

3.1 Spatial Distribution of Lyα Emission

To get an overview of the Lyα surface brightness (SB) distribution in LAB1, we first generate a Lyα narrow-band image by optimally summing all the Lyα fluxes over the relevant wavelength range. Here we follow the ‘matched filtering’ procedures for creating a narrow-band image (Herenz et al. 2020) using LSDCat (Herenz & Wisotzki 2017). Firstly, we apply spatial filtering to the continuum-subtracted KCWI datacube using a 2D Gaussian filter with a constant 1.2″ FWHM, which equals the seeing point spread function (PSF) measured from a bright star in the SSA22 field. Secondly, we apply a 1D Gaussian spectral filter with FWHM = 1000 km s$^{-1}$, which is the typical observed Lyα line width estimated via visual inspection. Thirdly, we use this filtered datacube to generate a SB cube. We can then choose appropriate S/N thresholds for the filtered datacube to produce SB maps and moment maps (see Section 3.3).

In the left panel of Figure 1, we present our narrow-band Lyα image. It is constructed by summing over all the voxels of the filtered datacube with S/N ≥ 4 over 4959 – 5009 Å, which should enclose all possible Lyα emission. To further examine whether the Lyα emission coincides with the identified sources, we also present the HST/STIS optical continuum image of LAB1$^5$.

We have also marked the positions of previously identified sources on each image as references. Among these sources, C1 and C15 are both LBGs (Steidel et al. 2000); ALMA-a, b and c are three submillimeter galaxies (Geach et al. 2016); K1 is a K-band selected galaxy (Kubo et al. 2015); c1 and c2 (the same as S1 in Geach et al. 2016) are two [O III] serendipitous sources; c1 is a Lyα serendipitous source at a lower redshift (z = 2.7542). The detailed information (especially spectroscopic redshifts, if available) of all the identified sources are presented in Table 2. The Lyα isophotes (contours with the same SB) with levels of SBN$_{Lyα}$ = [120, 80, 40, 15, 4] × 10$^{-9}$ erg s$^{-1}$ cm$^{-2}$ arcsec$^{-2}$ have also been overlaid onto each image.

Several prominent features are evident in Figure 1: (1) In general, the regions with the highest SB are associated with identified sources (e.g., C1, C15 and ALMA-a), although the position of the maximum Lyα SB may be offset from the continuum source (e.g., C15); (2) An exception worth noting is a tadpole-shaped structure (marked in Figure 1), which starts from the ALMA-ab sources, moves towards the north-west first and then north-east. Interestingly, although the ‘head’ of the tadpole overlaps with ALMA-a, its ‘tail’ does not overlap with any source; (3) The regions with identified continuum sources do not necessarily have significant Lyα emission (e.g., ALMA-c, c2, K1).

3.2 Spatial Distribution of [O III] and Hβ Emission

To test whether the extended Lyα emission is produced ‘in situ’ or ‘ex situ’ (the latter requires scattering), we further use MOSFIRE to map the spatial distribution of two other non-resonant lines, [O III] and Hβ, and quantitatively compare them with Lyα emission at the same spatial position. The positions of the four MOSFIRE slits are also shown in Figure 1.

Theoretically, we consider two principal scenarios of Lyα production: (1) photo-ionization + recombination (e.g., due to star formation); (2) collisional excitation + radiative de-excitation (e.g., due to cold accretion). For scenario 1, assuming case B recombination, we use the PyNeb package (Luridiana et al. 2015) to calculate F$_{Lyα}$/F$_{Hβ}$ for $T_{HI}$ (K) ∈ [10$^3$, 10$^4$] and $n_e$ (cm$^{-3}$) ∈ [1, 10$^4$], where $T_{HI}$ and $n_e$ are the kinetic temperature of the H I gas and electron number density, respectively. For scenario 2, assuming collisional ionization equilibrium, we use the Chianti package (Dere et al. 1997; Dere 2012; Dere et al. 2019) to calculate F$_{Lyα}$/F$_{Hβ}$ for the same ranges of $T_{HI}$ and $n_e$ as above. The derived F$_{Lyα}$/F$_{Hβ}$ as a function of $T_{HI}$ for both scenarios are shown in Figure 2. It can be seen that as $T_{HI}$ increases, the predicted F$_{Lyα}$/F$_{Hβ}$ is roughly constant for scenario 1, but decreases for scenario 2, as Lyα emissivity drops more quickly than Hβ.

Now we compare our spectroscopic data to the theoretical predictions above. For each MOSFIRE slit in Figure 1, we construct a corresponding pseudo-slit to extract a 2D spectrum from the 3D KCWI datacube via a 3D datacube visualization tool QFitsView (Davies et al. 2010; Ott 2012). We then integrate the flux density in the wavelength dimension for each line and convert it to a SB accounting for the slit width.

In Figure 3, we show the line SB for Lyα, [O III] and Hβ along each slit. Evidently, Lyα is not necessarily co-spatial with [O III] or Hβ, and is usually more extended along the slit. We further calculate F$_{Lyα}$/F$_{Hβ}$ (shown in red numbers) by integrating SBN$_{Lyα}$/SB$_{[O III]}$ along the slits for each identified source. We also calculate F$_{Lyα}$/F$_{Hβ}$ in two ways, where F$_{Lyα}$ is calculated either by integrating SBN$_{Lyα}$ by applying the HST/STIS optical continuum image of LAB1$^5$.

The KCWI and HST/STIS images have been registered to the same world-coordinate system using cross-correlation.

---

$^4$ https://github.com/Keck-DataReductionPipelines/MosfireDRP

$^5$ The KCWI and HST/STIS images have been registered to the same world-coordinate system using cross-correlation.
Figure 1. Ly$\alpha$ and continuum images of LAB1. Left: The narrow band Ly$\alpha$ image, obtained by collapsing the original KCWI datacube over 4959 – 5009 Å, which contains the Ly$\alpha$ line (see Section 2). The UV continuum near the wavelength of Ly$\alpha$ has been subtracted. Right: The HST/STIS optical continuum image. The positions of four MOSFIRE slits (Slit 1–4), two Lyman-break galaxies (C11 and C15), three submillimeter sources (ALMA-a, b, and c), a K-band selected galaxy (K1) and three [O III]/Ly$\alpha$ serendipitous sources (c1 to c3) have been marked on each image (see Table 2). The Ly$\alpha$ isophotes with levels of SB$_{Ly\alpha}$ = [120, 80, 40, 15, 4] $\times$ 10$^{-19}$ erg s$^{-1}$ cm$^{-2}$ arcsec$^{-2}$ have also been overlaid. All images have been registered to the same world-coordinate system.

The results in Figure 2 and 3 show that: (1) For slit 1 and 2, $F_{Ly\alpha}/F_{H\beta}$ are always smaller than the predicted value of scenario 1. Considering that Ly$\alpha$ is subject to heavier dust extinction than H$\beta$, this result suggests that scenario 1 itself is sufficient to explain the observed $F_{Ly\alpha}/F_{H\beta}$; (2) For slit 3 and 4, we do see $F_{Ly\alpha}/F_{H\beta}$ ratios ($\sim$ 50 – 70, see Table 3) higher than that predicted by scenario 1, but still far lower than those predicted by scenario 2 (especially in the $T_{HI}$ $\geq$ 10$^4$ K region, where both Ly$\alpha$ and H$\beta$ have been sufficiently excited). Simply scenario 1 and resonant scattering are sufficient to explain all the observed line ratios. Furthermore, we do not see a significant number of Ly$\alpha$ profiles that have a blue dominant peak (signature of cold accretion, see e.g., Zheng & Miralda-Escudé 2002; Dijkstra et al. 2006b; Faucher-Giguère et al. 2010) in these regions. Therefore, it is highly likely that photo-ionization + recombination is the main source of Ly$\alpha$ photons, and resonant scattering (as indicated by significant polarization detections from Hayes et al. 2011 and Beck et al. 2016) has substantially altered their spatial and kinematic distribution.

3.3 Profiles of Ly$\alpha$ Emission

In this section, we investigate the variations of spatially-resolved Ly$\alpha$ profiles in major emitting regions. Before proceeding, we first use [O III] to determine the systemic redshifts of three associated sources: C11, C15 and c1. Single Gaussian fits to the [O III] line profiles (see Appendix A for details) yield redshifts (after heliocentric correction) of 5500 km s$^{-1}$, 4400 km s$^{-1}$, and 3100 km s$^{-1}$ for C11, C15, and c1, respectively. Additionally, the scattering of Ly$\alpha$ photons out of the line-of-sight can also reduce the observed $F_{Ly\alpha}/F_{H\beta}$ ratio.
Gas Kinematics in LAB1
Figure 3. Surface brightness distributions of Ly$\alpha$ (blue), [O iii] (red) and H$\beta$ (green) along four MOSFIRE slits (the leftmost panels, (a) - (d) correspond to slits 1 - 4, respectively). For reference, the smoothed 2D spectra of H$\beta$ (the second column) and [O iii] (the third and fourth columns, for 4960 Å and 5008 Å, respectively) are also shown. Both the observed wavelengths ($\lambda_{\text{obs}}$) and the rest-frame wavelengths ($\lambda_{\text{rest}}$, assuming $z = 3.1000$) are shown. The positions of known sources are indicated with black arrows. We calculate $F_{[\text{O iii}]}/F_{H\beta}$ (shown in red numbers) by integrating $SB_{H\beta}$ and $SB_{[\text{O iii}]}$ along the slits for each identified source. We also calculate $F_{Ly\alpha}/F_{H\beta}$ (shown in green numbers) in two ways, where $F_{Ly\alpha}$ is calculated either by integrating $SB_{Ly\alpha}$ over the same region as H$\beta$ and [O iii] (as indicated by solid arrows), or by integrating over the full extent of Ly$\alpha$ (as indicated by dashed arrows). Note that the blue regions in the 2D spectra are negative images due to dithering.
4.3.1 Northern Region

Adjusting the dynamic range, we are able to discern more subtle boxes. We zoom in on these two regions in separate panels. By major Lyα corrected for the KCWI instrumental line spread function (LSF), \( \sigma \) S/N < 6 (for 3.1, and all the summations are carried out over 4959 – 5009 Å. 

\[
\Delta v_{\text{Ly} \alpha} = \sum_{k} \left( v_{\text{Ly} \alpha,k} - v_{\text{Ly} \alpha,xy} \right)^2 I_{\text{Ly} \alpha,k} \sum_{k} I_{\text{Ly} \alpha,k} 
\]

where \( I_{\text{Ly} \alpha,k} \) and \( v_{\text{Ly} \alpha,k} \) are the flux density and velocity (relative to a fiducial redshift) of the \( k \)th wavelength layer at position \( (x,y) \). In our moment analysis we fix the fiducial redshift of LAB1 at \( z = 3.1 \), and all the summations are carried out over 4959 – 5009 Å. 

Before applying Eqs. (1) and (2), we filter out all the voxels with S/N < 6 (for \( v_{\text{Ly} \alpha} \)) or 4 (for \( \sigma_{\text{Ly} \alpha} \)). The \( \sigma_{\text{Ly} \alpha} \) map has been further corrected for the KCWI instrumental line spread function (LSF), \( \sigma = 65 \text{ km s}^{-1} \).

The resulting moment maps are shown in Figure 4. The two major Lyα emitting regions have been delineated by rectangular boxes. We zoom in on these two regions in separate panels. Adjusting the dynamic range, we are able to discern more subtle boxes. We zoom in on these two regions in separate panels. By major Lyα corrected for the KCWI instrumental line spread function (LSF), \( \sigma \) S/N < 6 (for 3.1, and all the summations are carried out over 4959 – 5009 Å.

Table 3. \( \text{Ly} \alpha \), \([\text{O} \text{ III}]\) and \( \text{H}\beta \) fluxes and line ratios measured along four MOSFIRE slits.

| Slit No. | Restricted Regions | Extended Regions |
|---------|--------------------|------------------|
|         | Lyα               | [O III]          | Hβ              | Lyα/Hβ | [O III]/Hβ | Lyα | Lyα/Hβ |
| (1)     | (2)               | (3)             | (4)             | (5)    | (6)        | (7) | (8)    |
| 1       | 4.8               | 2.3             | 0.4             | 9.6    | 5.8        | 9.3 | 18.3   |

| 3       | 7.5               | 1.2             | 0.3             | 17.3   | 3.5        | 29.3| 68.1   |
| 4       | 9.2               | 4.3             | 0.6/1.1         | 30/2.2 | 23/2.34    | 32/2.42/2.34 | 2/0.52 | 24.3 | 51.8   |

\textbf{Notes.} Lyα, \([\text{O} \text{ III}]\) and \( \text{H}\beta \) fluxes measured by integrating along the four MOSFIRE slits (see Figure 1 and Table 1 for details) and the corresponding extracted pseudo-slits from the KCWI datacube and line ratios (Lyα/Hβ and \([\text{O} \text{ III}]/\text{H}\beta\)). The columns are: (1) the slit number (as marked in Figure 1); (2) the Lyα flux of the restricted regions (where \( I_{\text{Ly} \alpha} \) is calculated over the same region as \( \text{H}\beta \) and \([\text{O} \text{ III}]\), as indicated by solid arrows in Figure 3); (3) the \([\text{O} \text{ III}]\) flux; (4) the \( \text{H}\beta \) flux; (5) the Lyα/Hβ ratio; (6) the \([\text{O} \text{ III}]/\text{H}\beta\) ratio; (7)(8) same as (2)(5), but for extended regions (where \( I_{\text{Ly} \alpha} \) is calculated over the full extent of Lyα, as indicated by dashed arrows in Figure 3). All fluxes are in units of \( 10^{-17} \text{ erg s}^{-1} \text{ cm}^{-2} \).

significant outflow velocities can still be present in profiles with \( \Delta v_{\text{Ly} \alpha} \sim 0 \) (e.g., in our spectra 1 and 2).

Most Lyα profiles in the northern region are considerably asymmetric and consist of a ‘main peak’ and a ‘red bump’ (see spectrum 1 in Figure 5 as an example). Moreover, the main peak is redshifted towards the eastern region, and blueshifted towards the west. The largest \( v_{\text{Ly} \alpha} \) can be up to \( \sim 500 \text{ km s}^{-1} \), which explains the evident east-west \( v_{\text{Ly} \alpha} \) gradient in Figure 4. This shear in \( v_{\text{Ly} \alpha} \) appears to be perpendicular to the major axis of C15, which is consistent with the suggestion by Weijmans et al. (2010) that outflow or rotation is indicated.

As for \( \sigma_{\text{Ly} \alpha} \), its largest value (\( \sim 400 \text{ km s}^{-1} \)) is located slightly northwest of C15, beyond which \( \sigma_{\text{Ly} \alpha} \) gradually decreases moving away from C15. In general, the \( \sigma_{\text{Ly} \alpha} \) values in the northern region are much larger than the global \( \sigma_{\text{Ly} \alpha} \). This is unexpected if one were to assume that both Lyα and \([\text{O} \text{ III}]\) photons are emitted by the same sources, although the kinematics of Lyα have been altered by radiative transfer effects. We attempt to explain the broadening of Lyα in Section 4.

3.3.2 Southern Region

Multiple discrete continuum sources have been identified within the southern portion of LAB1, including the LB C11, three ALMA submm sources, and several very faint objects with spectroscopic confirmation (K1, c1, c2 and \( c_3 \)). We first use a large aperture to measure the local properties of LB C11. The LSF-corrected global line widths of Lyα and \([\text{O} \text{ III}]\) of C11 are 178 and 78 km s\(^{-1}\). The global velocity offset between Lyα and \([\text{O} \text{ III}]\) is \( \Delta v_{\text{Ly} \alpha} = +175 \text{ km s}^{-1} \) (i.e., redshifted with respect to systemic), and \( -197 \text{ km s}^{-1} \) between the Si ii 1526 absorption line (from LRIS observations) and Lyα. Similar velocity offsets between Lyα and interstellar absorption features are commonly observed in ‘down the barrel’ spectra of LBGs, and are generally interpreted as signatures of outflow (Steidel et al. 2010). However, they are inconsistent with the detection of significant offset between Lyα and \([\text{O} \text{ III}]\) by McLinden et al. (2011). This may be due to the high asymmetry of the \([\text{O} \text{ III}]\) profile of C11.

Most Lyα profiles from spatial locations near C11 exhibit double peaks – a red dominant peak + a blue ‘bump’ (see spectrum 10 in Figure 5 as an example). The position of the red dominant peak tends to move towards more blueshifted velocities along the northwest-southeast direction. The largest \( v_{\text{Ly} \alpha} \) is \( \sim 300 \text{ km s}^{-1} \), which gives rise to the \( v_{\text{Ly} \alpha} \) northwest-southeast gradient in Figure 4. This shear in \( v_{\text{Ly} \alpha} \) appears to be parallel to the major axis of C11, consistent with Weijmans et al. (2010).

As for \( \sigma_{\text{Ly} \alpha} \), its largest value (\( \sim 500 \text{ km s}^{-1} \)) is located in the
Figure 4. The first ($v_{\text{Ly} \alpha}$) and second ($\sigma_{\text{Ly} \alpha}$) moment maps of LAB1. The two major Ly$\alpha$ emitting regions have been delineated by rectangular boxes (dashed white lines), and their zooming-in views are shown in the right panels. For the northern region, the colorbar limits have been adjusted accordingly to account for the smaller value range. The positions of the identified continuum sources are indicated by circles with labels. The Ly$\alpha$ SB isophotes (solid white lines) with levels of $S_{\text{Ly} \alpha} = [120, 80, 40, 15, 4] \times 10^{-19} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ arcsec}^{-2}$ have also been overlaid onto each image for visual reference.
southwest corner, while the majority of the spectra around C11 have a rather homogeneous $\sigma_{\text{Ly}\alpha} \sim 400$ km s$^{-1}$. Again, these values are much larger than $\sigma_{\text{H}\alpha,\text{HI}}$.

The Ly$\alpha$ profiles near the ALMA sources are more complex – most of them are very broad, highly asymmetric, and have multiple peaks. Some of the profiles (e.g., the northeast corner) are even dominated by a ‘blue peak’, as shown in spectrum 4 in Figure 5.

On the $\nabla_{\text{Ly}\alpha}$ map, there is an alternate pattern of positive and negative $\nabla_{\text{Ly}\alpha}$ from the east to the west. Yet again, we see a similar coherent velocity structure that coincides with the high SB ‘tadpole’ structure (see Section 3.1). This structure is also seen on the $\sigma_{\text{Ly}\alpha}$ map, but with a slightly different trend – starting from the south, first going towards northeast, and then turning northwest. The largest $\sigma_{\text{Ly}\alpha}$ values ($\sim 500$ km s$^{-1}$) still overlap with ALMA-a, which indicates that the ALMA source may be responsible for the Ly$\alpha$ line broadening (e.g., via starburst-driven outflows).

Our $\nabla_{\text{Ly}\alpha}$ and $\sigma_{\text{Ly}\alpha}$ maps are qualitatively similar to the ones presented in a recent work by Herenz et al. (2020), albeit with slight differences in the extent of the Ly$\alpha$ emitting regions and the number of spaxels included, due to different FOVs of instruments and S/N threshold choices. The alternate pattern of positive and negative $\nabla_{\text{Ly}\alpha}$ is consistent with the left panel in their Figure 7, and the large $\sigma_{\text{Ly}\alpha}$ values near ALMA-ab sources are consistent with the right panel in their Figure 7.

4 RADIATIVE TRANSFER MODELING USING THE MULTIPHASE CLUMPY MODEL

4.1 Methodology

Although the moment map analysis above provides a cursory overview of the apparent gas velocity field, it is purely phenomenological and could even be misleading, in the sense that if radiative transfer effects dominate, the observed $\nabla_{\text{Ly}\alpha}$ would not necessarily be linked directly to the local gas kinematics. To gain more physical insight and to account for the possibly important radiative transfer effects, we generated a series of model spectra using MCRT and fit them to the observed Ly$\alpha$ spectra at different positions in LAB1.

Our first attempt was to fit the Ly$\alpha$ profiles using the widely used ‘shell model’ (Verhamme et al. 2006; Dijkstra et al. 2006b), as most line profiles are fairly broad and multi-peaked with significant flux close to line center, the fits either fail to reproduce the major features or have inexplicably large intrinsic line widths (see e.g., Orlitová et al. 2018). Therefore, we adopt a more sophisticated and physically realistic multiphase ‘clumpy model’ instead. As described in Gronke & Dijkstra (2016), the geometric setup of this ‘clumpy model’ is a number of spherical H I clumps moving within a hot ($T \sim 10^5$–$10^6$ K), ionized inter-clump medium (ICM) (see also Laursen et al. 2013). This model predicts the Ly$\alpha$ spectra produced by a central Ly$\alpha$ emitting source, accounting for the scattering by H I (both in the clumps and the ICM)\(^9\). It has 14 parameters in total (see the detailed formulation in Gronke & Dijkstra 2016), among which the most important ones are the cloud covering factor ($f_{\text{cl}}$) that describes the mean number of clumps per line-of-sight from the center to the boundary of the simulation sphere, the H I number density in the ICM ($\rho_{\text{H}\alpha,\text{ICM}}$), and kinematic parameters of the clumps and ICM. Specifically, the clump motion is assumed to be a superposition of an isotropic Gaussian random motion (characterized by $\sigma_{\text{cl}}$, the velocity dispersion of the clumps) and a radial uniform outflow with a constant velocity $V_{\text{cl}}$. In addition, we consider an outflow velocity of the low density H I in the ICM, $V_{\text{ICM}}$.

9 As we will show below, the scattering process washes out the information about the Ly$\alpha$ emitting source, i.e., the initial spatial or spectral shape of the source does not significantly affect the emergent spectra.

and a post-processed parameter, the velocity shift with respect to $z = 3.1000$, $\Delta v$. This $\Delta v$ parameter represents the best-fit systemic redshift of the Ly$\alpha$ source function relative to $z = 3.1000$ (the initial guess for the systemic redshift).

Note that Ly$\alpha$ radiative transfer in such a multiphase medium exhibits two characteristic regimes defined by the values of $f_{\text{cl}}$. If $f_{\text{cl}}$ is (much) greater than a critical value $f_{\text{cl},\text{crit}}$ (which is a function of other model parameters, such as the kinematics and H I column density of the clumps), the photons would escape as if the medium is homogeneous and the emergent spectra are similar to the ones predicted by the aforementioned ‘shell model’ (Gronke et al. 2017). Otherwise, for fewer clumps per line-of-sight, the photons preferentially travel in the ionized ICM and escape closer to the line center of Ly$\alpha$. As most of our observed Ly$\alpha$ spectra have considerable flux near the line center, we expect $f_{\text{cl}} \lesssim f_{\text{cl},\text{crit}}$ in our cases, and will focus on that regime\(^10\).

Based on these considerations, we further construct a five-dimensional hypercubic grid by varying five crucial physical parameters: [$\log n_{\text{H}\alpha,\text{ICM}}, F_{\text{Ly}\alpha}, \sigma_{\text{cl}}, V_{\text{ICM}}, V_{\text{cl}}$]\(^11\). The prior ranges of $\log n_{\text{H}\alpha,\text{ICM}}$ (cm$^{-3}$), $F_{\text{Ly}\alpha}$ and $[\sigma_{\text{cl}}, V_{\text{ICM}}, V_{\text{cl}}]$ (km s$^{-1}$) are [–8, –6], [0.1, 0.6] and [0, 800] (with spacings of 0.4, 0.1 and 100, respectively). We fix the subdominant parameters, such as the ICM temperature $T_{\text{ICM}}$ to $10^{5}$ K, and the clump column density to $10^{6}$ cm$^{-2}$ in order to reduce the dimensionality of the parameter space\(^11\).

Such a configuration amounts to 26244 models in total. Each model is calculated via radiative transfer using 10000 Ly$\alpha$ photon packages generated from a Gaussian intrinsic spectrum $N(0, \sigma_{\text{cl}})$, where $\sigma_{\text{cl}} = 12.85$ km s$^{-1}$ is the canonical thermal velocity dispersion of $T = 10^{5}$ K gas\(^11\). The sixth parameter, $\Delta v$, is varied continuously in post-processing. To properly explore the multimodal posterior of the parameters, we further use a python nested sampling package dynesty (Skilling 2004, 2006; Speagle 2020) to fit the Ly$\alpha$ spectra.

To demonstrate the feasibility of this fitting routine using clumpy models, we selected eleven representative Ly$\alpha$ spectra from the high SB regions, as shown in Figure 5. All of the spectra presented have been smoothed spatially by a 3 pixel × 3 pixel boxcar and were extracted by using an $R = 3$ pixel (0.9 arcsec) aperture. For each spectrum, we used 1500 live points (the initial randomly drawn samples from the prior) to calculate a set of clumpy models via linear flux interpolation on the grid and convolved with the KCWI LSF before comparing them to the observed Ly$\alpha$ profiles. The best-fit spectra are also shown in Figure 5.

4.2 Results

In Figure 5, one can see that most of the model fits match the observations reasonably well. The values of the fitted parameters are presented in Table 4, and the derived joint and marginal posterior probability distributions are presented in Appendix D. We find that different parameters affect the model spectra in different ways –

\(^10\) Note that the model spectra are sensitive to $\sim f_{\text{cl}}/f_{\text{cl},\text{crit}}$ but not to certain individual model parameters, such as the H I column density or the shape of the clumps (Hansen & Oh 2006).

\(^11\) For convenience we vary $F_{\text{Ly}\alpha}$ rather than $f_{\text{cl}}$ when generating clumps, but they are directly related via $f_{\text{cl}} = 3\rho_{\text{H}\alpha,\text{ICM}}/4\pi F_{\text{Ly}\alpha}$, where $r_{\text{cl}} = 5$ kpc is the radius of the simulation sphere and $r_{\text{cl}} = 50$ pc is the clump radius (hence $f_{\text{cl}} = 75 F_{\text{Ly}\alpha}$ in our case).

\(^12\) Here we modeled each observed spectrum with a set of parameters of the scattering medium independently, whereas in reality the Ly$\alpha$ photons are likely to be scattered by a common medium with spatially-varying parameters. The application of a more advanced, self-consistent model is beyond the scope of this work but will be explored in the future.

\(^13\) Note that we did not employ the commonly used ‘core-skipping’ technique, as it may cause artifacts in a multiphase medium.
Figure 5. Eleven representative continuum-subtracted, spatially-resolved Lyα profiles from the high SB regions in LAB1. All the spectra have been smoothed by a 3 pixel x 3 pixel boxcar (0.9") spatially and Gaussian smoothed (σ = 0.5 Å) in the wavelength dimension. The multiphase clumpy model best-fits (red, with orange 1-σ Poisson error bars) and the observed Lyα profiles (black, with grey 1-σ error bars) have both been normalized. The observed Lyα spectra have also been shifted by −Δυ to their local systemic redshifts. For each subpanel, the x-axis is the velocity (in km s⁻¹) with respect to the local systemic redshift, and the y-axis is the normalized line flux. The spectrum number of each spectrum has been marked on the SB map (the right panel). For visual reference, the horizontal and vertical black dashed lines in each subpanel indicate zero flux level and zero velocity with respect to the local systemic redshift, respectively.

Table 4. Fitted parameters of the multiphase clumpy model and derived quantities.

Notes. Fitted parameters (averages and 2.5% - 97.5% quantiles, i.e., 2-σ confidence intervals) of the multiphase clumpy model, derived quantities and spectral moments. The columns are: (1) the spectrum number (as marked in Figure 5); (2) the right ascension of the center of the extracted region; (3) the declination of the center of the extracted region; (4) the H I number density in the ICM; (5) the cloud volume filling factor; (6) the velocity dispersion of the clumps; (7) the radial outflow velocity of the clumps; (8) the H I outflow velocity in the ICM; (9) the velocity shift relative to z = 3.1000 (a negative/positive value means that the model spectrum has been blue/redshifted to match the data); (10) the clump covering fraction (defined as the number of clumps per line-of-sight) normalized by the critical clump covering fraction. In our case f_{cl} = 75 F_α. The critical clump covering fraction, f_{cl,Em}, determines different physical regimes and is calculated via Eq. (B3) (see Appendix B for a detailed derivation); (11) the optical depth at the Lyα line center of the H I in the ICM; (12) the first moment of the center of the extracted region; (13) the second moment of the center of the extracted region (corrected for KCW1 LSF).
The effects of each individual physical parameter in \([n_{\text{ICM}}, F_v, \sigma_{\text{cl}}, v_{\text{ICM}}, \Delta v]\) (taking spectrum 10 as an example). From the top left to the bottom right panel, one parameter is varied at a time (as shown in lines and labeled with different colors) and others are fixed (to the best-fit parameter values of spectrum 10, see Table 4). The red line in each panel represents the best-fit model of spectrum 10. The \(y\)-axis is the normalized line flux. It can be seen that different parameters affect the model spectra in different ways – \(n_{\text{ICM}}\) determines the overall shape and the trough depth of the spectrum; \(F_v\) and \(v_{\text{ICM}}\) determine the shapes and strengths of the peak(s); \(\sigma_{\text{cl}}\) determines the width of the spectrum; \(v_{\text{ICM}}\) determines the location of the main peak and the trough; \(\Delta v\) shifts the spectrum in the velocity dimension.

Specifically, spectra 1 and 2 (near the LBG C15) are clearly single-peaked, although spectrum 1 has a subdominant red bump. Interestingly, although spectrum 1 appears to be broader and has a larger \(\sigma_{\text{Ly} \alpha}\) on the moment map, it actually requires a smaller \(\sigma_{\text{cl}}\) (\(\sim 150 \text{ km s}^{-1}\)) than spectrum 2. The fit of spectrum 1 has a very large \(v_{\text{Ly} \alpha}\) (\(\sim 800 \text{ km s}^{-1}\)) and a negligible \(v_{\text{ICM}}\), whereas the fit of spectrum 2 has comparable \(v_{\text{Ly} \alpha}\) and \(v_{\text{ICM}}\) (both \(\sim 500 \text{ km s}^{-1}\)). This is due to the fact that multiphase outflows increase the asymmetry as well as the width of the spectra, and this degeneracy is not captured by the moment analysis. In particular, for spectrum 1, the optical depth at the \(\text{Ly} \alpha\) line center \(\tau_{\text{Ly} \alpha}\) \(\sim 1\), so the \(\text{Ly} \alpha\) photons likely interact with the ICM prior to the clumps (as opposed to spectrum 2 where \(\tau_{\text{Ly} \alpha} \ll 1\)). This implies that photons can then scatter approximately orthogonally off the clumps (see Appendix B), which yields an additional broadening of the spectrum that is larger than \(\sigma_{\text{cl}}\). The derived \(\Delta v\) (\(\sim 200 \text{ km s}^{-1}\)) is also consistent with the C15 systemic redshift (\(z = 3.0975\)) measured from [O III]. Also note that although spectrum 1 exhibits a blue dominant peak and a smaller red ‘hump’ (which is commonly interpreted as a signature of inflows), our outflow model has successfully reproduced the observed line profile.

Spectrum 3 has a fairly narrow main peak, which yields the lowest \(\sigma_{\text{cl}}\) (\(\sim 100 \text{ km s}^{-1}\)) of all eleven sampled spectra. The fit has comparable \(v_{\text{Ly} \alpha}\) and \(v_{\text{ICM}}\) (both \(\sim 350 \text{ km s}^{-1}\)) and a small \(\Delta v\) (\(\sim 50 \text{ km s}^{-1}\)). It also has some dubious emission on the far blue side, which is not captured by the clumpy models. Increasing \(\sigma_{\text{cl}}\) in order to include both the red and blue peaks could potentially provide a better fit but would lack physical motivation.

Spectra 4 and 5 (the tail of the tadpole) both possess two comparable peaks and a trough in the middle. The best-fit of the former is single-peaked, while the latter is double-peaked and captured the trough. Both fits have very large \(\sigma_{\text{cl}}\) (\(> 500 \text{ km s}^{-1}\)) to account for the line widths. The fit of spectrum 4 has comparably large \(v_{\text{Ly} \alpha}\) and \(v_{\text{ICM}}\) (both \(\sim 700 \text{ km s}^{-1}\)), whereas spectrum 5 has a \(v_{\text{Ly} \alpha}\) of \(\sim 500 \text{ km s}^{-1}\) and a negligible \(v_{\text{ICM}}\).

Spectra 6 and 7 (the body of the tadpole) are both multi-peaked and dominated by a red peak. The best-fits both have \(\sigma_{\text{cl}} \sim 450 \text{ km s}^{-1}\). They have moderate \(v_{\text{Ly} \alpha}\) (\(\sim 200 \text{ and } 400 \text{ km s}^{-1}\), respectively) and small \(v_{\text{ICM}} < 50 \text{ km s}^{-1}\) (dictated by the location of the absorption features).

Spectra 8 and 9 (the head of the tadpole, near ALMA-a) are both very broad (\(\sigma_{\text{cl}} \sim 500 \text{ km s}^{-1}\)) and red-dominant double-peaked with a deep trough between two peaks. They both have high \(F_v\) (\(\sim 0.5\)) and moderate \(v_{\text{Ly} \alpha}\) (\(\sim 250 \text{ km s}^{-1}\)) and \(v_{\text{ICM}}\) (\(\sim 400 \text{ km s}^{-1}\)).

Spectra 10 and 11 (near the LBG C11) are also red-dominant double-peaked, although with slightly narrower line widths (\(\sigma_{\text{cl}} \sim 400 \text{ km s}^{-1}\)). Compared with spectra 8 and 9, they have

\[n_{\text{ICM}} = 3 \times 10^{-8} \text{ cm}^{-3}, F_v = 0.28, \sigma_{\text{cl}} = 356 \text{ km s}^{-1}\]

\[v_{\text{ICM}} = 299 \text{ km s}^{-1}, \Delta v = -132 \text{ km s}^{-1}\]
lower $F_V$ ($<0.3$), comparable $v_{\perp}$ ($\sim 250 \text{ km s}^{-1}$) and lower $v_{\perp,\text{ICM}}$ ($<300 \text{ km s}^{-1}$). The derived $\Delta v$ of spectrum 10 ($\sim 150 \text{ km s}^{-1}$) is also consistent with the C11 systemic redshift ($z = 3.0980 \pm 0.0001$) measured from [O III]. Notably, the prominent double peak profiles in this region require a considerable outflow velocity for both the clumps and the ICM. This strongly suggests the presence of outflows, which is consistent with the indication of the large global velocity offsets between Ly$\alpha$, [O III] and SI.

It is noteworthy that although the observed $v_{\perp,\text{ICM}}$ is fairly small in many positions (e.g., spectra 4 – 9), large $\sigma_{v_{\perp}}$, $v_{\perp}$ and non-zero $v_{\perp,\text{ICM}}$ are still preferred by the broad, asymmetric Ly$\alpha$ profiles. This concerns us that the first moment does not fully capture the gas kinematic information encoded in the Ly$\alpha$ profiles. Second moments may be helpful in quantifying the line widths, whose possible physical interpretation is the random velocity dispersion of H I clumps. Furthermore, the outflow velocity (parameterized as $v_{\perp}$ and $v_{\perp,\text{ICM}}$ in the model) may be difficult to determine directly from the observed spectra (especially for complex Ly$\alpha$ profiles), but might be retrieved using realistic radiative transfer modeling.

In addition, we note that both the average and the standard deviation of all the derived $\Delta v$ are fairly small ($\langle \Delta v \rangle \sim 122 \text{ km s}^{-1}$, $\sigma(\Delta v) = 87 \text{ km s}^{-1}$), despite the large outflow velocities indicated by many of the Ly$\alpha$ profiles. This corresponds to an average systemic redshift of LAB1, $(\zeta_{\text{sys}}) = 3.0983 \pm 0.0004$.

We caution that the effect of Ly$\alpha$ absorption from the intergalactic medium (IGM) is not modeled in this work. It is expected that at $z \sim 3$ this effect is in general non-negligible on the blue side of the spectrum (Dijkstra et al. 2007; Laursen et al. 2011). However, we do not expect the effect of the IGM to be significant here, as it would cause sharp absorption troughs and yield multiple peaks, which should be clearly visible given the widths of the observed spectra (see Byrohl & Gronke 2020 for a discussion of this effect) instead of simply attenuating the spectrum smoothly.

To recap, the main results of our analysis are:

(i) The observed Ly$\alpha$ spectra require relatively few clumps per line-of-sight ($f_{\text{cl}} \lesssim f_{\text{cl},\text{tot}}$) as they have significant fluxes at the line center. Therefore, they are very different from the spectra of most Ly$\alpha$ emitting galaxies at essentially all redshifts (e.g., Steidel et al. 2010; Erb et al. 2014; Trinh et al. 2015; Yang et al. 2016, 2017; Gronke 2017; Ortolivo et al. 2018), which can usually be reproduced by a uniform medium (e.g., the ‘shell model’) or by a multiphase medium with a large number of H I clumps ($f_{\text{cl}} \gg f_{\text{cl},\text{tot}}$).

(ii) The velocity dispersion of the scattering clumps yields a broadening of the spectra from the intrinsic line width $\sigma_1 \sim 13 \text{ km s}^{-1}$ to $\gg 100 \text{ km s}^{-1}$ as observed. This is possible when $f_{\text{cl}} \sim \alpha_{\text{f},\text{cl,\text{tot}}}$ with $\alpha \sim$ a few$^{17}$. Such a process may be crucial in galaxies where the observed Ly$\alpha$ line is always broader, usually by at least a factor of two, than the corresponding non-resonant lines such as [O III], H$\alpha$ or H$\beta$ (e.g., Ortolivo et al. 2018).

(iii) While the widths of the spectra are set primarily by the velocity dispersion of the clumps, i.e., $\sigma_{\text{Ly} \alpha} \sim \sigma_1$, we found that the clump bulk outflow can also cause additional broadening, as seen in spectrum 1. In this case, one might naively assume that the photons do not interact with the clumps due to their large velocity offsets ($v_{\perp} \gg \sigma_1$). However, if $n_{\text{ICM}} \gtrsim 1$, the photons may first interact

15 This is also notable in cases where an [O III] measurement is available and the velocity offset between Ly$\alpha$ and [O III] is close to zero (e.g., spectra 1 and 2).

16 The success of shell model fitting may no longer be achieved when the model parameters are further constrained by additional observations (e.g., optical emission lines or UV absorption lines, see Ortolivo et al. 2018).

17 Note that the scattering off the surface of the clumps broadens the spectrum as long as $\sigma_2 > \sigma_1$ (and $f_{\text{cl}} \sim f_{\text{cl},\text{tot}}$). Hence, the emergent spectra are insensitive to the exact value of $\sigma_1$ with the ICM, which significantly reduces the parallel component of $v_{\perp}$ ($v_{\perp,\text{ICM}}$) appearing to the photons, and hence greatly increases the optical depth. This result suggests that we may have interpreted our model too naively (e.g., using single-scattering approximation), especially considering that the kinematics of our model are clearly simplistic and not strictly hydrodynamically stable (we usually expect $v_{\perp} \sim v_{\perp,\text{ICM}}$, i.e., the clouds are entrained by the local flow, see e.g., Klein et al. 1994; Li et al. 2020)\textsuperscript{18}. Moreover, although we found that significant outflow velocities ($\gtrsim 100 \text{ km s}^{-1}$) are required to reproduce the observed spectra, the exact values may still be subject to considerable uncertainties, due to the internal degeneracies and the presumably more complicated kinematics in reality (e.g., Steidel et al. 2010 show that gas outflows even within the same galaxy have a range of velocities that goes from 0 to 800 km s$^{-1}$ with varying effective optical depths).

(iv) In our best-fit spectra, the H I in the ICM is responsible for the absorption feature close to the line center (cf. spectrum 5 or 6). However, several tentative absorption features can be present in a single spectrum (e.g., spectra 5, 6, 7 and 9), and they are not captured simultaneously by our model. These multiple features might be caused by the H I in the outer CGM / IGM, where the probability of back-scattering into the line-of-sight is negligible.

The derived values of our fitted parameters also fit into a broader picture in at least two ways:

(i) The $\sigma_{v_{\perp}}$ values correspond to reasonable dark matter halo masses. The dynamical mass of the LAB1 halo can be estimated from the velocity dispersion and physical size (assuming spherical symmetry):

$$M_{\text{dyn}} = \frac{3\pi^2 R}{G} = 6.9 \times 10^9 \left(\frac{\sigma_{v_{\perp}}}{100 \text{ km s}^{-1}}\right)^2 \left(\frac{R}{\text{kpc}}\right) M_\odot.$$  \hspace{0.5cm} (3)

Taking $R \sim 100$ kpc, the highest $\sigma_{v_{\perp}}$ ($\sim 700 \text{ km s}^{-1}$) corresponds to $M_{\text{dyn}} \sim 10^{13.5} M_\odot$. This result is consistent with the predicted halo masses from the Millennium simulations at $z = 3.06$. As calculated by Kubo et al. (2016), the halo masses range from $10^{12.2}$ to $10^{14.0} M_\odot$ (with median $10^{13.2} M_\odot$) for the De Lucia & Blaizot (2007) model, and from $10^{12.4}$ to $10^{14.2} M_\odot$ (with median $10^{13.2} M_\odot$) for the Guo et al. (2011) model.

(ii) The $V_{\text{cl}}$ values correspond to reasonable survival times of the clumps. Here we consider two different criteria proposed by Li et al. (2020) and Gronke & Oh (2018), respectively. Following Li et al. (2020), assuming the ionized medium has H I number density $n_{\text{hot}} = 0.01 \text{ cm}^{-3}$, an outflow velocity $v_{\perp} \sim 500 \text{ km s}^{-1}$ corresponds to a cloud lifetime $t_{\text{cloud}} \sim 100$ Myr. The cooling time of the hot medium, $t_{\text{cool,hot}} \sim 30$ Myr $\lesssim t_{\text{life}}$. Whereas following Gronke & Oh (2018), the cooling time of the mixing layer $t_{\text{cool,\text{mix}}} \sim 3$ Myr, and the cloud-crushing time $t_c \sim 1$ Myr $\gg t_{\text{cool,\text{mix}}}$, which implies possible survival of the cold gas. So either criterion indicates that the clumps can survive for a fairly long time, and may even grow in mass as they accrete the cooling hot material from the ambient medium.

Recently, Herenz et al. (2020) have reported a significant detection of He II $\lambda 1640$ emission in three regions of LAB1 (which are close to C15, the tail of the tadpole structure, and C11, respectively) as well as a non-detection of C IV $\lambda 1548, 1550$ doublet. They have carried out a detailed analysis and concluded that their observed He II/Ly$\alpha$ and C IV/Ly$\alpha$ ratios are consistent with cooling radiation, feedback driven shocks, and/or photo-ionisation from an embedded AGN. We examined our MOSFIRE spectra around these regions but did not find additional rest-UV collisionally excited emission lines near Ly$\alpha$ that are significant, although we do

18 We do see $v_{\perp} \sim v_{\perp,\text{ICM}}$ in our fits of spectra 3, 4, 5, 10 and 11.
see significant outflow velocities in these three regions (cf. spectra 1, 2, 5, 10, and 11). More observations are needed to distinguish these different powering mechanisms.

In summary, the multiphase clumpy model is versatile enough to reproduce the diverse Lyα morphologies observed. The fitting results are still, not surprisingly, model dependent – different assumptions on the geometry and moving pattern of the H i gas may yield different results. Furthermore, our modeling with parameters of scattering medium varying independently at different locations can be handled in a more self-consistent manner, as in reality the Lyα photons are likely to be scattered by a common, spatially varying medium. Nonetheless, our analysis is a first attempt to model the spatially-resolved Lyα profiles in LAB1 with more physically realistic clumpy models. It provides us with insights on the gas kinematics and will serve as the foundation of more advanced radiative transfer modeling in the future. One promising future direction is to use more elaborate clump velocity profiles (e.g., consistent with absorption line observations) which can alter $f_{\text{cl,ot}}$(cf. Appendix B).

We will explore such new physical regimes in our future work.

5 CONCLUSIONS

We have carried out deep spectroscopic observations of SSA22-LAB1 at $z = 3.1$ using KCWI and MOSFIRE. The main conclusions of our analysis are:

(i) By applying matched filtering to the KCWI datacube, we have created a narrow-band Lyα image of LAB1. The most prominent feature is a tadpole-shaped structure, whose ‘head’ overlaps with one of the ALMA sources yet whose ‘tail’ does not associate with any identified sources;

(ii) By comparing the spatial distributions and intensities of Lyα and Hβ, we find that recombinations of photo-ionized H i gas followed by resonant scattering is sufficient to explain all the observed Lyα/Hβ ratios;

(iii) Using both moment map analysis and MCRT modeling, we have managed to extract physical information from the spatially-resolved Lyα profiles. We find that moment maps can be used as a crude indicator of the H i gas kinematics, but realistic MCRT modeling needs to be invoked to extract detailed kinematic information and make physical interpretations. By fitting a set of multiphase, ‘clumpy’ models to the observed Lyα profiles, we are able to reason-sonably constrain many physical parameters, namely the H i number density in the ICM, the cloud volume filling factor, the random velocity and outflow velocity of the clumps, the H i outflow velocity of the ICM and the local systemic redshift. Our model has successfully reproduced the diverse Lyα morphologies at different locations, and the main results are: (1) The observed Lyα spectra require relatively few clumps per line-of-sight ($f_{\text{cl}} \lesssim f_{\text{cl,ot}}$) as they have significant fluxes at the line center; (2) The velocity dispersion of the clump outflow velocity appearing to the photons, and hence greatly increases the optical depth of the clumps; (4) The H i in the ICM is responsible for the absorption feature close to the Lyα line center.

We caution that there are still a number of caveats to this study. For example, our MCRT modeling is inherently model dependent, in particular on the specific assumptions about the kinematics of the cold clumps. A combination of results from hydrodynamical simulations and additional observations (e.g., absorption line studies) may help constrain the actual gas kinematics better. We intend to explore these possibilities in our future work.

ACKNOWLEDGEMENTS

We thank the referee for insightful comments that have significantly improved the paper. We also thank Phil Hopkins for providing us with adequate computational resources. ZL acknowledges Michael Zhang, for his professional guidance and kind company during the excruciating debugging process. The data presented herein were obtained at the W. M. Keck Observatory, which is operated as a scientific partnership among the California Institute of Technology, the University of California and the National Aeronautics and Space Administration. The Observatory was made possible by the generous financial support of the W. M. Keck Foundation. We are also grateful to the dedicated staff of the W.M. Keck Observatory who keep the instruments and telescopes running effectively. MG was supported by NASA through the NASA Hubble Fellowship grant HST-HF2-51409 awarded by the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., for NASA, under contract NAS5-26555. Numerical calculations were run on the Caltech compute cluster “Wheeler,” allocations from XSEDE TG-AST130039 and PRAC NSF.1713353 supported by the NSF, and NASA HEC SMD-16-7592. This research made use of montage. It is funded by the National Science Foundation under Grant Number ACI-1440620, and was previously funded by the National Aeronautics and Space Administration’s Earth Science Technology Office, Computation Technologies Project, under Cooperative Agreement Number NCCS-626 between NASA and the California Institute of Technology.

Gas Kinematics in LAB1 13
APPENDIX A: GAUSSIAN FITS TO THE [OIII] PROFILES OF LBGs C11 AND C15

In order to determine the systemic redshifts of two LBGs, C11 and C15, we fitted the [O III] profiles (5008.24 Å) with single Gaussians.
We used the PySpecKit package (Ginsburg & Mirocha 2011) to fit the [OIII] profiles with a single Gaussian model:

\[
F_\lambda = F_\lambda^0 e^{-\left(\frac{\lambda - \lambda_0}{\sigma}\right)^2}
\]

(A1)

The fitting results and derived values with 1-σ uncertainties of the free parameters \((F_\lambda^0, \lambda_0\) and \(\sigma\)) are shown in Figure A1. The systemic redshifts of C11 and C15 are therefore determined to be \(z(C11) = 3.0980 \pm 0.0001, z(C15) = 3.0975 \pm 0.0001\) (accounting for the typical redshift achievement by MOSFIRE measurements reported in Steidel et al. 2014).

**APPENDIX B: DERIVATION OF THE CRITICAL CLUMP COVERING FRACTION**

Here we analytically derive the critical clump covering fraction, \(f_{cl, crit}\), for a multimultiphase medium whose kinematics have been defined earlier in this work, i.e., H\(_I\) clumps with a constant outflow velocity \(v_{cl}\) and a velocity dispersion \(\sigma_{cl}\), and an inter-clump medium (ICM) with a constant outflow velocity \(v_{ICM}\). The optical depth of the H\(_I\) in the ICM at the Ly\(_\alpha\) intrinsic frequency is approximated as \(\tau_{ICM}\), i.e., the optical depth at the line center\(^{19}\).

The large widths of the observed spectra imply that photons escape in a single long flight – after they have been scattered off the surface of a fast moving clump (Gronke et al. 2017). It follows that \(f_{cl, crit}\) is given by the condition that on average one clump interacts with a photon at its intrinsic frequency.

The width in velocity space of each clump, \(\tilde{\sigma}\), is determined by:

\[
\tau_{cl}(\pm \tilde{\sigma}/2) = \frac{4}{3} N_{HI, cl} \sigma_{HI}(\pm \tilde{\sigma}/2) = 1
\]

(B1)

where \(\tau_{cl}\) is the optical depth of the clump, \(N_{HI, cl}\) is the H\(_I\) column density of the clump, and \(\sigma_{HI}\) is the Ly\(_\alpha\) cross section of the clump. The factor 4/3 is simply due to the spherical geometry of the clump. Using the core approximation of the Ly\(_\alpha\) cross section \((\sigma_{HI}(v) \propto \exp(-v^2/\tilde{\sigma}_{HI}^2))\), the solution to Eq. (B1) can be explicitly written as \(\tilde{\sigma} = 2\sqrt{\ln \tau_{HI}}\), where \(\tilde{\sigma}_{HI}(v = 0)\), and \(v_{th}\) is the thermal velocity dispersion of H\(_I\) within the clumps. For the H\(_I\) column density and temperature of the clumps used in this work, \(\sqrt{\tilde{\sigma}} \approx 78\ km\ s^{-1}\).

Under the assumption that all photons are injected at the Ly\(_\alpha\) line center (which is a reasonable approximation for our setup since the width of the intrinsic spectrum \(\sigma_{I} \ll \sigma_{cl}\)), the average number of clumps per line-of-sight that intersect with \(v = 0\) in velocity space is:

\[
f_{cl} = \int_{-\tilde{\sigma}}^{\tilde{\sigma}} N(v, \mu = v_{cl, ||}, \sigma = \sigma_{cl}) dv
\]

(B2)

where \(N\) denotes the normal distribution function for the velocity distribution of the clumps\(^{20}\). Here \(v_{cl, ||}\) is a component of \(v_{cl}\) that is parallel to the trajectories of photons. The reason for considering \(v_{cl, ||}\) rather than \(v_{cl}\) is explained below.

Given the considerations above, demanding \(f_{cl} = 1\) yields the critical number of clumps per line-of-sight (i.e., the clump covering fraction):

\[
f_{cl, crit} = \frac{2}{\text{erf} \left( \frac{-v_{cl, ||} + 2\sigma_{cl} \sqrt{\ln \tau_{cl}}}{\sqrt{2} \sigma_{cl}} \right) + \text{erf} \left( \frac{v_{cl, ||} + 2\sigma_{cl} \sqrt{\ln \tau_{cl}}}{\sqrt{2} \sigma_{cl}} \right)}.
\]

(B3)

where \(\text{erf}(x)\) is the Gauss error function.

Note that this equation is a generalization of equation (12) in Gronke et al. (2017), where the radial velocity distribution of the clumps is approximated as a tophat profile. It converges to that equation when \(v_{cl, ||} \ll \sigma_{cl}\). For \(v_{cl, ||} \gg \sigma_{cl}\), this equation yields very large values of \(f_{cl, crit}\).

Here we discuss \(v_{cl, ||}\) for two different cases: (1) If \(\tau_{ICM} \ll 1\), initially the photons do not interact with the ICM. Therefore, \(v_{cl, ||} \approx v_{cl}\); (2) If \(\tau_{ICM} \sim 1\) (up to a few), the photons can interact with the ICM prior to the clumps, and thus are likely to scatter orthogonally to the clump bulk outflow. Therefore, \(v_{cl, ||} \approx 0\) (with details depending on the exact value of \(\tau_{ICM}\) and the clump distribution).

We do not consider \(\tau_{ICM} \gg 1\) cases, where the multiphase, clumpy medium converges to a homogeneous medium that would fail to reproduce the observed spectra presented in this work (cf. discussion in §4).

**APPENDIX C: JUSTIFICATION OF USING SPATIALLY-INTEGRATED MODELS TO FIT THE SPATIALLY-RESOLVED Ly\(_\alpha\) PROFILES**

In this work, we have fitted spatially-resolved Ly\(_\alpha\) profiles with spatially-integrated models, which are derived from Ly\(_\alpha\) photons from the entire scattering region. Here we emphasize that qualitatively, these spatially-integrated models are very similar to the binned models, which are derived from Ly\(_\alpha\) photons within a certain impact parameter range.

We illustrate this in Figure C1. With spectra 1 and 2 as two examples, we binned all the scattered photons according to their impact parameters, \(b\) (the projected distance to the simulation center perpendicular to the line-of-sight). Assuming the largest impact parameter of all the photons is \(b_{max}\), we made three photon bins within the 2σ range (0.05 < \(b/b_{max}\) ≤ 0.35, 0.35 < \(b/b_{max}\) ≤ 0.65 and 0.65 < \(b/b_{max}\) ≤ 0.95) and constructed three binned model spectra with these photon bins respectively. It can be seen the binned models are qualitatively very similar to the integrated model. Therefore, it is approximately correct to model the spatially-resolved profiles at positions away from the Ly\(_\alpha\) emitting sources with spatially-integrated models.

The aim of our modeling in this work is to roughly extract the velocities and densities of H\(_I\) that the Ly\(_\alpha\) photons ‘experience’ in situ. In our following work, we plan to model the spatially-resolved profiles in a more self-consistent way (e.g., modeling the spatially-resolved Ly\(_\alpha\) profiles with a common scattering medium).

**APPENDIX D: POSTERIOR PROBABILITY DISTRIBUTIONS DERIVED FROM NESTED SAMPLING**

Here we present the joint and marginal posterior probability distributions of the multiphase clumpy model parameters for all eleven representative Ly\(_\alpha\) spectra derived from nested sampling. For each spectrum, we also show the best-fit, the observed Ly\(_\alpha\) profile and five model spectrum samples from nested sampling.

This paper has been typeset from a TeX/LaTeX file prepared by the author.
Figure A1. Single Gaussian fits to the observed [O\textsc{iii}] profiles of two LBGs, C11 and C15. The [O\textsc{iii}] emission is spatially integrated over the ranges indicated by black solid arrows in Figure 3, which include all the significant [O\textsc{iii}] emission of C11 and C15. The observed fluxes (shown in black) with 1-\sigma uncertainties (shaded in grey), the best-fit model (shown in red) and best-fit parameters (with 1-\sigma uncertainties) are shown in each panel. Note that skylines are present near the [O\textsc{iii}] lines, as indicated by large flux uncertainties.

Figure C1. Justification of using spatially-integrated models to fit the spatially-resolved Ly\textalpha\ profiles. Left: Configuration of the multiphase, clumpy model and the way we construct our photon bins for the observer. Right: Comparison of integrated models and binned models for spectra 1 and 2. Assuming the largest impact parameter of all the photons is $b_{\text{max}}$, we made three photon bins within the 2\sigma range ($0 < b/b_{\text{max}} \leq 0.05$, $0.05 < b/b_{\text{max}} \leq 0.35$, $0.35 < b/b_{\text{max}} \leq 0.65$, $0.65 < b/b_{\text{max}} \leq 0.95$) and constructed three binned model spectra with these photon bins respectively. It can be seen the binned models are qualitatively very similar to the integrated model.
Figure D1. Joint and marginal posterior probability distributions of the multiphase clumpy model parameters for all eleven representative Ly\(\alpha\) spectra derived from nested sampling. The vertical black dashed lines indicate the [2.5\%, 50\%, 97.5\%] quantiles (i.e., 2-\(\sigma\) confidence intervals). The vertical red dashed lines indicate the locations of the maximum posterior probability. The upper right panels show the best-fits (red, with orange 1-\(\sigma\) Poisson errors), the observed Ly\(\alpha\) profiles (black, with grey 1-\(\sigma\) error bars) and five model spectrum samples from nested sampling (blue) in the same way as Figure 5.
