Information Inequalities for Joint Distributions, with Interpretations and Applications

Mokshay Madiman, Member, IEEE, and Prasad Tetali, Member, IEEE

Abstract—Upper and lower bounds are obtained for the joint entropy of a collection of random variables in terms of an arbitrary collection of subset joint entropies. These inequalities generalize Shannon’s chain rule for entropy as well as inequalities of Han, Fujishige and Shearer. A duality between the upper and lower bounds for joint entropy is developed. All of these results are shown to be special cases of general, new results for submodular functions—thus, the inequalities presented constitute a richly structured class of Shannon-type inequalities. The new inequalities are applied to obtain new results in combinatorics, such as bounds on the number of independent sets in an arbitrary graph and the number of zero-error source-channel codes, as well as new determinantal inequalities in matrix theory. A new inequality for relative entropies is also developed, along with interpretations in terms of hypothesis testing. Finally, revealing connections of the results to literature in economics, computer science, and physics are explored.

Index Terms—Entropy inequality; inequality for minors; entropy-based counting; submodularity.

I. INTRODUCTION

Let $X_1, X_2, \ldots, X_n$ be a collection of random variables. There are the familiar two canonical cases: (a) the random variables are real-valued and possess a probability density function, in which case $h$ represents the differential entropy, or (b) they are discrete, in which case $H$ represents the discrete entropy. More generally, if the joint distribution has a density $f$ with respect to some reference product measure, the joint entropy may be defined by $-E[\log f(X_1, X_2, \ldots, X_n)]$; with this definition, $H$ corresponds to counting measure and $h$ to Lebesgue measure. The only assumption we will implicitly make throughout is that the joint entropy is finite, i.e., neither $-\infty$ nor $+\infty$.

We wish to discuss the relationship between the joint entropies of various subsets of the random variables $X_1, X_2, \ldots, X_n$. Thus we are motivated to consider an arbitrary collection $C$ of subsets of $\{1, 2, \ldots, n\}$. The following conventions are useful:

- $[n]$ is the index set $\{1, 2, \ldots, n\}$. We equip this set with its natural (increasing) order, so that $1 < 2 \ldots < n$.

Any other total order would do equally well, and indeed we use this flexibility later, but it is convenient to fix a default order.)

- For any set $s \subset [n]$, $X_s$ stands for the collection of random variables $(X_i : i \in s)$, with the indices taken in their increasing order.

- For any index $i$ in $[n]$, define the degree of $i$ in $C$ as $r(i) = |\{t \in C : i \in t\}|$. Let $r_-(s) = \min_{i \in s} r(i)$ denote the minimal degree in $s$, and $r_+(s) = \max_{i \in s} r(i)$ denote the maximal degree in $s$.

First we present a weak form of our main inequality.

Proposition I: [Weak degree form] Let $X_1, \ldots, X_n$ be arbitrary random variables jointly distributed on some discrete sets. For any collection $C$ such that each index $i$ has non-zero degree,

$$\sum_{s \in C} \frac{H(X_s | X_s^c)}{r_+(s)} \leq H(X_n) \leq \sum_{s \in C} \frac{H(X_s)}{r_-(s)},$$

(1)

where $r_+(s)$ and $r_-(s)$ are the maximal and minimal degrees in $s$. If $C$ satisfies $r_-(s) = r_+(s)$ for each $s$ in $C$, then also holds for $h$ in the setting of continuous random variables.

Proposition I unifies a large number of inequalities in the literature. Indeed,

1) Applying to the class $C_1$ of singletons,

$$\sum_{i=1}^{n} H(X_i | X_n \setminus i) \leq H(X_n) \leq \sum_{i=1}^{n} H(X_i).$$

(2)

The upper bound represents the subadditivity of entropy noticed by Shannon. The lower bound may be interpreted as the fact that the erasure entropy of a collection of random variables is not greater than their entropy; see Section VI for further comments.

2) Applying to the class $C_{n-1}$ of all sets of $n-1$ elements,

$$\frac{1}{n-1} \sum_{i=1}^{n} H(X_n \setminus i | X_i) \leq H(X_n) \leq \frac{1}{n-1} \sum_{i=1}^{n} H(X_n \setminus i).$$

(3)

This is Han’s inequality [23], [10], in its prototypical form.

3) Let $r_+ = \min_{i \in [n]} r(i)$ and $r_- = \max_{i \in [n]} r(i)$ be the minimal and maximal degrees with respect to $C$. Using $r_- \leq r_-(s)$ and $r_+ \leq r_+(s)$, we have

$$\frac{1}{r_+} \sum_{s \in C} H(X_s | X_s^c) \leq H(X_n) \leq \frac{1}{r_-} \sum_{s \in C} H(X_s).$$

The upper bound is Shearer’s lemma [9], known in the combinatorics literature [43]. The lower bound is new.

The paper is organized as follows. First, in Section II we present the notions of fractional coverings and packings using hypergraphs, which provide a useful language for the information inequalities we present, are developed. In Section III we present the main technical result of this paper, which is a new inequality for submodular functions. Section IV presents the main entropy inequality of this paper, which strengthens Proposition I, and gives a very simple proof as a corollary of the general result for submodular functions. This entropy inequality is developed in two forms, which we call the strong fractional form and the strong degree form; Proposition I may then be thought of as the weak degree form. A different manifestation of the upper bound in this weak degree form then be thought of as the weak degree form. A different inequality was recently proved (in a more involved manifestation of the upper bound in this weak degree form. A different inequality is developed in two forms, which we call the strong fractional form and the strong degree form; Proposition I may present the main technical result of this paper, which is a new inequality for submodular functions. A different manifestation of the upper bound in this weak degree form then be thought of as the weak degree form. A different inequality was recently proved (in a more involved manifestation of the upper bound in this weak degree form.

II. ON HYPERGRAPHS AND RELATED CONCEPTS

It is appropriate here to recall some terminology from discrete mathematics. A collection $C$ of subsets of $[n]$ is called a hypergraph, and each set $s$ in $C$ is called a hyperedge. When each hyperedge has cardinality 2, then $C$ can be thought of as the set of edges of an undirected graph on $n$ labelled vertices. Thus all the statements made above can be translated into the language of hypergraphs. In the rest of this paper, we interchangeably use “hypergraph” and “collection” for $C$, “hyperedge” and “set” for $s$ in $C$, and “vertex” and “index” for $i$ in $[n]$.

We have the following standard definitions.

**Definition I:** The collection $C$ is said to be $r$-regular if each index $i$ in $[n]$ has the same degree $r$, i.e., if each vertex $i$ appears in exactly $r$ hyperedges of $C$.

The following definitions extend the familiar notion of packings, coverings and partitions of sets by allowing fractional counts. The history of these notions is unclear to us, but some references can be found in the book by Scheinerman and Ullman [44].

**Definition II:** Given a collection $C$ of subsets of $[n]$, a function $\alpha : C \to R^+$, is called a fractional covering, if for each $i \in [n]$, we have $\sum_{s \in C : i \in s} \alpha(s) \geq 1$.

Given $C$, a function $\beta : C \to R^+$ is a fractional packing, if for each $i \in [n]$, we have $\sum_{s \in C : i \in s} \beta(s) \leq 1$.

If $\gamma : C \to R^+$ is both a fractional covering and a fractional packing, we call $\gamma$ a fractional partition.

Note that the standard definition of a fractional packing of $[n]$ using $C$ (as in [44]), would assign weights $\beta_i$ to the elements, (rather than sets) $i \in [n]$, and require that, for each $s \in C$, we have $\sum_{i \in s} \beta_i \leq 1$. Our terminology can be justified, if one considers the “dual hypergraph,” obtained by interchanging the role of elements and sets – consider the 0-1 incidence matrix (with rows indexed by the elements and columns by the sets) of the set system, and simply switch the roles of the elements and the sets.

The following simple lemmas are useful.

**Lemma I:** (Fractional Additivity) Let $\{a_i : i \in [n]\}$ be an arbitrary collection of real numbers. For any $s \subset [n]$, define $a_s = \sum_{j \in s} a_j$. For any fractional partition $\gamma$ using any hypergraph $C$, $a_{[n]} = \sum_{s \in C} \gamma(s)a_s$. Furthermore, if each
\[ a_i \geq 0, \text{ then } \sum_{s \in C} \beta(s)a_s \leq a_{[n]} \leq \sum_{s \in C} \alpha(s)a_s \]  
for any fractional packing \( \beta \) and any fractional covering \( \alpha \) using \( C \).

**Proof:** Interchanging sums implies
\[
\sum_{s \in C} \alpha(s) \sum_{i \in s} a_i = \sum_{i \in [n]} \sum_{s \in C} a_i \alpha(s) \mathbb{1}_{\{i \in s\}} \geq \sum_{i \in [n]} a_i,
\]
using the definition of a fractional covering. The other statements are similarly obvious.

We introduce the notion of quasiregular hypergraphs.

**Definition III:** The hypergraph \( C \) is quasiregular if the degree function \( r : [n] \to \mathbb{Z}_+ \) defined by \( r(i) = |\{s \in C : s \ni i\}| \) is constant on \( s \), for each \( s \in C \).

**Example:** One can construct simple examples of quasiregular hypergraphs using what are called bi-regular graphs in the graph theory literature. Consider a bipartite graph on vertex sets \( V_1 \) and \( V_2 \) (i.e., all edges go between \( V_1 \) and \( V_2 \)), such that every vertex in \( V_1 \) has degree \( r_1 \) and every vertex in \( V_2 \) has degree \( r_2 \). Such a graph always exists if \( |V_1|r_1 = |V_2|r_2 \). Now consider the hypergraph on \( V_1 \cup V_2 \) with hyperedges being the neighborhoods of vertices in the bipartite graph. This hypergraph is quasiregular (with degrees being \( r_1 \) and \( r_2 \)), and it is not regular if \( r_1 \) is different from \( r_2 \).

There is a sense in which all quasiregular hypergraphs are similar to the example above; specifically, any quasiregular hypergraph has a canonical decomposition as a disjoint union of regular subhypergraphs.

**Lemma II:** Suppose the hypergraph \( C \) on the vertex set \([n] \) is quasiregular. Then one can partition \([n] \) into disjoint subsets \( \{V_m\} \), and \( C \) into disjoint subhypergraphs \( \{C_m\} \) such that each \( C_m \) is a regular hypergraph on vertex set \( V_m \).

**Proof:** Consider the equivalence relation on \([n] \) induced by the degree, i.e., \( i \) and \( j \) are related if \( r(i) = r(j) \). This relation decomposes \([n] \) into disjoint equivalence classes \( \{V_m\} \). Since \( C \) is quasiregular, all indices in \( s \) have the same degree for each set \( s \in C \), and hence each \( s \in C \) is a subset of exactly one equivalence class \( V_m \). Q.E.D.

The notion of quasiregularity is related to what we believe is an important and natural fractional covering/packing pair. As long as there is at least one set \( s \) in the hypergraph \( C \) that contains \( i \), we have
\[
\sum_{s \in C, s \ni i} \frac{1}{r_-(s)} = \sum_{s \in C} \frac{1_{\{i \in s\}}}{r_-(s)} \geq \sum_{s \in C} \frac{1_{\{i \in s\}}}{r(i)} = 1,
\]
so that \( \alpha(s) = \frac{1}{r_-(s)} \) provide a fractional covering. Similarly, the numbers \( \beta(s) = \frac{1}{r_+(s)} \) provide a fractional packing.

**Definition IV:** Let \( C \) be any hypergraph on \([n] \) such that every index appears in at least one hyperedge. The fractional covering given by \( \alpha(s) = \frac{1}{r_-(s)} \) is called the degree covering, and the fractional packing given by \( \beta(s) = \frac{1}{r_+(s)} \) is called the degree packing.

The following lemma is a trivial consequence of the definitions.

**Lemma III:** If \( C \) is quasiregular, the degree packing and degree covering coincide and provide a fractional partition of \([n] \) using \( C \). In particular, \( a_{[n]} = \sum_{s \in C} a_s/r_-(s) \).

One may define the weight of a fractional packing as follows.

**Definition V:** Let \( \gamma \) be a fractional partition (or a fractional covering or packing). Then the weight of \( \gamma \) is \( w(\gamma) = \sum_{s \in C} \gamma(s) \).

There are natural optimization problems associated with the weight function. The problem of minimizing the weight of \( \alpha \) over all fractional coverings \( \alpha \) is the called the optimal fractional covering problem, and that of maximizing the weight of \( \beta \) over all fractional packings \( \beta \) is the called the optimal fractional packing problem. These are linear programming relaxations of the integer programs associated with optimal covering and optimal packing, which are of course important in many applications. Much work has been done on these problems, including studies of the integrality gap (see, e.g., [44]).

One may also define a notion of duality for fractional partitions.

**Definition VI:** For any hypergraph \( C \), define the complimentary hypergraph as \( \bar{C} = \{s^c : s \in C\} \). If \( \alpha \) is a fractional covering (or packing) using \( C \), the dual fractional packing (respectively, covering) using \( \bar{C} \) is defined by
\[
\bar{\alpha}(s^c) = \frac{\alpha(s)}{w(\alpha) - 1}.
\]

To see that this definition makes sense (say for the case of a fractional covering \( \alpha \)), note that for each \( i \in [n] \),
\[
\sum_{s^c \in \bar{C}, s^c \ni i} \bar{\alpha}(s^c) = \sum_{s \in C, i \notin s} \frac{\alpha(s)}{w(\alpha) - 1} = \frac{\sum_{s \in C} \alpha(s) - \sum_{s \in C, i \in s} \alpha(s)}{w(\alpha) - 1} \leq \frac{w(\alpha) - 1}{w(\alpha) - 1} = 1.
\]

### III. A NEW INEQUALITY FOR SUBMODULAR FUNCTIONS

The following definitions are necessary in order to state the main technical result of this paper.

**Definition VII:** The set function \( f : 2^{[n]} \to \mathbb{R} \) is submodular if
\[
f(s) + f(t) \geq f(s \cup t) + f(s \cap t)
\]
for every $s, t \subset [n]$. If $-f$ is submodular, we say that $f$ is supermodular.

**Definition VIII:** For any disjoint subsets $s$ and $t$ of $[n]$, define $f(s \cup t) = f(s \cup t) - f(t)$. For a fixed subset $t \subseteq [n]$, the function $f_t : 2^{[n] \setminus t} \to \mathbb{R}$ defined by $f_t(s) = f(s \cup t)$ is called $f$ conditional on $t$.

For any $s \subset [n]$, denote by $< s$ the set of indices less than every index in $s$. Similarly, $> s$ is the set of indices greater than every index in $s$. Also, the index $i$ is identified with the set $\{i\}$; thus, for instance, $< i$ is well-defined. We also write $[i : i+k]$ for $\{i, i+1, \ldots, i+k-1, i+k\}$. Note that $[n] = [1 : n]$.

**Lemma IV:** Let $f : 2^{[n]} \to \mathbb{R}$ be any submodular function with $f(\phi) = 0$.

1) If $s, t, u$ are disjoint sets, 
\[ f(s \cup t, u) \leq f(s \cup t), \tag{5} \]

2) The following “chain rule” expression holds for $f([n])$:
\[ f([n]) = \sum_{i \in [n]} f(i < i). \]

**Proof:** First note that if $s, t, u$ are disjoint sets, then submodularity implies
\[ f(s \cup t \cup u) + f(t) \leq f(s \cup t) + f(t \cup u), \]
which is equivalent to $f(s \cup t, u) \leq f(s \cup t)$.

The “chain rule” expression for $f([n])$ is obtained by induction. Note that $f([2]) = f(1) + f(2|1) = f(1|\phi) + f(2|1)$ since $f(\phi) = 0$. Now assume the chain rule holds for $[n]$, and observe that
\[ f([n+1]) = f([n]) + f(n+1|n) = \sum_{i \in [n+1]} f(i < i), \]
where we used the induction hypothesis for the second equality.

**Theorem I:** Let $f : 2^{[n]} \to \mathbb{R}$ be any submodular function with $f(\phi) = 0$. Let $\gamma$ be any fractional partition with respect to any collection $\mathcal{C}$ of subsets of $[n]$. Then
\[ \sum_{s \in \mathcal{C}} \gamma(s) f(s \setminus s^c \setminus > s) \leq f([n]) \leq \sum_{s \in \mathcal{C}} \gamma(s) f(s < s). \]

**Proof:** The chain rule (actually a slightly extended version of it with additional conditioning in all terms that can be proved in exactly the same way) implies
\[ f(s < s) = \sum_{j \in s} f(j < j \cap s < s). \tag{6} \]

Thus
\[ \sum_{s \in \mathcal{C}} \alpha(s) f(s < s) \leq \sum_{s \in \mathcal{C}} \alpha(s) \sum_{j \in s} f(j < j \cap s < s) \]
\[ \geq \sum_{s \in \mathcal{C}} \alpha(s) \sum_{j \in s} f(j < j) \]
\[ \geq \sum_{j \in \mathcal{C}} f(j < j) \sum_{s \in \mathcal{C}} \alpha(s) 1_{\{j \in s\}} \]
\[ \leq \sum_{j \in \mathcal{C}} f(j < j) \]
\[ \geq f([n]), \]
where (a) follows by the chain rule (6), (b) follows from (5), (c) follows by interchanging sums, and (d) follows by the definition of a fractional covering.

The lower bound may be proved in a similar fashion by a chain of inequalities. Indeed,
\[ \sum_{s \in \mathcal{C}} \beta(s) f(s \setminus s^c \setminus > s) \]
\[ \geq \sum_{s \in \mathcal{C}} \beta(s) \sum_{j \in s} f(j < j \cap s, s^c \setminus > s) \]
\[ \leq \sum_{s \in \mathcal{C}} \beta(s) \sum_{j \in s} f(j < j) \]
\[ \leq \sum_{j \in \mathcal{C}} f(j < j) \]
\[ \leq f([n]), \]
where (a), (b), (c) follow as above, and (e) follows by the definition of a fractional partition.

**Remark 1:** The key new element in this result is the fact that one can use, for any ordering on the ground set $[n]$, the conditional values of $f$ that appear in the upper and lower bounds for $f([n])$. Because of (5), this is an improvement over simply using $f$. The latter weaker inequality has been implicit in the cooperative game theory literature; various historical remarks explicating these connections are given in Section X.

**Corollary I:** Let $f : 2^{[n]} \to \mathbb{R}$ be any submodular function with $f(\phi) = 0$, such that $f(j)$ is non-decreasing in $j$ for $j \in [n]$. Then, for any collection $\mathcal{C}$ of subsets of $[n]$, 
\[ \sum_{s \in \mathcal{C}} \beta(s) f(s \setminus s^c \setminus > s) \leq f([n]) \leq \sum_{s \in \mathcal{C}} \alpha(s) f(s < s), \]
where $\beta$ is any fractional packing and $\alpha$ is any fractional covering of $\mathcal{C}$.

**Proof:** The proof is almost exactly the same as that of Theorem I; the only difference being that the validity there of (d) for fractional coverings and of (e) for fractional packings is guaranteed by the non-negativity of $f(j < j)$. •
Observe that if \( f \) defines a polymatroid (i.e., \( f \) is not only submodular but also non-decreasing in the sense that \( f(s) \leq f(t) \) if \( s \subset t \)), then the condition of Corollary I is automatically satisfied.

IV. ENTROPY INEQUALITIES

A. Strong Fractional Form

The main entropy inequality introduced in this work is the following generalization of Shannon’s chain rule.

**Theorem I’**:[STRONG FRACTIONAL FORM] For any collection \( \mathcal{C} \) of subsets of \([n]\),
\[
\sum_{s \in \mathcal{C}} \beta(s) H(X_s | X_{s^c \cap s}) \leq H(X_{[n]}) \leq \sum_{s \in \mathcal{C}} \alpha(s) H(X_s | X_{<s})
\]
and
\[
\sum_{s \in \mathcal{C}} \gamma(s) h(X_s | X_{s^c \cap s}) \leq h(X_{[n]}) \leq \sum_{s \in \mathcal{C}} \gamma(s) h(X_s | X_{<s}),
\]
where \( \beta \) is any fractional packing, \( \alpha \) is any fractional covering, and \( \gamma \) is any fractional partition of \( \mathcal{C} \).

One can give an elementary proof of Theorem I’ as a refinement of that given by Llewellyn and Radhakrishnan for Shearer’s lemma (see [43]). However, instead of giving the proof in terms of entropy (which one may find in the conference paper [35]), we have proved in Theorem I a more general result that holds for the rather wide class of submodular set functions. To see that Theorem I’ follows from Theorem I, we need to check that the joint entropy set function \( f(s) = H(X_s) \) is a submodular function with \( f(\emptyset) = 0 \). The submodularity of \( f \) is a well known result that to our knowledge was first explicitly mentioned by Fujishige [17], although he appears to partially attribute the result to a 1960 paper of Watanabe that we have been unable to find. It follows from the fact that \( H(X_s) + H(X_t) - H(X_s \cup t) - H(X_s \cap t) = H(X_s|t, X_t|s) \) is a conditional mutual information (see, e.g., Cover and Thomas [10]), which is guaranteed to be non-negative by Jensen’s inequality. To see that the “correct” definition of \( f(\emptyset) = 0 \), note that the “unconditional” entropy \( H(X_s) \) should be equal to \( H(X_s|X_\emptyset) \), but the latter is \( H(X_s) - H(X_\emptyset) \) by definition, which suggests that \( H(X_\emptyset) = 0 \).

Again, we would like to stress the freedom given by Theorem I’ in terms of choice of ordering. For convenience of notation, we simply chose one labelling of the indices using the natural numbers and used the ordering \( 1 < 2 \ldots < n \), but one may equally well use another labelling or ordering.

**Remark 2:** It is natural to ask what choices of fractional packing and covering optimize the lower and upper bounds respectively. For a given collection of subset entropies, the optimal choices are clearly the solution of a linear program. Indeed, the best upper bound is obtained, for \( w_s = H(X_s | X_{<s}) \), by solving:

\[
\begin{align*}
\text{Minimize} & \quad \sum_{s \in \mathcal{C}} \alpha(s) w_s \\
\text{subject to} & \quad \alpha(s) \geq 0 \text{ and } \sum_{s \in \mathcal{C}, s \ni t} \alpha(s) \geq 1.
\end{align*}
\]

When the subset entropies are all equal, this is just the problem of optimal fractional covering discussed in Section III.

B. Strong Degree Form

The choice of \( \alpha \) as the degree covering and \( \beta \) as the degree packing in Theorem I’ gives the strong degree form of the inequality.

**Theorem II:**[STRONG DEGREE FORM] Let \( \mathcal{C} \) be any collection of subsets of \([n]\), such that every index \( i \) appears in at least one element of \( \mathcal{C} \). Then
\[
\sum_{s \in \mathcal{C}} \frac{H(X_s | X_{s^c \cap s})}{r_+ (s)} \leq H(X_{[n]}) \leq \sum_{s \in \mathcal{C}} \frac{H(X_s | X_{<s})}{r_- (s)}.
\]

If \( \mathcal{C} \) is quasirregular, then the above inequality also holds for \( h \) in place of \( H \).

**Remark 3:** This also proves Proposition I. Indeed, since conditioning reduces entropy, Proposition I is just the loose form of Theorem II obtained by dropping the conditioning on \( \prec s \) in the upper bound, and including conditioning on \( \succ s \) in the lower bound.

**Remark 4:** The collections \( \mathcal{C} \) for which the results in this paper hold need not consist of distinct sets. That is, one may have multiple copies of a particular \( s \subset [n] \) contained in \( \mathcal{C} \), and as long as this is taken into account in counting the degrees of the indices (or checking that a set of coefficients forms a fractional packing or covering), the statements extend. We will make use of this feature when developing applications to combinatorics in Section V.

**Remark 5:** Using the previous remark, one may write down Theorem II with arbitrary numbers of repetitions of each set in \( \mathcal{C} \). This gives a version of Theorem I’ with rational coefficients, following which an approximation argument can be used to obtain Theorem I’. This proof is similar to the one alluded to by Friedgut [15] for the version without ordering. Thus Theorem II is actually equivalent to Theorem I’.

The strong degree form of the inequality generalizes Shannon’s chain rule. In order to see this, simply choose the collection \( \mathcal{C} \) to be \( \mathcal{C}_1 \), the collection of all singletons. For this collection, Theorem II says
\[
\sum_{i=1}^{n} H(X_i | X_{[n]\setminus i}) \leq H(X_{[n]}) \leq \sum_{i=1}^{n} H(X_i | X_{<i}),
\]
which is precisely Shannon’s chain rule (see, e.g., Shannon [45] and Cover and Thomas [10]), since the upper and lower bounds are identical. Note in contrast the looseness of the upper and lower bounds in (2), which are tight if and only if the random variables \( X_i \) are independent.

Application of Theorem II to non-symmetric collections is also of interest. For instance, choosing \( \mathcal{C} \) to be the class of all sets of \( k \) consecutive integers yields \( r_- = 1 \) and \( r_+ = k \). Thus
\[
\sum_{j \in [n]} \frac{H(X_j | X_{[j,i]} \setminus X_{<j})}{H(X_{[j,i]} \setminus X_{<j})} \in \left[ \frac{1}{k}, 1 \right],
\]
(7)
where \( l(j) = \min\{j + k - 1, n\} \). These examples make it clear that Theorem II is rather powerful and generalizes well known results in addition to producing new ones.

C. Weak Fractional Form

Theorems I’ and II can be weakened by removing the conditioning in the upper bound, and adding conditioning in the lower bound; from the latter, one obtains the weak degree form of Proposition I, and from the former, one obtains the weak fractional form of our main inequality.

**Proposition II:** [Weak Fractional Form] For any hypergraph \( G \) on \([n]\),

\[
\sum_{s \in C} \beta(s) H(X_s | X_{s'}) \leq H(X_{[n]}) \leq \sum_{s \in C} \alpha(s) H(X_s)
\]

(8)

and

\[
\sum_{s \in C} \gamma(s) h(X_s | X_{s'}) \leq h(X_{[n]}) \leq \sum_{s \in C} \gamma(s) h(X_s),
\]

(9)

where \( \beta \) is any fractional packing, \( \alpha \) is any fractional covering, and \( \gamma \) is any fractional partition of \( C \).

**Remark 6:** While the main inequality as stated in both its degree form (Theorem II) and its fractional form (Theorem I’) seems novel, the bounds have been known to various levels of generality, as pointed out in the Introduction. In the discrete mathematics community, particular forms of the upper bound have been well known ever since the introduction of Shearer’s lemma by Chung, Graham, Frankl and Shearer [9] (see also Radhakrishnan [43] and Kahn [25]). In the level of generality of Proposition II, the fractional form was demonstrated by Friedgut [15] in terms of hypergraph projections. Friedgut’s proof of the upper bound is perhaps not as transparent as the one we give. In the information theory community, both the upper and lower bounds of Proposition II have been known for the special case of the hypergraphs \( C_k \) (consisting of all sets of \( k \) elements out of \( n \)), since the work of Han [23] and Fujishige [17]. In this paper, we unify and extend all of these results.

**Remark 7:** In the case of independent random variables, the joint entropy \( H(X_s) = H(X_s | X_{s'}) = \sum_{i \in s} H(X_i) \) is additive. Thus in that case, for any quasiregular hypergraph \( C \), Proposition I holds with equality, and this is just Lemma III with \( a_s = H(X_s) \). Similarly, thanks to Lemma I, Proposition II holds with equality for independent random variables when \( \alpha = \beta \) is a fractional partition.

We believe that both the degree formulations of Proposition I and Theorem II, and the fractional formulations of Theorem I’ and Proposition II are useful ways to think about these inequalities, and that they pave the way to the discovery of new applications. We illustrate this by using the degree formulation to count independent sets in graphs in Section V and by using the fractional formulation to obtain new determinantal inequalities in Section VI.

V. An Application to Counting

A. Entropy and Counting

It is necessary to recall some terminology from graph theory. For our purposes, a graph \( G = (V, E) \) consists of a finite vertex set \( V \) and a collection \( E \) of two-element subsets of \( V \) called edges (allowing repetition, i.e., self-loops). Thus \( G \) is a special case of a hypergraph, each hyperedge having cardinality 2. Two vertices are said to be adjacent, if there is an edge containing both of them. An independent set of \( G \) is a subset \( V_I \) of \( V \) such that no two vertices in \( V_I \) are adjacent.

Given a graph \( F = (V(F), E(F)) \), the set \( \text{Hom}(G, F) \) of homomorphisms from \( G \) to \( F \) is defined as

\[
\text{Hom}(G, F) = \{ x: V \rightarrow V(F) \ s.t. \ uv \in E \Rightarrow x(u)x(v) \in E(F) \}.
\]

Let \( K_{a,b} \) denote the complete bipartite graph between parts of sizes \( a \) and \( b \) respectively.

Shearer’s lemma, and more generally, entropy-based arguments, have proved very useful in combinatorics. Shearer’s lemma was (implicitly) introduced by Chung, Graham, Frankl and Shearer [9], and Kahn [25] stated an extension using the more familiar entropy notation. Recent applications of Shearer’s lemma to difficult problems (where counting bounds are a key step in obtaining the results) include Füredi [19], Friedgut and Kahn [16], Kahn [26], [25], Brightwell and Tetali [6], and Galvin and Tetali [21]. Radhakrishnan [43] provides a nice survey of entropy ideas used for counting and various applications; see also the book by Alon and Spencer [1].

The general strategy of entropy-based proofs in counting is as follows:

- To count the number of objects in a certain class \( C \) of objects, consider a randomly drawn object \( X \) from the class and note that its entropy is \( H(X) = \log |C| \).
- Represent \( X \) using a collection of discrete random variables, and apply a Shearer-type lemma to bound \( H(X) \) using certain subset entropies for a clever choice of hypergraph dictated by the problem.
- Perform an estimation of the resulting bound, using Jensen’s inequality if necessary.

Below, we follow this direction of work and demonstrate a counting application of the new inequality. In particular, we use Theorem I’ to bound the number of independent sets of an arbitrary graph, the number of proper graph colorings with a fixed number of colors, and more generally the number of graph homomorphisms.

B. Counting graph homomorphisms

Using Shearer’s entropy inequality as a key ingredient, Kahn [27] recently showed a bound on the number of independent sets of a regular graph \( G \), building on his earlier result [25] for bipartite, regular graphs. Kahn’s proof extends in a straightforward way, as observed by D. Galvin [20], to also provide an upper bound on the number of homomorphisms from a \( d \)-regular graph \( G \) to arbitrary graph \( F \). Theorem IV below extends the observations of Kahn and Galvin to bound
the number of graph homomorphisms from an arbitrary graph $G$ to an arbitrary graph $F$.

**Theorem III:** (Graph Homomorphisms) For any $N$-vertex graph $G$ and any graph $F$,

$$|\text{Hom}(G,F)| \leq \prod_{v \in V} |\text{Hom}(K_{p(v),p(v)},F)|^{\frac{1}{d(v)}},$$

where $p(v)$ denotes the number of vertices preceding $v$ in any ordering induced by decreasing degrees.

**Proof:** Let $X$ be chosen uniformly at random from Hom$(G,F)$. The random homomorphism $X$ can be represented by the values it assigns to each $i \in V$, i.e., $X = (X(1),X(2),\ldots,X(n)) = (X_1,X_2,\ldots,X_n)$, where $X_i \in V_F$. By definition, $X_i$ and $X_j$ are connected in $F$ if $i$ and $j$ are connected in $G$. We aim to bound $H(X)$ from above.

Let $\prec$ denote an ordering on vertices according to the decreasing order of their degrees (ties may be broken, for instance, by using an underlying lexicographic ordering of $V$). For each $i \in V$, let

$$P(i) = \{j \in V : (i,j) \in E \text{ and } j \prec i\},$$

and define $p(i) = |P(i)|$. Consider the collection $C$ to be the collection of $P(i)$, and in addition, $p(i)$ copies of singleton sets $\{i\}$, for each $i$. Then observe that each $i$ is covered by $d(i)$ sets in $C$, i.e., the degree of $i$ in the collection $C$ is $r(i) = d(i)$. Indeed, each $i$ appears in $d(i) - p(i)$ sets of the form, $P(j)$, corresponding to each $j$ such that $i \prec j$ and $(i,j) \in E$, and once in each of the $p(i)$ singleton sets $\{i\}$.

By the upper bound in Theorem II applied to this collection $C$, we have

$$H(X) \leq \sum_{i \in V} \frac{1}{\min_{j \in P(i)} d(j)} H \left( X_{P(i)} | X_{\prec P(i)} \right) + \sum_{i \in V} \frac{p(i)}{d(i)} H(X_i | X_{\prec i})$$

$$\leq \sum_{i \in V} \left( \frac{1}{d(i)} H(X_{P(i)}) + \frac{p(i)}{d(i)} H(X_i | X_{P(i)}) \right),$$

by relaxing the conditioning and by the fact that the chosen ordering makes $j \in P(i)$ imply $d(j) \geq d(i)$.

Let $q_i$ denote the probability mass function of $X_{P(i)}$, which takes its values in $X_i = \{x_{P(i)} : x \in \text{Hom}(G,F)\}$. In other words, $q(x_{P(i)})$ is the probability that $X_{P(i)} = x_{P(i)}$, under the uniform distribution on $X$. Finally, let $R(x_{P(i)})$ be the number of values that $X_i$ can take given that $X_{P(i)} = x_{P(i)}$, i.e., the support size of the conditional distribution of $X_i$ given $X_{P(i)} = x_{P(i)}$. Note that this is also the number of possible extensions of the partial homomorphism on $P(i)$ to a partial homomorphism on $P(i) \cup \{i\}$.

Then

$$H(X_{P(i)} + p(i)H(X_i | X_{P(i)})$$

$$\leq \sum_{x_{P(i)} \in X_i} q(x_{P(i)}) \log \frac{1}{q(x_{P(i)})} + p(i)q(x_{P(i)})H(X_i | X_{P(i)} = x_{P(i)})$$

$$\leq \sum_{x_{P(i)} \in X_i} q(x_{P(i)}) \log \frac{R(x_{P(i)})p(i)}{q(x_{P(i)})}$$

$$\leq \log \sum_{x_{P(i)} \in X_i} R(x_{P(i)})p(i),$$

where $R(x_{P(i)})$ is the cardinality of the range of $X_i$ given that $X_{P(i)} = x_{P(i)}$, and we have bounded $H(X_i | X_{P(i)} = x_{P(i)})$ by $\log R(x_{P(i)})$, and the last inequality follows by Jensen’s inequality. Thus

$$H(X) \leq \sum_{i \in V} \frac{1}{d(i)} \log \left( \sum_{x_{P(i)} \in X_i} R_i(x_{P(i)})p(i) \right).$$

The proof is completed by observing that, for any $i \in V$,

$$\sum_{x_{P(i)} \in X_i} R_i(x_{P(i)})p(i) \leq |\text{Hom}(K_{p(i),p(i)},F)|.$$  

Indeed, first note that every (partial) homomorphism $x_{P(i)}$ of $P(i)$ for any graph $G$ (regardless of the ordering $\prec$) is trivially a valid (partial) homomorphism of one side of $K_{p(i),p(i)}$, since each side of this bipartite graph has no edges and $|P(i)| = p(i)$. Furthermore, for a valid $x_{P(i)}$, the number of extensions $R_i(x_{P(i)})$ to $i$ is the same whether the graph is $G$ or $K_{p(i),p(i)}$, since it only depends on $F$. This proves (11).

Note that the inequality (11) can be strict, since there can be partial homomorphisms of one side of $K_{p(i),p(i)}$ to a given $F$ which are not necessarily valid while considering (partial) homomorphisms from $G$ to $F$, since the induced graph on $P(i)$, for a given $i$, might have some edges. (This corrects the claim in [21] that (11) holds with equality.)

C. Counting independent sets

By choosing appropriate graphs $F$, various corollaries can be obtained. In particular, it is well known that the problem of counting independent sets in a graph can be cast in the language of graph homomorphisms. Choose $F$ to be the graph on two vertices joined by an edge, and with a self-loop on one of the vertices. Then, by considering the set of vertices of $G$ that are mapped to the un-looped vertex in $F$, it is easy to see that each homomorphism from $G$ to $F$ corresponds to an independent set of $G$. This yields the following corollary.

**Corollary II:** (Independent Sets) Let $G = (V,E)$ be an arbitrary graph on $N$ vertices, and let $I(G)$ denote the set...
corresponds to the number of (proper) vertices of \( G \). Thus the above theorem yields a corresponding upper bound on the number of \( r \)-colorings of a graph \( G \), by replacing \( \text{Hom}(K_{p(v)},p(v)),F \) in [10] with the number of \( r \)-colorings of the complete bipartite graph \( K_{p(v),p(v)} \).

VI. AN APPLICATION TO DETERMINANTAL INEQUALITIES

The connection between determinants of positive definite matrices and multivariate normal distributions is classical. For example, Bellman’s text [3] on matrix analysis makes extensive use of an “integral representation” of determinants in terms of an integrand of the form \( e^{-\langle x,Ax \rangle} \), which is essentially the Gaussian density. The classical determinantal inequalities of Hadamard and Fischer then follow from the subadditivity of entropy. This approach seems to have been first cast in probabilistic language by Dembo, Cover and Thomas [11], who further showed that an inequality of Szasz can be derived (and generalized) using Han’s inequality. Following this well-trodden path, Proposition II yields the following general determinantal inequality.

**Corollary III:**[DETERMINANTAL INEQUALITIES] Let \( K \) be a positive definite \( n \times n \) matrix and let \( C \) be a hypergraph on \( [n] \). Let \( K(s) \) denote the submatrix corresponding to the rows and columns indexed by elements of \( s \). Then, using \( |M| \) denote the determinant of \( M \), we have for any fractional partition \( \alpha^* \),

\[
\prod_{s \in C} \left( \frac{|K|}{|K(s)|} \right)^{\alpha^*(s)} \leq |K| \leq \prod_{s \in C} |K(s)|^{\alpha^*(s)}.
\]

The proof follows from Proposition II via the fact that any positive definite \( n \times n \) matrix \( K \) can be realized as the covariance matrix of a multivariate normal distribution \( N(0,K) \), whose entropy is

\[
H(X_{[n]}) = \frac{1}{2} \log \left( (2\pi e)^n |K| \right),
\]

and furthermore, that if \( X_{[n]} \sim N(0,K) \), then \( X_s \sim N(0,K(s)) \). Note that an alternative approach to proving Corollary III would be to directly apply Theorem I to the known fact (called the Koteljanskii or sometimes the Hadamard-Fischer inequality) that the set function \( f(s) = \log |K(s)| \) is submodular.

For an \( r \)-regular hypergraph \( C \), using the degree partition in Corollary III implies that

\[
|K|^r \leq \prod_{s \in C} |K(s)|.
\]

Considering the hypergraphs \( C_1 \) and \( C_{n-1} \) then yields the Hadamard and prototypical Szasz inequality, while the Fischer inequality follows by considering \( C = \{s,s^c\} \), for an arbitrary \( s \subset [n] \).

We remark that one can interpret Corollary III using the all-minors matrix-tree theorem (see, e.g., Chaiken [7] or Lewin [32]). This is a generalization of the matrix tree theorem of Kirchhoff [29], which states that the determinant of any cofactor of the Laplacian matrix of a graph is the total number of distinct spanning trees in the graph, and interprets all minors of this matrix in terms of combinatorial properties of the graph.
VII. Duality and Monotonicity of Gaps
Consider the weak fractional form of Theorem I, namely
\[ \sum_{s \in C} \gamma(s) f(s|s') \leq f([n]) \leq \sum_{s \in C} \gamma(s) f(s). \]
We observe that there is a duality between the upper and lower bounds, relating the gaps in this inequality.

**Theorem IV:** [Duality of Gaps] Let \( f : 2^n \to \mathbb{R} \) be a submodular function with \( f(\emptyset) = 0 \). Let \( \gamma \) be an arbitrary fractional partition using some hypergraph \( C \) on \([n]\). Define the lower and upper gaps by
\[ \text{Gap}_L(f, C, \gamma) = f([n]) - \sum_{s \in C} \gamma(s) f(s|s') \]
and
\[ \text{Gap}_U(f, C, \gamma) = \sum_{s \in C} \gamma(s) f(s) - f([n]). \]  
(12)

Then
\[ \frac{\text{Gap}_U(f, C, \gamma)}{w(\gamma)} = \frac{\text{Gap}_L(f, C, \bar{\gamma})}{w(\bar{\gamma})}, \]  
(13)
where \( w \) is the weight function and \( \bar{\gamma} \) is the dual fractional partition defined in Section III.

**Proof:** This follows easily from the definitions. Indeed,
\[ f([n]) - \sum_{s' \in \bar{C}} \bar{\gamma}(s') f(s'|s) \]
\[ = f([n]) - \sum_{s \in C} \frac{\gamma(s)}{w(\gamma) - 1} \left[ f([n]) - f(s) \right] \]
\[ = \sum_{s \in C} \frac{\gamma(s) f(s)}{w(\gamma) - 1} - \left[ \frac{w(\gamma)}{w(\gamma) - 1} - 1 \right] f([n]) \]
\[ = 1 \frac{w(\gamma) - 1}{w(\gamma) - 1} \left[ \sum_{s \in C} \gamma(s) f(s) - f([n]) \right], \]
and
\[ w(\bar{\gamma}) = \sum_{s' \in \bar{C}} \bar{\gamma}(s') = \sum_{s \in C} \frac{\gamma(s) w(\gamma)}{w(\gamma) - 1} = \frac{w(\gamma)}{w(\gamma) - 1}. \]
Dividing the first expression by the second yields the result. \( \square \)

Note that the upper bound for \( f([n]) \) with respect to \((C, \gamma)\) is equivalent to the lower bound for \( f([n]) \) with respect to the dual \((\bar{C}, \bar{\gamma})\), implying that the collection of upper bounds for all hypergraphs and all fractional coverings is equivalent to the collection of lower bounds for all hypergraphs and all fractional packings. Also, it is clear that under the assumptions of Corollary I, one can state a duality result extending Theorem IV by replacing \( \gamma \) by any fractional covering \( \alpha \), and \( \bar{\gamma} \) by the dual fractional packing \( \bar{\alpha} \).

From Theorem IV, it is clear by symmetry that also
\[ \frac{\text{Gap}_L(f, C, \gamma)}{w(\gamma)} = \frac{\text{Gap}_U(f, C, \bar{\gamma})}{w(\bar{\gamma})}. \]  
(14)

The gaps in the inequalities have especially nice structure when they are considered in the weak degree form, i.e., for the fractional partition using a \( r \)-regular hypergraph \( C \), all of whose coefficients are \( 1/r \). The associated gaps are
\[ g_L(f, C) = f([n]) - \frac{1}{r} \sum_{s \in C} f(s|s'), \]
and
\[ g_U(f, C) = \frac{1}{r} \sum_{s \in C} f(s) - f([n]). \]  
(15)

**Corollary IV:** [Duality for Regular Collections] Let \( f : 2^n \to \mathbb{R} \) be a submodular function with \( f(\emptyset) = 0 \). For a \( r \)-regular collection \( C \),
\[ \frac{g_L(f, \bar{C})}{g_U(f, \bar{C})} = \frac{r}{|C| - r}. \]

Let us now specialize to the entropy set function \( e(s) \), we use this to mean either \( H(X_s) \) (if the random variables \( X_s \) are discrete) or \( h(X_s) \) (if the random variables \( X_s \) are continuous). The special hypergraphs \( C_k, k = 1, 2, \ldots, n \), consisting of all \( k \)-sets or sets of size \( k \), are of particular interest, and a lot is already known about the gaps for these collections. For instance, Han’s inequality [23] already implies Proposition I for these hypergraphs, and Corollary IV applied to these hypergraphs implies that
\[ \frac{g_L(e, C_{n-k})}{g_U(e, C_k)} = \frac{k}{n-k}, \]
recovering an observation made by Fujishige [17]. Indeed, Theorem IV and Corollary IV generalize what [17] interpreted using the duality of polymatroids, since our assumptions are weaker and the assertions broader. Fujishige [17] considered these gaps important enough to merit a name: building on terminology of Han [23], he called the quantity \( g_U(e, C_k) \) a “total correlation”, and \( g_L(e, C_k) \) a “dual total correlation”.

In two particular cases, the gaps have simple expressions as relative entropies (see Section III for definitions). First, note that the lower gap in Han’s inequality (3) is related to the dependence measure that generalizes the mutual information.
\[ (n-1) g_L(e, C_{n-1}) = g_U(e, C_1) \]
\[ = \sum_{i \in [n]} e\{i\} - e([n]) \]  
(16)
\[ = D(P_{X_{[n]}} || P_{X_1} \times \ldots \times P_{X_n}). \]

It is trivial to see that the gap is zero if and only if the random variables are independent.

Second, the lower gap in Proposition I with respect to the singleton class \( C_1 \) is related to the upper gap in the prototypical form (3) of Han’s inequality.
\[ g_L(e, C_1) = (n-1) g_U(e, C_{n-1}) \]
\[ = \sum_{i \in [n]} D(P_{X_{[n]\setminus{i}}} || P_{X_{[n]\setminus{i}} \setminus {X_{<i}}} \setminus {P}). \]  
(17)
(Here the last equality comes from simple manipulation of the pointwise log likelihoods.) Note that for the gap to be zero,
each of the relative entropies on the right must be zero. In particular, \( D(P_{X_i|X_{[2:n]}}, P_{X_1}) = 0 \), which implies that \( X_1 \) is independent of the remaining random variables. By applying the same fact to the collection of random variables under different orderings, one sees that \( X_{[n]} \) must be an independent collection of random variables.

The latter observation is relevant to the study of the erasure entropy of a collection of random variables, defined by Verdú and Weissman [50] to be

\[
H^-(X_{[n]}) = \sum_{i=1}^{n} H(X_i|X_{[n] \setminus i}).
\]

They give several motivations for defining these quantities; most significantly, the erasure entropy has an operational significance as the number of bits required to reconstruct a symbol erased by an erasure channel. Theorem 1 in [50] states that \( H^-(X_{[n]}) \leq H(X_{[n]}) \) with equality if and only if the \( X_i \) are independent. The inequality here is simply the lower bound of Proposition I applied to the singleton class \( C_1 \), and is thus a special case of our results. The difference between the joint entropy of \( X_{[n]} \) and its erasure entropy is just \( g_L(e, C_1) \), and the characterization of equality in terms of independence follows from the remarks above. It would be interesting to see if the more general bounds on joint entropy developed here can also be given an operational meaning using appropriate erasure-type channels.

Apart from the eponymous duality between the total and dual total correlations discussed above, these quantities also satisfy a monotonicity property, sometimes called Han’s theorem (cf., [23]). Since this complements the duality result, we state it below in the more general submodular function setting.

**Corollary V: Monotonicity of Gaps** Let \( f : 2^{[n]} \to \mathbb{R} \) be a submodular function with \( f(\emptyset) = 0 \), and let \( g_L(f, C_k) \) and \( g_U(f, C_k) \) be defined by (15). Then both \( g_L(f, C_k) \) and \( g_U(f, C_k) \) are monotonically decreasing in \( k \).

**Proof:** Proposition I, applied to the collection \( C_k \), immediately implies that \( 0 = g_U(f, C_k) \leq g_U(f, C_{k+1}) \), for \( k \in [n] \), on observing that \( r_+(s) = r_-(s) = \binom{n-1}{k-1} \). To obtain the full chain of inequalities, first note that for any \( s \) in \( C_{k+1} \),

\[
f(s) \leq \frac{1}{k} \sum_{i \in s} f(s \setminus i).
\]

Thus

\[
g_U(f, C_k) - g_U(f, C_{k+1}) = \frac{1}{\binom{n-1}{k-1}} \sum_{s \in C_k} f(s) - \frac{1}{\binom{n}{k}} \sum_{s \in C_{k+1}} f(s) \\
\geq \frac{1}{\binom{n-1}{k-1}} \left[ \sum_{s \in C_k} f(s) - \frac{1}{n-k} \sum_{s \in C_{k+1}} \sum_{i \in s} f(s \setminus i) \right].
\]

To complete the proof, note that

\[
\sum_{s \in C_k} f(s) = \sum_{i \in [n]} f(s \setminus i)
\]

\[
= \sum_{i \in [n]} \sum_{s \in C_k, i \notin s} f(s)
\]

\[
= (n-k) \sum_{s \in C_k} f(s)
\]

Again specializing to the joint entropy function, let

\[
e_k^U = \frac{1}{\binom{n}{k}} \sum_{s : |s| = k} e(s)
\]

denote the joint entropy per element for subsets of size \( k \) averaged over all \( k \)-element subsets, and

\[
e_k^L = \frac{1}{\binom{n}{k}} \sum_{s : |s| = k} e(s) e(s^c)
\]

denote the corresponding average of conditional entropy per element. Since \( g_U(e, C_k) = n e_k^U - e([n]) \) and \( g_L(e, C_k) = e([n]) - n e_k^L \), Corollary V asserts that \( e_k^U \) is decreasing in \( k \), while \( e_k^L \) is increasing in \( k \). Dembo, Cover and Thomas [11] give a nice interpretation of this fact, briefly outlined below.

Suppose we have \( n \) sensors collecting data relevant to the task at hand. For instance, the sensors might be measuring the temperature of the ocean at various points, or they might be evaluating the probability that a human face is in a collection of camera images taken along the boundary of a high-security site, or they might be taking measurements of neurons in a monkey’s brain. Suppose due to experimental conditions, at any time, we only have access to a random subset of \( m \) sensor measurements out of \( n \). Then Han’s monotonicity theorem implies that, on average, we are getting more information as \( m \) increases, etc.

**VIII. Entropy Power Inequalities**

Theorem I’ implies similar inequalities for entropy powers. Recall that the entropy power of the random vector \( X_s \) is

\[
\mathcal{N}(X_s) = e^{2h(X_s)/|s|}.
\]

This is sometimes standardized by a constant \((2\pi e)\), which is convenient in the continuous case as it allows for a comparison with a multivariate normal distribution. For discrete random variables, one can replace \( h \) by \( H \) in the above definition.

**Corollary VI:** Let \( \gamma \) be any fractional partition of \([n]\) using the hypergraph \( C \). Then

\[
\mathcal{N}(X_{[n]}) \leq \sum_{s \in C} w_s \mathcal{N}(X_s),
\]

where \( w_s = \frac{\gamma(s)|s|}{n} \) are weights that sum to 1 over \( s \in C \).

**Proof:** First note that

\[
\sum_{s \in C \setminus \emptyset} w_s = \sum_{s \in C} \frac{\gamma(s)}{n} \sum_{i \in s} 1 = \sum_{i \in [n]} \frac{1}{n} \sum_{s \in C, s \ni i} \gamma(s) = 1,
\]

Thus

\[
g_U(f, C_k) - g_U(f, C_{k+1}) = \frac{1}{\binom{n-1}{k-1}} \sum_{s \in C_k} f(s) - \frac{1}{\binom{n}{k}} \sum_{s \in C_{k+1}} f(s) \\
\geq \frac{1}{\binom{n-1}{k-1}} \left[ \sum_{s \in C_k} f(s) - \frac{1}{n-k} \sum_{s \in C_{k+1}} \sum_{i \in s} f(s \setminus i) \right].
\]
since \( \gamma \) is a fractional partition. Thus
\[
\exp \left\{ \frac{2h(X_n)}{n} \right\} \leq \exp \left\{ \frac{2}{n} \sum_{s \in C} \gamma(s) h(X_s) \right\} = \exp \left\{ \sum_{s \in C} w_s \frac{2h(X_s)}{|s|} \right\} \leq \sum_{s \in C} w_s \mathcal{N}(X_s),
\]
where the first inequality follows from Proposition II, and the last inequality follows by Jensen’s inequality. 

Remark 8: Corollary VI generalizes an implication of Theorem 16.5.2 of Cover and Thomas [10], which looks at the collections of \( k \)-sets. Note that, as in the special case covered in [10], Corollary VI continues to hold with the entropy power \( \mathcal{N} = \mathcal{N}_2 \) replaced throughout by any of the quantities \( \mathcal{N}_c(X_s) = \exp \left\{ c h(X_s) / |s| \right\} \) for any \( c > 0 \). As in the case of entropy, the bounds on the entropy powers associated with the hypergraphs \( C_m \) and the degree covering satisfy a monotonicity property. Indeed, by Theorem 16.5.2 of [10],
\[
\frac{1}{n} \sum_{s \in C, n-m} \mathcal{N}_c(X_s)
\]
is a decreasing sequence in \( m \).

More interesting than entropy power inequalities for joint distributions, however, are entropy power inequalities for sums of independent random variables with densities. Introduced by Shannon [45] and Stam [48] in seminal contributions, they have proved to be extremely useful and surprisingly deep– with connections to functional analysis, central limit theorems, and to the determination of capacity and rate regions for problems in information theory. Recently the first author showed (building on work by Arstein, Ball, Barthe and Naor [2] and Madiman and Barron [33]) the following generalized entropy power inequality. For independent real-valued random variables \( X_i \) with densities and finite variances,
\[
\mathcal{N} \left( \sum_{i \in [n]} X_i \right) \geq \sum_{s \in C} \gamma(s) \mathcal{N} \left( \sum_{i \in s} X_i \right),
\]
for any fractional partition \( \gamma \) with respect to any hypergraph \( C \) on \([n]\). Inequality (18) shares an intriguing similarity of form to the inequalities of this paper, although it is much harder to prove.

The formal similarity between results for joint entropy and for entropy power of sums extends further. For instance, the fact that
\[
\frac{1}{n} \sum_{s \in C, n-m} \mathcal{N} \left( \sum_{i \in s} X_i \right)
\]
is an increasing sequence in \( m \), can be thought of as a formal dual of Han’s theorem. It is an open question whether upper bounds for entropy power of sums can be obtained that are analogous to the lower bound in Theorem I'.

IX. AN INEQUALITY FOR RELATIVE ENTROPY, AND INTERPRETATIONS

Let \( A \) be either a countable set, or a Polish (i.e., complete separable metric) space equipped as usual with its Borel \( \sigma \)-algebra of measurable sets. Let \( \mathbb{P} \) and \( \mathbb{Q} \) be probability measures on the Polish product space \( A^n \). For any nonempty subset \( s \) of \([n]\), write \( \mathbb{P}_s \) for the marginal probability measure corresponding to the coordinates in \( s \). Recall the definition of the relative entropy:
\[
D(\mathbb{P}_s || \mathbb{Q}_s) = E_{\mathbb{P}} \left[ \log \frac{d\mathbb{P}_s}{d\mathbb{Q}_s} \right] \in [0, \infty]
\]
when \( \mathbb{P}_s \) is absolutely continuous with respect to \( \mathbb{Q}_s \), and \( D(\mathbb{P}_s || \mathbb{Q}_s) = +\infty \) otherwise.

One may also define the conditional relative entropy by
\[
D(\mathbb{P}_{s|t} || \mathbb{Q}_{s|t} | \mathbb{P}) = E_{\mathbb{P}} D(\mathbb{P}_{s|t} || \mathbb{Q}_{s|t}),
\]
where \( \mathbb{P}_{s|t} \) is understood to mean the conditional distribution (under \( \mathbb{P} \)) of the random variables corresponding to \( s \) given particular values of the random variables corresponding to \( t \); then \( E_{\mathbb{P}} \), denotes the averaging using \( \mathbb{P} \) over the values that are conditioned on. With this definition, it is easy to verify the chain rule
\[
d(s \cup t) = D(\mathbb{P}_{s|t} || \mathbb{Q}_{s|t} | \mathbb{P}) + d(t)
\]
for disjoint \( s \) and \( t \), so that following the terminology developed in Section III we have
\[
d(s|t) = D(\mathbb{P}_{s|t} || \mathbb{Q}_{s|t} | \mathbb{P}).
\]
We have freely used (regular) conditional distributions in these definitions; the existence of these is justified by the fact that we are working with Polish spaces.

Theorem V: Let \( \mathbb{Q} \) be a product probability measure on \( A^n \), where \( A \) is a Polish space as above. Suppose \( \mathbb{P} \) is a probability measure on \( A^n \) such that the set function \( d : 2^{[n]} \to [0, \infty] \) given by
\[
d(s) = D(\mathbb{P}_s || \mathbb{Q}_s)
\]
does not take the value \(+\infty\) for any \( s \subset [n] \). Then \( d(s) \) is supermodular.

Proof: For any nonempty \( s, t \subset [n] \), we have
\[
d(s \cup t) + d(s \cap t) - d(s) - d(t) = \left[ d(s \cup t) - d(t) \right] - \left[ d(s) - d(s \cap t) \right] = d(s \cup t \setminus t | t) - d(s \setminus s \cap t | s \cap t).
\]
Since \( s \cup t \setminus t = s \setminus s \cap t \), it would suffice to prove for disjoint sets \( s' \) and \( t \) that
\[
d(s'|t) \geq d(s'|t')
\]
for any \( t' \subset t \).

However observe that, since \( \mathbb{Q} \) is a product probability measure,
\[
d(s'|t) = E_{\mathbb{P}_s} D(\mathbb{P}_{s'|t} || \mathbb{Q}_{s'}) = E_{\mathbb{P}_t} E_{\mathbb{P}_{s'|t}} D(\mathbb{P}_{s'|t} || \mathbb{Q}_{s'})
\]
and
\[ d(s'|t') = E_{P_{s'}} D(\mathbb{P}_{s'\mid t'} \parallel Q_{s'}) = E_{P_{s'}} D(E_{P_{s'}} \parallel \mathbb{P}_{s'\mid t'} \parallel Q_{s'}), \]
so that (20) is an immediate consequence of the convexity of relative entropy (see, e.g., [10]).

Based on the supermodularity proved in Theorem V, Theorem I applied to \(-d(s)\) immediately implies the following corollary.

**Corollary VII:** Under the assumptions of Theorem V,
\[ \sum_{s \in C} \gamma(s) D(\mathbb{P}_{s \mid t} \parallel Q_{s} \parallel \mathbb{P}) \geq D(\mathbb{P}_{s \mid t} || Q_{s}) \]
\[ \geq \sum_{s \in C} \gamma(s) D(\mathbb{P}_{s} || Q_{s} || \mathbb{P}), \]
where \(\gamma\) is any fractional partition using any hypergraph \(C\) on \([n]\).

**Remark 9:** We mention a hypothesis testing interpretation for the following easier-to-parse corollary of Corollary VII: for \(r\)-regular hypergraphs \(C\) on \([n]\),
\[ D(\mathbb{P}_{s \mid t} || Q_{s} || \mathbb{P}) \geq \frac{1}{r} \sum_{s \in C} D(\mathbb{P}_{s} || Q_{s}). \] (22)
Suppose \(\mathbb{P}\) and \(Q\) are two competing hypotheses for the joint distribution of \(X_{[n]}\). Then it is a classical fact due to Chernoff (see, e.g., Cover and Thomas [10], where it is called Stein’s lemma) that the best error exponent for a hypothesis test between \(\mathbb{P}\) and \(Q\) based on a large number of i.i.d. observations of the random vector \(X_{[n]}\) is given by \(D(\mathbb{P}_{s || t} || Q_{s} || \mathbb{P})\). One may ask the following question: If one has partial access to all observations (for instance, one observes only \(X_{s}\) out of each \(X_{[n]}\)), then how much is our capacity to distinguish between the two hypotheses \(\mathbb{P}\) and \(Q\) worsened? Corollary VII can be interpreted as giving us estimates that relate our capacity to distinguish between the two hypotheses given all the data to our capacity to distinguish between the two hypotheses given various subsets of the data.

Interestingly, Corollary VII implies a tensorization property of the entropy functional \(\text{Ent}_{Q}(f) = E_{Q}[f \log f] - (E_{Q} f) \log(E_{Q} f)\), defined for positive functions \(f\). From the special case of Corollary VII corresponding to Han’s inequality (i.e., the hypergraph \(C_{n-1}\)), one obtains the classical tensorization property, as noticed by Massart [38]. We present below a generalized tensorization inequality for the entropy functional with respect to a product measure by utilizing the power of Corollary VII more fully.

**Corollary VIII:** Let \(C\) be an \(r\)-regular hypergraph on \([n]\). Then
\[ \text{Ent}_{Q_{s}}(g) \leq \frac{1}{r} E_{Q} \sum_{s \in C} \text{Ent}_{Q_{s}}(g) \]

We omit the proof, which is based on the observation that \(\text{Ent}_{Q}(f) = (E_{Q} f) D(\mathbb{P} \parallel Q)\), where \(\mathbb{P}\) is the probability measure such that \(\mathbb{E} \frac{\mathbb{P}}{E} \mathbb{E} = \frac{E}{E_Q}\), and follows the same line of argument as in [38].

The tensorization property of the entropy functional is of enormous utility in functional analysis, and the study of isoperimetry, concentration of measure, and convergence of Markov processes to stationarity. For instance, see Gross [22], Bobkov and Ledoux [4], and Kontoyiannis and Madiman [30], where the classical tensorization property is used to prove logarithmic Sobolev inequalities for Gaussian, Poisson and compound Poisson distributions respectively.

**X. Historical Remarks**

It turns out that the main technical result of this paper, Theorem I, is related to a wide body of work in a number of fields, including the study of combinatorial optimization of set functions in computer science, the study of cooperative games in economics, the study of capacities in probability theory, and of course the study of structural properties of entropy in information theory, which has been our present focus. In this section, we sketch these connections and place our work in context.

The following terminology is useful.

**Definition IX:** The set function \(f\) is fractionally subadditive if
\[ f([n]) \leq \sum_{s \in C} \gamma(s) f(s), \]
for any \(C \subset 2^{[n]}\), and for any fractional partition \(\gamma : C \rightarrow \mathbb{R}_{+}\) of \([n]\). If the inequality is reversed, we say \(f\) is fractionally superadditive.

Note that Theorem I has the following corollary (basically Proposition II for general submodular functions), obtained by using (5) to weaken the upper bound in Theorem I.

**Corollary IX:** If \(f\) is submodular and \(f(\phi) = 0\), then it is fractionally subadditive.

This result has a long history, and has rarely been explicitly stated in the literature although aspects of it have been rediscovered on multiple occasions in various fields. First we describe how it is implicit in the classical theory of cooperative games.

In cooperative game theory, a set function \(f : 2^{[n]} \rightarrow \mathbb{R}_{+}\) is called a value function; it can be thought of as describing the payoff that can be obtained by arbitrary coalitions of \(n\) players, and it is canonical to take \(f(\phi) = 0\). Different assumptions on the value function \(f\) correspond to different kinds of games. For instance, a balanced game is one for which the value function is fractionally superadditive, i.e.,
\[ f([n]) \geq \sum_{s \in C} \gamma(s) f(s) \]
holds for every fractional partition \(\gamma\). If the value function \(f\) is supermodular, the corresponding game is said to be a convex game.

One solution concept for cooperative games is the core, a subset of Euclidean space representing possible allocations of the payoff to players. (We do not bother to define it here; it suffices for our brief remarks here to know that such a notion...
exists.) The fundamental Bondareva-Shapley theorem [5], [46] states that the game with transferable utility associated with the value function $f$ has a non-empty core if and only if it is balanced. Separately, it is known from even earlier work of Kelley [28] (see also Shapley [47] who rediscovered it in the language of games) that a convex game has a non-empty core. Putting these together, one sees that a convex game must be balanced. This yields a statement very similar to that of Corollary IX.

Much more recently, yet another related approach to the relationship between submodularity and fractional subadditivity has come from the theory of combinatorial auctions. Lehmann, Lehmann and Nisan [31] showed that every submodular function is “XOS” (terminology that again we do not bother to explain here). Feige [14] showed that XOS and fractionally subadditive are identical. We refer the reader to the mentioned papers for definitions and details.

To summarize, the literature from cooperative game theory and combinatorial auction theory imply Corollary IX.

While we had expected direct proofs of Corollary IX to exist in the literature, we had initially been unable to find a reference. After the first version of this paper was written and presented at various venues, we were informed by Alan Sokal that it has indeed been explicitly stated and proved in the French statistical physics literature by Moulin Kolagier and Pinchon [40] (see also van Enter, Fernández and Sokal [49], where it is applied to entropy in a statistical physics context).

The above discussion is also related to the theory of polymatroids. A nondecreasing and submodular set function $f: 2^n \rightarrow \mathbb{R}_+$ with $f(\emptyset) = 0$ is sometimes called a $\beta$-function. This class of functions has been intensely studied ever since the pioneering work of Edmonds [13], who used them to define polymatroids. Note that the nondecreasing property (i.e., $f(t) \leq f(s)$ whenever $t \subset s \subset [n]$) implies that $f$ is non-negative. It is pertinent to note that the extra properties inherent in polymatroid theory are not required for Corollary IX and Theorem I (for instance, a non-negativity requirement for $f$ would rule out an application to the differential entropy); so Theorem I is really just a basic fact about submodular functions.

XI. DISCUSSION

The inequalities presented in this note are contributions to a large body of work on the structural properties of the entropy function for joint distributions. While the origins of such work clearly lie in Shannon’s foundational paper, let us again mention (see also the discussion after Theorem I’) that the important observation of submodularity of the joint entropy function goes back at least to Fujishige [17]. There have also been interesting new developments in the last few years, namely the discovery of the so-called “non-Shannon inequalities”. Motivated by the goal of characterizing the possible joint entropy set functions $\phi(s) = H(X_s)$ for the discrete entropy as the underlying joint distribution is varied arbitrarily, Zhang and Yeung [51] revealed a fascinating phenomenon: if one thinks of each such $\phi$ (corresponding to any joint distribution on $n$ copies of a discrete alphabet) as being a vector of dimension $2^n$, then the set of vectors one obtains in this manner is a strict subset of the set of vectors corresponding to polymatroidal functions for any $n \geq 4$. The constraints on joint entropy that are not automatic consequences of a polymatroid property were termed “non-Shannon inequalities” in [51]. For more recent developments on this subject, one may consult Ibinson, Linden and Winter [24], Matúš [39], or Dougherty, Freiling and Zeger [12].

In the context of these works, it is pertinent to note that all of the inequalities in this paper are Shannon inequalities, in the sense that they follow from submodularity of an entropy function. Indeed, our study was based on the set function $\phi(s) = H(X_s)$, from consideration of which our main entropy inequality (Theorem I’) was derived. However, since we now know from the mentioned literature that entropy satisfies additional constraints beyond submodularity, a natural question arises. If it is true that the set function $\phi(s) = H(X_s)$ is itself submodular, so that Theorem I’ then follows by an application of Corollary IX to $\phi$ rather than an application of Theorem I to $\phi$, then we would have a tighter outer bound on the space of joint entropy set functions. The following counterexample shows that this is not the case.

**Proposition III:** The set function $\phi(s)$ is not submodular.

**Proof:** We construct a counterexample with $n = 4$ random variables. Consider the sets $s = \{1, 3\}$ and $t = \{3, 4\}$. Then $s \cup t = \{1, 3, 4\}$ and $s \cap t = \{3\}$. If $\phi$ is submodular, then since $s$ contains the first element,

$$H(X_s) + H(X_{s|X_{c,t}}) \geq H(X_{s|t}) + H(X_{s|t} | X_{c>(s \cap t)}),$$

which in our case becomes

$$H(X_{\{1,3\}}) + H(X_{\{3,4\}|X_{\{1,2\}}} \geq H(X_{\{1,3,4\}}) + H(X_{\{3\}|X_{\{1,2\}}}).$$

(25)

By the chain rule,

$$H(X_{\{1,3,4\}}) = H(X_{\{1,3\}}) + H(X_{\{4\}|X_{\{1,3\}}}),$$

and

$$H(X_{\{3,4\}|X_{\{1,2\}}} = H(X_{\{4\}|X_{\{2,3\}}} + H(X_{\{3\}|X_{\{1,2\}}}),$$

so that (25) reduces to

$$H(X_{\{1,3\}}) + H(X_{\{4\}|X_{\{2,3\}}} + H(X_{\{3\}|X_{\{1,2\}}}) \geq H(X_{\{1,3,4\}}) + H(X_{\{3\}|X_{\{1,2\}}}),$$

and thence simply to

$$H(X_{\{4\}|X_{\{2,3\}}} \geq H(X_{\{4\}|X_{\{1,3\}}}).$$

However, this is in general not true since conditioning reduces entropy, and thus the hypothesis of submodularity is falsified.

Note, however, that such a counterexample is only possible when $s \cup t$ is strictly smaller than the index set $[n]$.

The relationship between the inequalities for discrete and continuous entropy in this paper is worth noting. Observe that a slightly more general class of inequalities holds for discrete entropy as compared to differential entropy (for instance, only fractional partitions are allowed in the differential entropy
context in Theorem I’); however, this is not surprising and indeed follows from the equivalences explored by Chan [8].

The structural properties of entropy discussed in this work are not just of abstract interest. Some applications, to determinantal inequalities and counting problems, have already been mentioned in earlier sections. The inequalities discussed also have close connections with several classical multiterm information theoretic problems, including the Slepian-Wolf data compression problem and the multiple access channel. In particular, for the Slepian-Wolf problem where data from n sources is to be losslessly compressed in a distributed fashion, it is the set function \( H(X_n|X_{n'}) \) rather than \( H(X_n) \) that plays the key role. Consequently, the lower bound in Theorem I’ has a crucial significance: it is equivalent to the existence of a rate point whose sum rate is the same as the rate achievable for non-distributed compression (namely \( H(X_n) \)), and is one way of showing that no extra cost is paid in terms of asymptotic rate for the distributed nature of the task. These connections merit a separate and more detailed exploration, as asymptotic rate for the distributed nature of the task. These connections merit a separate and more detailed exploration, as asymptotic rate for the distributed nature of the task. These connections merit a separate and more detailed exploration, as asymptotic rate for the distributed nature of the task.

Chain rules for entropy and relative entropy have played an important role in information theory since their recognition by Shannon. Here we have presented several inequalities for information in joint distributions that go beyond the chain rules but can also be thought of as deeper consequences of them. While these relate the information in projections of a random vector onto different subspaces, more general inequalities can be formulated that apply to a rich class of functions beyond projections (such as the sum), and these are described along with applications to additive combinatorics and matrix analysis in the follow-up works [34], [37]. We anticipate further extensions and applications of these inequalities in the future.

ACKNOWLEDGMENT

We are indebted to Andrew Barron for many useful discussions, and for the indirect influence of Andrew’s joint work [33] with MM on entropy power inequalities. We thank the organizers of the IEEE International Symposium on Information Theory 2006 in Seattle where we met and initiated this work, and Ravindra Bapat, Uriel Feige, Gil Kalai and Alan Sokal for help with references. PT is thankful to the Theory Group at Microsoft Research for hosting him during the period this research was carried out. We are also deeply indebted to three anonymous referees for very thorough feedback that eliminated an error and significantly improved the paper.
