Abstract. [Purpose] This preliminary study aimed to determine the cardiorespiratory endurance of children with cerebral palsy (CP) using a case series study in order to provide the reference data required for interventions appropriate for South Korean CP sufferers, since aerobic ability evaluation and interventions for children with CP are not well recognized in South Korea. [Subjects and Methods] Four children and adolescents with CP GMFCS (Gross Motor Function Classification System) level I and II and two normally developing children (ND) (age: 7–15 years) were studied. Cycle ergometer testing was performed to determine their VO2 peak and RER peak concentrations as well as VE peak and 6MWT distance. [Results] The VO2 peak was lower in subject E (CP) at 44.5 than in subject B (ND), and it was lower in subject A (ND) at 22.9 than in subject C (CP). The 6MWT distance was longer in subjects A and B (ND) than in age-matched CP subjects. [Conclusion] This case report demonstrates that the cardiorespiratory parameters values of CP children were similar to those reported previously. Further research is required to evaluate the normative values of CP and the optimal cardiorespiratory parameters.

Key words: Cardiorespiratory endurance, Ergometer test, Cerebral palsy

INTRODUCTION

Cerebral palsy (CP), defined as a nonprogressive injury to the brain, covers numerous neurological conditions, which result in abnormal development of movement and postural control. Injury to the brain typically results in impairments in motor function, such as muscle weakness, spasticity, and decreased selective motor control, which are primary causes of children with CP limitations in the performance of activities of daily living and participation1). Children with CP have a decreased level of daily physical activity in comparison to their healthy peers. They do not use their physical reserves sufficiently during the day to achieve optimal levels of daily physical activity to their healthy peers. They do not use their physical reserves sufficiently during the day to achieve optimal levels of daily physical activity comparison1). Children with CP need to maintain a higher level of physical fitness than healthy children in order to maintain the natural growth process as they grow older1). The peak oxygen uptake (VO2 peak), typically used as a measure of aerobic fitness, is lower in children with CP, as has been shown through exercise tests using cycle ergometry or a treadmill4, 5). The maximum aerobic physical fitness, VO2 peak, is an internationally acknowledged measure of the fitness of the cardiorespiratory system. Three studies4–6) have studied VO2 peak in children and adolescents with CP during a maximal exercise test. These studies compared VO2 peak to the values observed in normally developing (ND) children and adolescents5, 6). The most functional and appropriate way to assess VO2 peak in children with CP who are able to walk independently is a progressive walking or running-based maximal exercise test4, 7). Various researchers have developed treadmill walking maximal exercise tests to assess individuals with CP and to investigate the effectiveness of rehabilitation programs4–6, 8–11).

However, these methods limit the generalization of the results to actual daily walking, because a variety of comfortable walking speeds are exhibited by children with different types of CP8). Therefore, it is important to test children under general conditions that are comparable to daily living conditions. For estimating the maximal aerobic capacity, an adapted cycle ergometer test specifically developed for CP can be used12, 13). This aerobic test has the advantage of reducing errors that are produced when walking with diverse patterns. Currently, studies of ergometer aerobic tests14) have provided insufficient evidence of their effect12, 15). Furthermore, no direct cardiorespiratory results have been considered in the aerobic measurements16). Although Unnitan et al.17) studied the effect of uphill walking on children with diplegic...
CP, and measured the physical fitness of adult male CP subjects\(^{18}\), their evaluations were performed using an arm ergometer. Therefore, their score does not reflect changes in fitness resulting from a mainly leg-based training program.

Timed walking tests may offer a less expensive, simpler, and safer alternative to laboratory testing of children with CP\(^{10, 19}\). Among such tests, the 6-min walk test (6MWT) has been shown to predict cardiorespiratory fitness in both healthy and severely disabled children, whether used with or without gas collection\(^{20, 21}\).

Novac et al.\(^{22}\) systematically discussed the most effective and applicable interventions for children with CP. In their reports of the literature, the most recommended and applicable intervention was green light intervention, and they emphasized the importance of fitness training for aerobic fitness. Before children with CP perform aerobic fitness tests, their aerobic ability should be measured. However, previous studies have reported inconsistent results and utilized various measurement methods and environments. Thus, it is necessary to provide a precise method and measurement for base data to obtain accurate reference values. Accordingly, this preliminary study aimed to determine the cardiorespiratory endurance of children with CP using a case series study in order to provide the reference data required for interventions appropriate for South Korean CP sufferers, since aerobic ability evaluation and interventions for it for children with CP are not well recognized in South Korea.

**SUBJECTS AND METHODS**

Six children participated in this study. Four subjects (3 boys, 1 girl) had a diagnosis of bilateral or unilateral spastic CP, and 2 subjects (1 boy, 1 girl) were children with normal development. Four children with CP GMFCS (Gross Motor Function Classification System) level I and II and two normally developing children (age: 7–15 years) were studied (Table 1). Subjects with CP were recruited from a Medical Center in Gyeonggi-do South. This study complied with the ethical principles of the Declaration of Helsinki, and all the subjects and parents received explanations regarding the purpose and procedure of the study before voluntarily agreeing to take part. All parents signed an informed consent statement before the start of the measurements. Before testing, a medical examination was completed and anthropometric data were collected. The inclusion criteria were GMFCS levels I to II, uni- or bilateral spastic CP, age of 5–16 years, ability to walk continuously for 6 min, and ability to provide informed consent. Potential subjects were excluded if they had received orthopedic surgery or neurosurgery and/or botulinum toxin injection within the previous 6 months, or had cardiac or respiratory conditions that could have been negatively affected by the proposed training. All the selected subjects were also free of intellectual problems and able to perform the test.

![Table 1. General characteristics of subjects](image-url)

| Subjects | Type       | GMFCS level | Gender (boys: 0, girls: 1) | Age (years) | Height (cm) | Weight (kg) |
|----------|------------|-------------|---------------------------|-------------|-------------|-------------|
| ND       | A          | -           | 0                         | 12          | 151         | 48          |
|          | B          | -           | 1                         | 7           | 115         | 22          |
|          | C          | Spastic bilateral | 1 | 0 | 12 | 140 | 31 |
|          | D          | Spastic bilateral | 2 | 0 | 15 | 155.4 | 46 |
| CP       | E          | Spastic unilateral | 2 | 1 | 7 | 116 | 32 |
|          | F          | Spastic unilateral | 2 | 0 | 10 | 138 | 38 |

CP: cerebral palsy; ND: normally developing children; GMFCS: Gross Motor Function Classification Scale

**RESULTS**

The ages of the subjects were distributed as follows: two were aged 7 years, two were aged 12 years, one was aged...
physical activities of children with CP in terms of aerobic normal children. Numerous studies have reported the lower min) as well as shorter walking distances in set times than abilities than normal peers 26). Verschuren et al. 6) reported children and adolescents with CP have lower physical activity, which then leads to a cycle of deconditioning and further physical deterioration and reduction in activity. However, as seen in this study, the child with CP aged 7 (subject E) had a lower VO2 peak value than the normally developing child (subject B), and the child with CP aged 12 (subject C) had a higher VO2 peak value than the normally developing child (subject A). Subject B (ND) had a lower VO2 peak than subject E (CP), consistent with the results of previous studies 6, 13). One study 6) reported that a child with CP had a VO2 peak value of 42 mL/kg/min, which was close to our study result of 44.5 mL/kg/min; however, the interpretation of the results of this previous are limited, because the subjects were aged from 7 to 17 years. With regard to the comparison of the results of subjects A and C, it is necessary to determine the reason for the higher VO2 peak value in children with CP than in normal children, considering of various possibilities. A child with GMFCS level I can perform gross motor skills such as running and jumping and participate in physical and dynamic activities. In contrast, a child with CP at GMFCS level II cannot participate in physical and dynamic activities such as playground activities owing to his/her limited abilities. Despite examining only one case in this study, our results suggest children with CP who have small body mass and high functional level have even higher VO2 peak values than normal children. Nsenga et al. 13) reported that children with CP at GMFCS levels I and II can have cardiorespiratory endurance similar to that of normal children of similar ages.

Table 2. Subjects’ peak cardiorespiratory responses to ergometry

| Type | Subjects | VO2 peak (ml/kg/min) | RER peak | VE peak (l/min): maximum ventilation per minute | HR peak (beats/min): peak heart rate | 6MWT (m): 6-min walk test |
|------|----------|----------------------|----------|-----------------------------------------------|-------------------------------------|--------------------------|
| ND   | A        | 22.9                 | 0.82     | 18.5                                          | 105                                 | 580                      |
|      | B        | 56.5                 | 0.97     | 23.8                                          | 135                                 | 450                      |

VO2 peak (ml/kg/min): peak oxygen uptake; RER peak: peak respiratory exchange ratio; VE peak (l/min): maximum ventilation per minute; HR peak (beats/min): peak heart rate; 6MWT (m): 6-min walk test

DISCUSSION

This preliminary study aimed to determine the cardiorespiratory endurance of children with CP using a case series study to provide the reference data required for interventions appropriate for South Korean CP sufferers, since aerobic ability evaluation and interventions for it for children with CP are not well recognized in South Korea.

Children with CP have lower VO2 peak values (ml/kg/min) as well as shorter walking distances in set times than normal children. Numerous studies have reported the lower physical activities of children with CP in terms of aerobic abilities 4, 5, 17, 26), and some studies have reported that children and adolescents with CP have lower physical activity abilities than normal peers 5). Verschuren et al. 6) reported that comparisons with normative data sets suggest that adolescents with CP tend to participate in less structured and lower intensity physical activities than healthy adolescents.

Durstine et al. 27) described a vicious circle in which persons with a chronic disease or disability experience less physical activity, which then leads to a cycle of deconditioning and further physical deterioration and reduction in activity. However, as seen in this study, the child with CP aged 7 (subject E) had a lower VO2 peak value than the normally developing child (subject B), and the child with CP aged 12 (subject C) had a higher VO2 peak value than the normally developing child (subject A). Subject B (ND) had a lower VO2 peak than subject E (CP), consistent with the results of previous studies 6, 13). One study 6) reported that a child with CP had a VO2 peak value of 42 mL/kg/min, which was close to our study result of 44.5 mL/kg/min; however, the interpretation of the results of this previous are limited, because the subjects were aged from 7 to 17 years. With regard to the comparison of the results of subjects A and C, it is necessary to determine the reason for the higher VO2 peak value in children with CP than in normal children, considering of various possibilities. A child with GMFCS level I can perform gross motor skills such as running and jumping and participate in physical and dynamic activities. In contrast, a child with CP at GMFCS level II cannot participate in physical and dynamic activities such as playground activities owing to his/her limited abilities. Despite examining only one case in this study, our results suggest children with CP who have small body mass and high functional level have even higher VO2 peak values than normal children. Nsenga et al. 13) reported that children with CP at GMFCS levels I and II can have cardiorespiratory endurance similar to that of normal children of similar ages.

Hoofwijk et al. 13) investigated ventilation in children with CP and healthy control groups. The former showed higher values (41.4) than the latter (33.6). This result was used as an explanation for the lower VO2 of children with CP. The present study found comparable values for children and adolescents with CP and normally developing subjects. The ventilation peak (VEpeak) value for child C (CP) was higher (25.3) than that (18.5) of child A (ND). Similarly, the child E (CP) showed a higher value (32.5) than that (25.3) of child B (ND). Therefore, these results support the explanation of Hoofwijk et al. 13).

The 6MWT was used to measure the functional walking capacity. The total distance walked was recorded as the 6MWT distance. The distance walked strongly correlated with the 6MWT VO2 peak (r = .948) and was related more modestly to the cycle-ergometer VO2 peak (r = .625) 19). In this study, VO2 was not collected while performing the
6MWT. However, the results of the present study show that children with CP (C and E) walked shorter distances than normal children (A and B). Nsenga et al.\textsuperscript{19} reported that the 6MWT distance increased after aerobic training, showing a correlation between the cardiorespiratory capacity and 6MWT distance. Although a previous study suggested there is no significant correlation between the ergometer VO\textsubscript{2} peak and 6MWT distance, Maanum et al.\textsuperscript{28} reported that the 6MWT distance was a significant predictor of cardiorespiratory capacity for children with spastic CP.

Two children with CP showed RER > 1.0. This finding suggests that many children with CP do not produce maximal effort. Peak RER is generally used as a secondary criterion for maximal effort; however, large individual variations may be present depending on the test modes and protocols\textsuperscript{29}. The average peak RER values in the present study (0.87–1.36) were comparable to the average values reported in previous studies of children with CP (0.9–1.15), and most studies have reported a peak HR of 190 bpm\textsuperscript{30}. These results do not support the finding that the children did not produce their maximal effort because of the lower peak HR values. However, the present study conducted ergometer tests and not treadmill tests; furthermore, there was an age difference among the subjects.

Thus far, most studies of children with CP have focused on cycle ergometer or treadmill walking tests\textsuperscript{6, 8-10}, seeking to verify the effectiveness of these tests\textsuperscript{12, 13-15, 17}. However, the available literature on the cardio-respiratory capacity of children with CP focuses on treadmill walking rather than cycle ergometry. Treadmill tests have both supporters and critics. Verschuren et al.\textsuperscript{15} noted that treadmill protocols such as the Bruce and Balke tests are not appropriate for children with CP. Furthermore, treadmill testing is difficult for some results for children with CP because they suffer from severe balance issues\textsuperscript{31}. It is difficult to compare the children from all studies that have provided information about VO\textsubscript{2} peak for children and adolescents with CP. Although many studies have recognized the importance of fitness for maintaining aerobic capacity, it is not easy to conduct aerobic tests with children with CP owing to the limitations described in the studies cited above. Among studies with a high evidence level, the accuracy of the results may not be that high owing to the use of arm ergometry rather than a test of the lower extremities. Other studies include a case study\textsuperscript{13} with a low evidence level and studies with a small number of subjects\textsuperscript{12-14}. Accordingly, more evidence and data that can be used as a reference to provide fitness programs for school children with CP are needed in the future. This study aimed to determine the cardiorespiratory endurance of children with CP using a case series study in order to provide the reference data required for interventions appropriate for South Korean CP sufferers, since aerobic ability evaluation and interventions for it for children with CP are not well recognized in South Korea. Despite success in the study aims, the results should be interpreted with care, owing to the small number of participating subjects.

In conclusion, this case report reports cardiorespiratory parameter values that are similar to those that have been reported previously. Fitness training for aerobic fitness is an important intervention method for children with CP. Accordingly, it is necessary to provide evidence of cardiorespiratory fitness levels for children with CP when such fitness programs are conducted. Furthermore, it is necessary to provide precise methods and measurements for base data in every assessment to obtain accurate reference values. In this regard, our study will provide information about VO\textsubscript{2} peak values for an aerobic-fitness-related study conducted with children with CP in the future.
