ABSTRACT
We investigate an interacting dark sector scenario in which the vacuum energy is free to interact with cold dark matter (CDM), which itself is assumed to cluster under the sole action of gravity, i.e. it is in freefall (geodesic), as in $\Lambda$CDM. The interaction is characterized by a dimensionless coupling $q_V(z)$, in general a function of redshift. Aiming to reconstruct the evolution of the coupling, we use cosmic microwave background data from Planck 2015, along with baryon acoustic oscillation, redshift space distortion, and Type Ia supernova measurements to constrain various parametrizations of $q_V(z)$. We present the full linear perturbation theory of this interacting scenario and use Monte Carlo Markov Chains (MCMC) sampling to study five different cases: two cases in which we have $\Lambda$CDM evolution in the distant past, until a set redshift $z_{\text{trans}}$, below which the interaction switches on and $q_V$ is the single-sampled parameter, with $z_{\text{trans}}$ fixed at $z_{\text{trans}} = 3000$ and 0.9, respectively; a case where we allow this transition redshift to vary along with $q_V$; a case in which the vacuum energy is zero for $z > z_{\text{trans}}$ and then begins to grow once the interaction switches on; and the final case in which we bin $q_V(z)$ in four redshift bins to investigate the possibility of a dynamical interaction, reconstructing the redshift evolution of the function using Gaussian processes. We find that, in all cases where the high-redshift evolution is not modified, the results are compatible with a vanishing coupling, thus finding no significant deviation from $\Lambda$CDM.

Key words: dark energy – dark matter – cosmology: theory.

1 INTRODUCTION

Over the past 20 yr, observational cosmology has provided a wealth of evidence in support of the idea that the expansion of the Universe is accelerating. The first direct evidence for the acceleration came from Type Ia supernovae observations (Riess et al. 1998; Perlmutter et al. 1999) and subsequent measurements of the cosmic microwave background (CMB, Hinshaw et al. 2009; Aghanim et al. 2018) and other cosmological probes such as baryon acoustic oscillations (BAOs, Alam et al. 2017) have all confirmed the late-time dominance of a dark energy component in our Universe.

The standard cosmological model, $\Lambda$CDM, has been largely successful in explaining these measurements, with the cosmological constant, $\Lambda$, being the simplest driver of an accelerated expansion and cold dark matter (CDM) being responsible for structure formation. However, there are problems with $\Lambda$CDM which motivate the investigation of alternative models. These problems manifest in both the discrepancy between the predicted and observed values of the cosmological constant (Weinberg 1989; Adler, Casey & Jacob 1995), and in the tensions that exist between low-redshift probes of the expansion rate and structure growth and the corresponding values inferred from CMB measurements (for which a cosmological model must be assumed) (Macaulay, Wehus & Eriksen 2013; Bernal, Verde & Riess 2016).

In recent years, the precision of surveys has improved and these tensions have become more apparent, particularly in the value of the Hubble parameter today, $H_0$; the most recent CMB measurement, from the Planck satellite, is $H_0 = 67.4 \pm 0.5$ km s$^{-1}$ Mpc$^{-1}$ (Aghanim et al. 2018), whereas the most recent local determination, from the Hubble Space Telescope, is $H_0 = 73.45 \pm 1.66$ km s$^{-1}$ Mpc$^{-1}$ (Riess et al. 2018), a discrepancy of 3.7$. Other distance ladder-independent probes do not seem to ease the tension, with the LIGO measurement of $70^{+12.0}_{−8.0}$ km s$^{-1}$ Mpc$^{-1}$ (Abbott et al. 2017) and a recent HOliCOW quadruple lensed quasar measurement of $72.5^{+2.2}_{−2.1}$ km s$^{-1}$ Mpc$^{-1}$ (Birrer et al. 2018) falling between the CMB and distance ladder results.

The tension in $\sigma_8$, the amplitude of the linear matter power spectrum on a scale of 8 h$^{-1}$ Mpc, is less severe than that in $H_0$, but is yet another indicator of problems with $\Lambda$CDM. Once again,
the discrepancy appears between measurements of $\sigma_8$ at large and small scales, most noticeably the scales probed by the CMB and the smaller scale indicators of large-scale structure (LSS), such as galaxy cluster counts, weak-lensing and redshift space distortion (RSD) measurements (Battye, Charnock & Moss 2015), with LSS giving a lower value than CMB (Abbott et al. 2018).

It remains to be seen whether these tensions will survive as the next generation of surveys, satellites, and telescopes begins to provide us with data and new analysis techniques are developed. An interesting example of such a novel method has latterly been described in the literature, with compelling results (Aubourg et al. 2015; Macaulay et al. 2018). These authors invert the distance ladder, anchoring the Type 1a supernova measurements to BAOs rather than to the parallax distances of Cepheid variable stars. Using this method, along with 207 new DES supernovae, Macaulay et al. (2018) find a value of $H_0 = 67.77 \pm 1.30$ km s$^{-1}$ Mpc$^{-1}$, which is in excellent agreement with the derived value from Planck. This hints at an uncertainty in the measuring of parallax distances which could be leading to a miscalibration of the distances to the Cepheids. This uncertainty could be reduced by future data from Gaia (Beaton et al. 2018) and LSST (Ivezić et al. 2012). However, observational advances are just one way the $H_0$ and $\sigma_8$ tensions could be resolved; an alternative is to examine new theoretical models of dark energy.

In this work, we explore the phenomenology of a scenario in which the vacuum energy is free to interact with dark matter. The idea of a decaying vacuum energy as been afforded a great deal of study in the literature (see e.g. Bertolami 1986; Pavón 1991; Al-Rawai & Taha 1996; Shapiro & Sola 2002; Sola 2011; Wands, De-Santiago & Wang 2012) and other dynamical and interacting dark energy models have also been investigated, often with the conclusion that not only can cosmological tensions be resolved in such models, but they may even be favoured over $\Lambda$CDM (see e.g. Salvatelli et al. 2014; Wang et al. 2015; Zhao et al. 2017; Solà, Gómez-Valent & de Cruz Pérez 2017a; Di Valentino, Melchiorri & Mena 2017; Kumar & Nunes 2017; Solà, Gómez-Valent & de Cruz Pérez 2018a; Yang et al. 2018; Wang et al. 2018, for more details).

The specific scenario we here consider retains general relativity as the description of gravity, while allowing for a possible exchange of energy between CDM and the vacuum, i.e. a dark energy with an equation of state parameter $w = -1$ (Lemaître 1931; Lemaître 1934). This scenario does not introduce any additional dynamical degrees of freedom with respect to $\Lambda$CDM (Wands et al. 2012). The interaction allows for the energy density of the vacuum, $V$, to change, while CDM can freely cluster under the sole action of gravity i.e. CDM remains geodesic, as in $\Lambda$CDM. We investigate the possibility of such an interaction by choosing a simple parametrization and studying its behaviour as a function of redshift. As we show in Section 2, the interaction is described – in the synchronous comoving gauge and under the assumption of geodesic CDM – by a single background function $Q(z)$ which we model as $Q = q_V HV$, where $q_V(z)$ is a dimensionless function. Based on this, we consider five different cosmologies, with the general aim of investigating $q_V(z)$ with step functions in different redshift bins, using the values $q_V$ in each bin as parameters. In particular, a four bins case is essentially model-independent.

The first two cosmologies, which we name $Cfix$, consider a physical scenario in which we have a $\Lambda$CDM evolution in the past up to a fixed transition redshift $z_{trans}$. At $z$ lower than $z_{trans}$, the interaction switches on and the vacuum energy starts to evolve. The two cases differ in the redshift of the transition: in the first we assume that the interaction starts at high redshift, with $z_{trans} = 3000$; in the other we assume $z_{trans} = 0.9$, in order to compare with the same case considered by Salvatelli et al. (2014). For these two $Cfix$ cases we sample over the usual cosmological parameters, with the addition of the single interaction parameter, $q_V$.

The third case, $Cvar$, is similar to the first two, but we additionally sample over the transition redshift, $z_{trans}$. The fourth case, which we call seeded vacuum energy or SVE, mimics a physical scenario in which the coupling causes the vacuum energy to suddenly grow from zero up to a ‘seed’ value at $z_{trans}$. At lower redshifts, the interaction then behaves as in the previous three cases i.e. with a constant $q_V$, and the vacuum evolves accordingly. Therefore this case, like the third, has two free parameters: $q_V$ and $z_{trans}$. The fifth case we consider is the model-independent scenario in which we allow the interaction to evolve in four redshift bins, using four different values of the interaction strength $q_V$. We call this the $4bins$ case. We use MCMC techniques to constrain the coupling and transition redshifts in each case, using the latest observational data sets.

We draw attention to the previous work of some of the authors, Salvatelli et al. (2014), and wish to emphasize the differences between that Letter and the current paper. In this work, we make use of the new data that is now available, especially the Planck 2015 likelihood, along with new BAO, RSD, and Type Ia supernova data. We also use a less restrictive prior on the coupling parameter in our parameter inference, allowing us to investigate the possibility of an energy transfer both from dark matter to the vacuum and vice versa. We will discuss this further in Section 7.

The rest of the paper is organized as follows: in Section 2, we present the theory of the interacting vacuum scenario, including the equations governing the evolution of the background and perturbations. In Section 3, we outline the parametrization of the interaction and the methods of reconstruction studied in this work. In Section 4, we discuss the data and analysis methods used in our investigation, and in Section 5, we present our results, followed by a discussion in Section 6. We make some comments on other recent works in this area in Section 7, and we finally conclude with Section 8.

2 COLD DARK MATTER–VACUUM ENERGY INTERACTION

In this section, we outline the theoretical framework for the interacting vacuum scenario, beginning with a summary of the general covariant theory and progressing to the details of the scenario in a Friedmann–Lemaître–Robertson–Walker (FLRW) background with perturbations. See Wands et al. (2012) for more details.

2.1 Covariant theory of the interacting vacuum

In $\Lambda$CDM, the cosmological constant $\Lambda$ represents the vacuum energy of the Universe, and in a classical sense, this vacuum energy can be treated as a non-interacting perfect fluid with an equation of state parameter $w = -1$, as was realized by Lemaître (Lemaître 1931; Lemaître 1934).

The energy–momentum tensor of a perfect fluid is

$$T^\mu_\nu = P g^\mu_\nu + (\rho + P) u^\mu u_\nu ,$$

where $\rho$ is the energy density, $P$ the pressure, and $u^\mu$ the four velocity of the fluid.

We define the energy–momentum tensor of the vacuum as

$$T^\mu_\nu = -V g^\mu_\nu ,$$

where $V$ is the coupling.
and by comparison with (1) we can identify $V = -\dot{P} = \dot{\rho}$, i.e. $V$ is the vacuum energy density. This means that the equation of state parameter $w = P/\rho$ is equal to $-1$, as it is for the cosmological constant $\Lambda$. Moreover, this form of the vacuum energy–momentum tensor leaves the vacuum four velocity undefined and any four vector is an eigenvector of $\mathcal{T}_{\mu\nu}$. Therefore, all observers measure the same vacuum energy density $V$; in other words, the vacuum energy is boost invariant. In the following, $u^\mu$ therefore denotes the four velocity of CDM.

Denoting the energy–momentum tensor of CDM with $T_{\mu\nu}$ and its energy density with $\rho_c$,

$$T_{\mu\nu} = \rho_c u^\mu u_\nu,$$

we can introduce an interaction between CDM and the vacuum energy in the following way:

$$\nabla_\mu T^\mu_{\nu} = -Q_\nu,$$

$$\nabla_\mu \dot{T}^\mu_{\nu} = -\nabla_\nu V = Q_\nu,$$  \(\text{(4)}\)

where the interaction four vector $Q^\mu$ represents the energy–momentum flow between vacuum and CDM.

If $T_{\mu\nu} = T^\mu_{\nu} + T^{\mu\nu}_{\text{int}}$ is the total energy–momentum tensor, then the form of the interaction in equations (4) and (5) ensures the total conservation equation $\nabla_\mu T^\mu_{\nu \text{tot}} = 0$, which, in Einsteinian gravity, follows from the Bianchi identity $\nabla_\mu G^{\mu \nu} = 0$. We note that this scenario reduces to the standard $\Lambda$CDM case when $Q^\mu = 0$, as this implies $V = \text{constant}$.

We can project the interaction four vector in two parts parallel and orthogonal to the CDM four velocity:

$$Q^\mu = Qu^\mu + f^\mu,$$

where, in the frame of observers comoving with CDM, $Q$ represents the energy flow, and $f^\mu$ the momentum exchange between CDM and vacuum; $f^\mu$ is orthogonal to $u^\mu$ i.e. $f^\mu u_\mu = 0$.

Following Salvatelli et al. (2014) and Wang et al. (2014), we consider the simplest case of interaction: a pure energy exchange in the CDM frame wherein $f^\mu = 0$, and so $Q^\mu = Qu^\mu$. The four force, $f^\mu$, is related to the four acceleration $a^\mu = u^\mu \nabla_\mu u^\nu$ by

$$f^\mu = a^\mu /c.$$

Since we set $f^\mu = 0$, it follows that $a^\mu = 0$, meaning there is no acceleration of CDM due to the interaction and hence CDM remains geodesic. We may call this interacting scenario the geodesic CDM scenario (see also Wang et al. 2013). It follows from this geodesic CDM assumption that the effective sound speed of matter perturbations is zero and hence the Jeans length is also zero, meaning that there is no damping of matter perturbations on scales smaller than the Jeans length. However, the interaction will still affect structure growth, as discussed below in Section 2.3.

A second important consequence of the assumption of pure energy exchange is that, following (5), the CDM four velocity $u^\mu$ consequently defines a potential flow and the CDM fluid is thus irrotational (Borges & Wands 2017). This is a sufficient approximation of the behaviour of CDM at early times and on large scales, in a linear regime where only scalar perturbations are relevant for structure formation, but at late times, it is expected that non-linear structure growth will lead to vorticity. At late times, dark matter haloes are rotationally supported and in this non-linear regime, a gravitomagnetic frame-dragging vector field is generated (Bruni, Thomas & Wands 2014). Dark matter composed of a purely irrotational fluid would have strong observational signatures (in particular, the rapid formation and growth of supermassive black holes, Sawicki, Marra & Valkenburg 2013), so our assumption of the pure energy exchange which allows CDM to remain geodesic must break down below some length-scale. Further investigation of this limit is left to a future work.

2.2 Flat FLRW background

In a spatially flat FLRW background, equations (4) and (5) reduce to the coupled energy conservation equations,

$$\dot{\rho}_c + 3H \rho_c = -Q,$$

$$\dot{V} = Q,$$  \(\text{(8)}\) \(\text{(9)}\)

where $H$ is the Hubble expansion function and $Q$ is the interaction term.

2.3 Linear perturbations

We now consider the linear, scalar perturbations about the FLRW metric. With the inclusion of these, the line element in a general gauge becomes

$$ds^2 = -(1 + 2\phi)dt^2 + 2a\alpha\beta Bdx^i dt + a^2[(1 - 2\psi)\delta_{ij} + 2\delta_i\delta_j]dx^i dx^j.$$  \(\text{(10)}\)

The perturbed energy density of CDM is given by $\rho_c + \delta \rho_c$, and the perturbed four velocity of matter is

$$u^\mu = [1 - \phi, \ a^{-1}\partial^i v],$$

$$u_{\dot{\mu}} = [-1 - \phi, \ \partial_\dot{i} \theta],$$

where

$$\partial^i v = \dot{a} \dot{\psi} \ / \ a,$$

$$\theta = a(v + B).$$  \(\text{(11)}\) \(\text{(12)}\) \(\text{(13)}\) \(\text{(14)}\)

In the geodesic CDM scenario, where in (6) $f^\mu = 0$, the perturbed energy conservation equations for CDM and the vacuum become

$$\delta\dot{\rho}_c + 3H\delta\rho_c - 3\dot{\rho}_c \dot{\psi} + \rho_c \dot{\psi}^2 / a^2 (\theta + a^2 \dot{E} - aB) = -\delta Q - Q\phi,$$  \(\text{(15)}\)

$$\delta\dot{V} = \delta Q + Q\phi,$$  \(\text{(16)}\)

and the momentum conservation equations become

$$\dot{\theta} + \phi = 0,$$  \(\text{(17)}\)

$$-\delta V = Q\theta.$$  \(\text{(18)}\)

Considering that we are interested in the geodesic CDM scenario, with the interaction consisting of a pure energy exchange in the CDM frame, i.e. $Q^\mu = Qu^\mu$, the CDM four velocity $u^\mu$ acquires a central role, and it is therefore useful to consider a velocity-orthogonal slicing where $u^\mu$ coincides with the normal to the
constant-time hypersurfaces (Kodama & Sasaki 1984; Malik & Wands 2008).

In this case the spatial components of $u_{\nu}$ in equation (12) vanish, and so $\theta = 0$, which then implies $v + B = 0$ from equation (14). The main convenience of this time-slicing with $\theta = 0$ is that the vacuum is spatially homogeneous on these hypersurfaces, $\delta V = 0$, which follows from equation (18). In this slicing, we can then specify a gauge.

A convenient choice of gauge for the numerical analysis discussed later is the synchronous gauge comoving with the four velocity of CDM, fixed by setting $\phi = v = B = 0$. With this choice, equation (17) becomes an identity, equation (18) again implies $\delta V = 0$, and equation (16) therefore gives $\delta Q = 0$: both the interaction and the vacuum are spatially homogeneous with this gauge choice. The interaction therefore does not explicitly appear in the perturbation equations (15) and (16) and it is not necessary to evolve the vacuum perturbations once this choice of gauge is made.\footnote{We wish to emphasize that the vacuum is perturbed in a general space–time sense; it is only homogeneous in the frame of observers comoving with the geodesic CDM, where $\delta V = 0$.}

However, it is usual to use the density contrast $\delta_\rho = \delta \rho_c / \rho_c$ to describe matter perturbations. In doing so, the interaction is reintroduced via the evolution of $\rho_c$ from (8). We find that $\delta_\rho$ evolves as

$$\dot{\delta}_\rho = \frac{Q}{\rho_c} \delta_\rho + 3\dot{\psi} - \nabla^2 \dot{E}. \quad (19)$$

This point cannot be stressed enough, as it shows that the interaction has an effect on the perturbations and not just the background. This has important implications for cosmological structure growth, as we will further describe in Section 2.4.

One may feel that the discussion of perturbations in CDM and the vacuum only is too idealized, especially considering that in our numerical analysis described in Section 4, we make use of the Einstein–Boltzmann code CAMB (Lewis, Challinor & Lasenby 2000; Howlett et al. 2012) in which baryons and radiation are also included. In such a multicomponent case, a common gauge choice is that of the total-matter gauge, with a four velocity chosen to be the eigenvector of the total energy–momentum tensor (Kodama & Sasaki 1984). In such a gauge, the CDM would have a peculiar velocity and both the vacuum and the interaction would be inhomogeneous. However, CAMB works in the synchronous gauge comoving with CDM and therefore the perturbation equations of the other components remain unchanged when one modifies CAMB from its basic ΛCDM version. This greatly simplifies the analysis of the geodesic CDM scenario we consider in this paper.

### 2.4 Redshift space distortions in interacting cosmologies

An interacting scenario such as the one described above has a non-trivial effect on the growth of structure, as we will now explain. The peculiar velocities of galaxies, $v$, cause a stretching and squashing in their shapes when plotted in redshift space. In ΛCDM, where there is no interaction, these RSDs constrain structure growth because the divergence of the peculiar velocity field, $\nabla \cdot v$, is related to the time derivative of the density contrast,

$$\dot{\delta}_\rho = -\frac{1}{a} \nabla \cdot v. \quad (20)$$

One can write this time derivative in terms of a growth factor $f$ as

$$\dot{\delta}_\rho = -\delta_\rho H f. \quad (21)$$

where $f$ is defined as

$$f \equiv \frac{\ln D}{\ln a}. \quad (22)$$

and where $D$ is the amplitude of the linear growing mode (Hamilton 2001). These distortions therefore allow a constraint to be placed on the growth rate of structure in the form of $f \sigma_8$, where $\sigma_8$ is the amplitude of the linear matter power spectrum on a scale of $8h^{-1}$ Mpc. Equation (20) can be interpreted in relativistic perturbation theory as relating $\delta_\rho$ in the comoving-synchronous gauge of the previous section to $\nabla \cdot v$ in the Newtonian–Poisson gauge (Kodama & Sasaki 1984; Malik & Wands 2008).

However, in the interacting vacuum scenario, the interaction enters into the equation for the evolution of the density contrast (equation 19). Relating the $\nabla \cdot v$ term with the metric perturbations in the synchronous comoving gauge gives

$$\nabla \cdot v \equiv -a(3\dot{\psi} - \nabla^2 \dot{E}), \quad (23)$$

and so

$$\nabla \cdot v = -a\delta_\rho + \frac{aQ\delta_\rho}{\rho_c}, \quad (24)$$

and

$$\nabla \cdot v = -a\delta_\rho H f. \quad (25)$$

where $f_i$ is the modified growth rate in the interacting vacuum cosmology,

$$f_i = f - \frac{Q}{H \rho_c}. \quad (26)$$

This means that in the interacting vacuum scenario, the RSDs that we observe place a constraint on a new parameter that we may call $f_i \sigma_8$. This has been studied in Borges & Wands (2017), and a similar effect in a cosmology with a scalar field that conformally and disformally couples to dark matter was noted in Kimura et al. (2018).

An unmodified version of the code CAMB would compute the parameter $f \sigma_8$ as written in equation (33) of Ade et al. (2016a),

$$f \sigma_8(z) \equiv \frac{[\sigma_8^{(\text{vd})}(z)]^2}{[\sigma_8^{(\text{dd})}(z)]^2}, \quad (27)$$

where $\sigma_8^{(\text{vd})}$ is the smoothed density–velocity correlation and $\sigma_8^{(\text{dd})}$ the smoothed density autocorrelation. The peculiar velocity in equation (27) is the Newtonian–Poisson gauge velocity of the baryons and CDM. However, as we will explain in Section 4, we modify CAMB to include our interacting scenario. It follows that the modified CAMB actually computes the right-hand side of equation (27), which we may interpret as the parameter $f_i \sigma_8$. We can therefore safely use RSD data when attempting to constrain the interaction strength. However, this is not a direct constraint on the growth factor, $f$.

### 3 COUPLING FUNCTION RECONSTRUCTION

In order to constrain the interaction with available data, we write the covariant coupling in equation (6) as

$$Q = -q_V \frac{1}{3} \Theta V, \quad (28)$$

where $\Theta = \nabla_\mu u^\mu$ is the expansion scalar and $q_V$ is a dimensionless function that represents the strength of the coupling.
In an FLRW background, equation (28) reduces to
\[ \dot{Q}(z) = -q_V(z) H(z) V(z), \] (29)
and hence the energy conservation equations (8) and (9) become
\[ \dot{\rho}_c + 3H \rho_c = q_V(z) H(z) V(z). \] (30)
\[ V = -q_V(z) H(z) V(z). \] (31)

Now that we have the differential equations written in terms of the dimensionless coupling \( q_V(z) \), we need to model the evolution of this function in redshift in terms of some numerical parameter that we will later constrain with cosmological data.

In this paper, however, we are aiming to reconstruct the coupling rather than test specific models, adopting an agnostic standpoint regarding rather than test specific models, adopting an agnostic standpoint. It is worth stressing here that \( q_V(z) \) is a purely phenomenological parameter, used to implement the step function reconstruction. A true physical model producing an interaction between dark matter and vacuum energy scales with the redshift as \( Q(z) \propto V(z) \). Such an interaction is a sub-case of the linear couplings considered by Quercellini et al. (2008), and it greatly simplifies the solutions for \( \rho_c \) and \( V \), which can be now obtained analytically from equations (30) and (31).

Setting initial conditions at \( z = 0 \), we obtain
\[ \rho_c(z) = \rho_c^0 a^{-3} + V_0 q_v^{-3} \left( a^{-3} - a^{-q_v} \right), \] (32)
\[ V(z) = V_0 a^{-q_v}, \] (33)
where \( \rho_c^0 \) and \( V_0 \) are the present values of the energy density of CDM and vacuum, respectively. Furthermore, the equations for matter perturbations \( \delta_c \) follow equation (19).

Analytical expressions similar to equations (32) and (33) can be found in different redshift bins, in a way that guarantees the continuity of \( \rho_c \) and \( V \) across bin boundaries.

It is worth noting at this point that the choice of a constant \( q_V(z) \) is a strong assumption that has to be taken with a pinch of salt: it conveniently simplifies the equations but can give an unphysical model;\(^3\) we use it here only to give a phenomenological representation of a generic interaction in various redshift ranges, up to \( z = 0 \).

Hence, a first step we can take towards a more general description of the coupling is to consider a single-step function reconstruction for \( q_V(z) \), i.e. a \( q_V(z) \) that remains constant up to a certain redshift \( z_{\text{trans}} \) and vanishes for higher redshifts; this corresponds to a cosmology equivalent to \( \Lambda \)CDM and vacuum, respectively. Furthermore, the equations for matter perturbations \( \delta_c \) follow equation (19).

### 3.2 Binned reconstruction

In order to allow for a variation in redshift of the coupling function \( q_V(z) \), we reconstruct its evolution using a number of redshift bins \( N \), with the \( i \)-th bin being enclosed in the range \( [z_i-1, z_i] \), with \( z_0 = 0 \) and \( i = 1, \ldots, N \). For each of these bins the value at the centre of the range \( \bar{z}_i \) is \( q_V(\bar{z}_i) \) and we assume the function to take this constant value within the entire redshift bin. With this choice, we can generally reconstruct the value of the function at any point as
\[ q_V(z) = q_1 + \sum_{i=1}^{N-1} (q_i + 1 - q_1) \left[ \theta_i(z - z_{i}) - \theta_i(z - z_{i+1}) \right] \] (34)
or, equivalently,
\[ q_V(z) = q_1 + \sum_{i=1}^{N-1} (q_i + 1 - q_1) \left[ \theta_i(z - z_{i}) \right] \] (35)
\(^2\)Notice that adopting a step function reconstruction for \( q_V(z) \) introduces discontinuities in \( \dot{\rho}_c \) and \( V \) in equations (30) and (31) at the boundaries of the redshift bins; however this is not a problem, as the resulting \( \dot{\rho}_c \) and \( V(z) \) are continuous. In practice, we adopt a smoothed version of the step function reconstruction, so that even \( \dot{\rho}_c \) and \( V \) are continuous, see Section 3.2.

\(^3\)For instance, in an oversimplified model based on a negative constant \( q_V \) at all times the CDM density \( \rho_c \) would become negative at some point.
where $\theta_H$ is the Heaviside function. We choose however to adjust this reconstruction by introducing a smoothing at the border of the bins, controlled by the parameter $s$, substituting the Heaviside functions with smooth steps based on hyperbolic tangent functions. This allows us to avoid sharp transitions between values of the function $q_V(z)$, which could lead to numerical problems. Given that no derivatives of the coupling enter our equations, this should not be an issue in our case, but even so, we rewrite the reconstructed function as

$$q_V(z) = q_1 + \sum_{i=1}^{N-1} \frac{q_{i+1} - q_i}{2} \left[ 1 + \tanh \left( \frac{z - z_i}{s(z_i - z_{i-1})} \right) \right]. \quad (36)$$

Using equation (35) in equations (30) and (31) gives analytic expressions similar to equations (32) and (33) in each bin, matched at the bin boundaries; using equation (36) gives a smoothed version of the same $q_V(z)$. With this, we numerically obtain the densities $\rho_c$ and $V$ such that their derivatives $\dot{\rho}_c$ and $\dot{V}$ are continuous through the bin boundaries. We have checked that the numerical and analytical solutions for $\rho_c$ and $V$ match extremely well.

### 3.3 Seeded vacuum energy

In the cosmology described above, there is a standard $\Lambda$CDM evolution at high redshifts until the coupling switches on at $z_{\text{trans}}$ and the vacuum and CDM energies can begin to interact. Instead, in the SVE, we have designed a reconstruction that mimics a physical scenario in which for $z > z_{\text{trans}}$ we have a pure CDM (Einstein–de Sitter) evolution, rather than $\Lambda$CDM. In this scenario, the coupling causes the vacuum energy to suddenly grow from zero up to a ‘seed’ value at $z_{\text{trans}}$, a kind of fast transition; cf. Piattella et al. (2010) and Bertacca et al. (2011) for a similar idea for unified dark matter models. Then, at lower redshifts, the interaction is characterized as in the previous cases, i.e. with a constant $q_V$, and the vacuum evolves accordingly. The free parameter, $z_{\text{trans}}$ allows this rapid growth of vacuum to a non-zero value to occur even at very late times.

In practice, this set-up is achieved by some reverse engineering in CAMB. Since the coupling function $Q$ is proportional to $V$, if $V$ remained practically zero for the entire cosmic history we would never have any interaction. Instead, we ‘seed’ the growth of vacuum by inducing a sudden spike in its density at $z_{\text{trans}}$. The vacuum energy $V$ can then grow to a finite value and the transfer of energy between the vacuum and CDM via the coupling can begin.

### 3.4 Effects of the coupling

As mentioned in the Introduction, we are interested in the ability of these models to ease the tensions between low- and high-redshift observations. In particular, we focus on the tension between the local determination of $H_0$ and that inferred from CMB measurements of the angular size of the sound horizon at recombination, $\theta_{\text{MC}}$. In Fig. 1 we show the $H(z)$ obtained for three different values of $q_V$ and the same value of $\theta_{\text{MC}}$, also highlighting the resulting value of $H_0$, while the other cosmological parameters, i.e. the densities $\Omega_m h^2$ and $\Omega_k h^2$, primordial power spectrum amplitude and tilt $A_s$ and $n_s$, and the optical depth $\tau$, are fixed to the best fit of Planck 2015 (Ade et al. 2016a). We find that starting from the Planck value of $\theta_{\text{MC}}$, a positive $q_V$ leads to higher values of $H_0$ with respect to $\Lambda$CDM, thus moving in the direction required to ease the tension.

Figs 2–4 illustrate different aspects of the same three cosmologies. Given the definition of $Q$ in equation (29), a negative value for $q_V$ implies that CDM is decaying into the vacuum, thus with the

![Figure 1](https://example.com/fig1.png) **Figure 1.** The evolution of the Hubble function $H(z)$ for three cosmologies resulting in the same angular size of the sound horizon at recombination. Except for $q_V$ and $H_0$, whose values are shown in the label, all the other primary parameters are fixed to the Planck 2015 best fit.

![Figure 2](https://example.com/fig2.png) **Figure 2.** The evolution of the matter (dashed lines) and vacuum density (solid lines) parameters as a function of redshift, for a small positive and negative coupling. The $\Lambda$CDM case is shown in blue. Except for $q_V$ and $H_0$, whose values are shown in the label, all the other primary parameters are fixed to the Planck 2015 best fit.

![Figure 3](https://example.com/fig3.png) **Figure 3.** The CMB TT power spectrum for three cosmologies resulting in the same angular size of the sound horizon at recombination. Except for $q_V$ and $H_0$, whose values are shown in the label, all the other primary parameters are fixed to the Planck 2015 best fit. The data points are the TT observations of Planck 2015.
values of the density parameters $\Omega_b h^2$ and $\Omega_c h^2$ fixed at $z = 0$ we end up with a higher matter density in the past (see Fig. 2). However, because the cosmologies shown here have the same present value of the matter density $\Omega_c h^2$, they will have significantly different matter abundances at early times; this impacts other observables, e.g. CMB power spectra which are significantly affected by the amount of matter (see Fig. 3). Therefore if the only free parameters considered are $q_V$ and $H_0$ one would expect a positive correlation between the two, but it is crucial not to neglect the effect of matter abundance on predictions for cosmological probes and the resulting degeneracy of $\Omega_c h^2$ with $q_V$ and $H_0$.

In Fig. 4, the effect of the coupling on the evolution of perturbations is shown through its effect on the matter power spectrum $P(k, z)$; we can see that a positive value of $q_V$ suppresses the amplitude of $P(k, z)$, while on the contrary this is increased by a negative $q_V$. We stress that even though the results we comment on here refer to a case with constant $q_V$ up to $z = 1$ and vanishing at higher redshifts, the same qualitative behaviour also holds for different choices of the redshift evolution of $q_V$.

### 4 DATA AND ANALYSIS METHOD

We want to compare the predictions of the interacting vacuum model with recent cosmological data. For this analysis, we consider the Planck 2015 measurements of the CMB temperature and polarization (Aghanim et al. 2016; Ade et al. 2016a). For the Planck likelihood, we also vary the nuisance parameters that are used to model foregrounds as well as instrumental and beam uncertainties. We note that at the time of writing, the new Planck 2018 likelihood was not publicly available, but given the similarities between the Planck 2015 and 2018 results we do not expect that our results would change significantly were we to use the 2018 data presented in Aghanim et al. (2018).

In addition to the Planck CMB data, we utilize the BAO measurement from the 6dF Galaxy Survey (Beutler et al. 2011), the BAO scale measurement from the SDSS DR7 Main Galaxy Sample (Ross et al. 2015) and the combined BAO and RSD data from the SDSS DR12 consensus release (Alam et al. 2017) (data points listed in Table 1), together with the JLA Type Ia supernovae sample (Betoule et al. 2014). We refer to the combined data sets as Planck + Low-$z$, with Low-$z$ referring to the combination of all data set at redshifts lower than recombination.

#### 4.1 Implementation in CAMB

Now that we have chosen our methods of reconstruction, we need to obtain predictions for the cosmological observables. In order to do so, we use the Einstein–Boltzmann Code for the Anisotropies in the Microwave Background (CAMB); we modify the code so that it uses the $\rho_c(z)$ and $V(z)$ of our model rather than those computed internally within the $\Lambda$CDM framework. We therefore add a new module which solves the differential equations (30) and (31), with $q_V(z)$ computed at each redshift according to the methods described in Section 3. We use a Runge–Kutta algorithm, starting from the present day with initial conditions

\[
\rho_c^0 = 3H_0^2\Omega_c, \\
V_0 = 3H_0^2\Omega_V, \\
\tag{37}
\]

and then evolving the equations backwards in time. To solve the equations for CDM perturbations we make use of the routines present in CAMB, modifying the equation for CDM with the extra source term proportional to $q_V(z)$ described in equation (19).

On top of this, we make use of the MCMC sampler COSMOMC (Lewis & Bridle 2002; Lewis 2013) to sample the parameter space and compare our predictions with the cosmological data mentioned above. The six sampled parameters are therefore those of the minimal $\Lambda$CDM: the baryon and CDM densities at present day, $\Omega_b h^2$ and $\Omega_c h^2$; the optical depth, $\tau$; the primordial power spectrum amplitude and tilt, $A_s$ and $n_s$, and the Hubble constant $H_0$.

Furthermore, we also consider additional parameters depending on the specific cosmology we investigate:

(i) $C_{fix}$: the constant coupling $q_V$ with uniform prior $[-6, 3]$, controlling the evolution of the densities up to a fixed $z_{trans} = 3000$, with standard $\Lambda$CDM evolution at higher redshifts. We also consider a variation on this in which $z_{trans} = 0.9$, to compare directly with Salvatelli et al. (2014).

(ii) $C_{var}$: the constant coupling $q_V$ and the varying $z_{trans}$ with uniform priors $[-6, 3]$ and $[0.1, 10]$ respectively. At redshifts higher than $z_{trans}$, the coupling is turned off and we then have standard $\Lambda$CDM evolution. In order to test the stability of the results changing the prior choice, we also explored a logarithmic prior on $z_{trans}$, including also higher values of this parameter, finding no significant differences in our results. We choose therefore to present in the paper only the results obtained with the uniform prior.

(iii) SVE: a constant $q_V$ and the varying transition redshift $z_{trans}$. At redshifts higher than the transition redshift, CDM evolves in the

| Quantity | $z_{eff}$ | Measurement | Source |
|----------|-----------|-------------|--------|
| $D_s$    | 0.106     | 457 ± 27 ($r_{s}/r_{s, fid}$) Mpc | Beutler et al. (2011) |
| $D_s$    | 0.15      | (664 ± 25) ($r_{s}/r_{s, fid}$) Mpc | Ross et al. (2015) |
| $D_s$    | 0.32      | (1270 ± 14) ($r_{s}/r_{s, fid}$) Mpc | Alam et al. (2017) |
| $D_s$    | 0.57      | (2033 ± 21) ($r_{s}/r_{s, fid}$) Mpc | Alam et al. (2017) |
| $f/s_k$  | 0.32      | 0.392       | Alam et al. (2017) |
| $f/s_k$  | 0.57      | 0.445       | Alam et al. (2017) |
standard way according to the solution of the differential equations. For these parameters, we also use the uniform priors [−6, 3] and [0.1, 10] respectively.

(iv) 4bins: N = 4 low-redshift bins qₐ, with uniform priors [−6, 3], used to reconstruct the evolution in time of the coupling function qᵥ(z), with a return to standard ΛCDM for redshifts higher than the last bin. The number and redshift of the considered bins (zᵢ = {0.3, 0.9, 2.5, 10}) are chosen in order to compare our results with that from previous work by Salvatelli et al. (2014).

The choice of the prior range [−6, 3] for the qᵥ parameters arises from the fact that ρᵥ in equation (32) becomes singular when qᵥ = 3. While higher values of the coupling are theoretically possible, we choose to limit the parameter space to the non-physical part, in order to avoid issues with the sampling. Indeed, we find that this prior is sufficiently broad as to have no effect on our results.

A summary of the priors used on all parameters can be found in Table 2.

5 RESULTS

In this section, we present the results of our investigation, beginning with the two Cfix cases where the interaction is characterized by a constant parameter qᵥ up to a transition redshift, moving to the cases where the transition redshift zₜrans is allowed to vary (Cvar and SVE) and finally the 4bins case. We remark again that any integration is performed with initial values set today at z = 0. In particular a non-zero value for the vacuum V₀ is set as in equation (37).

In Table 3, we summarize results for the five cases; we report the marginalized constraints on the primary parameters sampled in our analysis, adding also the combination of derived parameters σ₉₀Ω₉₀², useful to assess the status of the tensions between high- and low-redshift probes.

5.1 Cfix case

As a baseline result, we report the constraints obtained assuming a constant value qᵥ for the coupling, up to a fixed redshift zₜrans = 3000. At higher redshifts, the interaction is turned off (qᵥ(z > zₜrans) = 0) and the vacuum assumes a constant value V = V(z = zₜrans). This choice is made so that the interaction affects the evolution of CDM and vacuum only after the last scattering surface; however, given our choice of QᵥV, the interaction is negligible during the matter-dominated era.

In Fig. 5, we show the 2D joint marginalized contours of qᵥ with H₀, Ω₉₀, and Ω₉₀ h². We point out that the constraints placed by Planck on qᵥ and H₀ are strongly degenerate. This effect is due to the change in the Universe’s expansion history caused by the interaction: we find that a larger H₀ requires a smaller coupling parameter qᵥ in order to recover the same expansion history. A similar degeneracy is also present between qᵥ and Ω₉₀. In general, the CMB data prefer positive values of qᵥ. Negative values of qᵥ imply that we would have a smaller CDM density at late times (see bottom right panel of Fig. 5), which would boost the amplitude of the acoustic peaks in the CMB temperature–temperature power spectrum by such an amount that the change could not be compensated for by equivalent changes in the other cosmological parameters.

We find that the Planck data alone allow for the coupling qᵥ to be non-vanishing; however, the ΛCDM limit of this model is within the 68 per cent confidence level region. The degeneracies between qᵥ, H₀, and Ω₉₀ are broken when the Low-z data sets are added to Planck. This is because the data directly probe the redshift range where the interaction is primarily effective. The combination of the Planck and Low-z data does not allow qᵥ to greatly deviate from zero and the cosmology is therefore very similar to ΛCDM.

5.2 Cfix with low transition redshift

We now consider a Cfix case in which we set the transition redshift to zₜrans = 0.9. This allows us to make a direct comparison with the so-called qᵥₐ case presented in Salvatelli et al. (2014), in which it was found that a null interaction was excluded at the 99 per cent confidence level.

This Cfix case should be seen as a simple single-step function reconstruction of an interaction that is negligible for z > zₜrans = 0.9. It is a single-parameter reconstruction where, as in Salvatelli et al. (2014) and in comparison to our 4bins case of Section 5.5, the first two bins are grouped together, with no interaction for z > zₜrans = 0.9. Note that in Salvatelli et al. (2014), the zₜrans = 0.9 value was also chosen because it was the best-fitting value resulting from a two parameter analysis, similar to our Cvar case in the next section.

Our results for this case are similar to that of the Cfix case with zₜrans = 3000. However, in this case, the CMB bound on qᵥ, and consequently the bound on the degenerate cosmological parameters, is less broad and more directly centred on qᵥ = 0 with respect to the zₜrans = 3000 case; this is due to the fact that the coupling is active for less time and therefore values of qᵥ that are significantly different from zero cannot be compensated by changes in Ω₉₀ h². This result differs from that found by Salvatelli et al. (2014) in that we do not exclude the ΛCDM limit of qᵥ = 0 at any confidence level. The marginalized 2D joint distributions for the relevant parameters in this case are shown in Fig. 6.

5.3 Cvar case

In Fig. 7, we show the results of the case where the transition redshift zₜrans is allowed to vary. In this case, we also find the ΛCDM limit to be a good fit to the data, both in the Planck and Planck + Low-z combinations respectively, as reported in Table 3. We find an evolution similar to both Cfix cases, with the inclusion of the Low-z data set breaking the degeneracies between qᵥ and the cosmological parameters in the Planck result. With both Planck alone and Planck + Low-z, we find that zₜrans is unconstrained, in contrast to a similar analysis in Salvatelli et al. (2014). For values of this parameter that correspond to the matter-dominated era, this Cvar case effectively reduces to the Cfix one, as V(z) and
Table 3. Marginalized values of the parameters and their 68 per cent confidence level bounds, obtained using Planck and Planck + Low-z. When only upper or lower bounds are found, we report the 95 per cent confidence level limit.

|          | 4bins        | 0.62 ± 0.60 | 0.06 ± 0.12 |
|          | q_n          | 0.0 ± 1.2 | -0.42 ± 0.10 |
|          | q_n          | 0.3 ± 1.9 | 0.88 ± 0.66 |
|          | q_n          | > -2.7 | -0.62 ± 1.3 |
|          | q_n          | Unconstrained | Unconstrained |
|          | q_n          | Unconstrained | Unconstrained |
|          | ztrans       | Unconstrained | Unconstrained |
|          | ztrans       | >1.7 | >1.4 |
consequently $q_V$ become negligible. For low values of $z_{\text{trans}}$ this case becomes extremely similar to $\Lambda$CDM, with $z_{\text{trans}} = 0$ acting as another $\Lambda$CDM limit of the model for any value the coupling can take.

5.4 SVE case

In Fig. 8, we show the results for the SVE cosmology. The first thing to notice is that this case is analogous to Cvar when $z_{\text{trans}}$ takes high values, with both data combinations favouring positive values of the coupling, i.e. a decay of vacuum energy density into CDM. This is due to the fact that in Cvar, even though $V(z)$ does not vanish, it becomes negligible in the past following the $\Lambda$CDM
function 4, thus allowing for a general evolution in redshift of the coupling both the and \( \Omega_m \) as obtained in the analysis with the Planck (red) and Planck + Low-z (yellow) data sets.

Figure 9. 4bins case: 68 per cent and the 95 per cent confidence level marginalized contours on \( q_i \), \( i = 1, \ldots, 3 \) and \( \Omega_m \) as obtained in the analysis with the Planck (red) and Planck + Low-z (yellow) data sets.

5.5 4bins case

In this case, we aim to update the work of Salvatelli et al. (2014), in which the coupling consists of \( N = 4 \) bins in redshift, with transitions at \( z = 0.3, 0.9, 2.5 \), and 10 and values \( q_i \) with \( i = 1, \ldots, 4 \), thus allowing for a general evolution in redshift of the coupling function \( q_i(z) \). In Fig. 9 and Table 3, we show the results obtained from the cosmological analysis with this 4 bins setup, considering the aforementioned anticorrelation. While still in agreement with a constant \( q_i(z) = 0 \) cosmology, the Planck + Low-z data set allows for a model with an oscillatory amplitude of vacuum energy–CDM interaction at low redshifts (See Section 6.3 for further discussion). This is in contrast to the results of many similar works. We will expand on this point in Section 7.

5.6 Evolution of \( f \sigma_8 \)

From these results, we can also examine how the interaction in each case affects the evolution of the \( f \sigma_8 \) parameter as computed by the modified CAMB, keeping in mind that in our interacting scenario this parameter does not directly constrain the growth factor, i.e. it rather represents \( f/\sigma_8 \), as discussed in Section 2.4. In Fig. 10, we plot the \( f \sigma_8 \) prediction for each case, using the mean posterior values of \( q_i \) from \( \text{Planck} + \text{Low-z} \) runs to obtain its evolution as a function of redshift. For illustrative purposes, we plot these predictions along with data points from various collaborations: 2dFGRS ( Percival et al. 2004), 6dFGRS (Beutler et al. 2012), WiggleZ (Blake et al., 2011), SDSS LRG (Samushia, Percival & Raccanelli2012), BOSS CMASS (Reid et al. 2012), and VIPERS (de la Torre et al. 2013).

This plot shows how the similar values of \( q_i \) obtained for Cfix, Cvar, and SVE lead to similar evolution histories for \( f \sigma_8 \), with the small positive values of \( q_i \) in these cases leading to a suppression of this quantity with respect to \( \Lambda \)CDM. Growth is suppressed with a positive coupling because our implementation in CAMB works by starting with the values of cosmological parameters at \( z = 0 \) and evolving them backwards in time. This means that, with a positive...
In all our results, we find a good agreement between the extended model and the standard cosmology with the addition of extra parameters. From this definition, it follows that a negative ∆DIC, indicating that ΛCDM is marginally preferred over the extended model. This comes from the fact that adding the Low-z data sets significantly shrinks the constraints around the ΛCDM limit of the model, thus disfavouring the extended case which, at this point, effectively reproduces a ΛCDM cosmology with the addition of extra parameters.

6.2 Effects on cosmological tensions
As we highlighted in Introduction, one of the motivations to explore the coupling scenarios discussed in this paper is to attempt to solve the tensions that exist between different observations, i.e. the discrepancies between low- and high-redshift measurements of the present-day expansion rate of the Universe and of the clustering of matter. In Fig. 11, we plot the H0 versus Ωm and σ8 versus Ωm 2D marginalized contours for every case considered, obtained using the Planck 2015 data set, comparing them with the constraints used assuming ΛCDM, in order to examine the effects of the interaction on the H0 and σ8 tensions.

We first note that for both of these combinations, the contours obtained for the Cfix, Cvar, and SVE are very similar, showing that changing the behaviour of V(z) after ztrans (from standard ΛCDM evolution to vanishing V(z)) has no significant effect if ztrans is already in an epoch where vacuum energy is negligible. In Fig. 12, we have plotted the ratio of the vacuum to CDM energy densities, for both a small positive and negative coupling and with two transition redshifts, ztrans = 0.9 and 10. The sign of the coupling and the transition redshift value have limited effect, as for each of the four values shown, the density ratio reaches 1/100 and 1 at very similar redshifts. The 4bins case instead yields broader constraints with respect to the other cases, an effect which is due to the higher number of coupling parameters and their degeneracies with the standard cosmological ones.

The left-hand panel of Fig. 11 shows how the coupling scenarios are able to apparently ease the tension between the local measurements of H0 (grey band) and the Planck measurement. However, this is only due to the extreme degeneracy between H0, Ωm, and qV that we highlighted in Section 5; the mean values obtained for H0 are actually lower than those found by Planck assuming ΛCDM, and the tension is eased only because of the much larger error bars. In Poulin et al. (2018), it was proposed that this tension could be relaxed with an Early Dark Energy component, affecting the evolution of the Universe at z > 3000; while not explored here, a high-redshift coupling between CDM and vacuum energy could in principle be used to mimic the effect of such a component. We leave the investigation of this possibility for a future work.

In the right-hand panel of Fig. 11, we instead highlight how reconciling the tension in σ8 is less feasible in this model. The errors on the cosmological parameters are once again enlarged by the degeneracies introduced by the coupling. This leads to lower values of σ8 being allowed, but these lower values subsequently necessitate higher values of Ωm in compensation, which are then disfavoured by the Low-z data.

6.3 Gaussian process reconstruction
We can use Gaussian processes to attempt to reconstruct the qV(z) function for the 4bin case. Gaussian processes have been widely used in cosmology to reconstruct smooth functions from observational data, particularly for functions such as H(z) and the dark energy equation of state w(z) (see e.g. Seikel, Clarkson & Smith 2012; Shafieloo, Kim & Linder 2012; Yang, Guo & Cai

| Parameter | Planck | Planck+Low-z |
|-----------|--------|--------------|
| Cfix | 1.1 | 3.8 |
| Cfix (ztrans = 0.9) | -1.2 | 0.4 |
| Cvar | -0.5 | 2.6 |
| SVE | -1.3 | 1.3 |
| 4bins | -1.6 | 3.1 |

We can use Gaussian processes to attempt to reconstruct the qV(z) function for the 4bin case. Gaussian processes have been widely used in cosmology to reconstruct smooth functions from observational data, particularly for functions such as H(z) and the dark energy equation of state w(z) (see e.g. Seikel, Clarkson & Smith 2012; Shafieloo, Kim & Linder 2012; Yang, Guo & Cai

MNRAS 488, 3423–3438 (2019)
Constraints on the interacting vacuum scenario

68 per cent and 95 per cent confidence levels on the $H_0 - \Omega_m$ plane (left-hand panel) and $\Omega_m - \sigma_8$ plane (right-hand panel) for the four cosmologies considered: $Cfix$ (yellow contours), $Cvar$ (dark blue contours), $4bins$ (red contours), and $SVE$ (green contours), with the $\Lambda$CDM Planck alone case plotted in black. The grey bands in the left-hand panel show the 68 per cent and 95 per cent confidence level on $H_0$ as obtained in Riess et al. (2018). These results are obtained with the analysis of the full Planck data set.

There has been some debate in the literature about the appropriate choice of kernel for various problems, with no clear-cut answer yet. For example, Seikel & Clarkson (2013) found that the Matérn class of kernels, and especially the Matérn ($\nu = 9/2$) kernel was the most successful at reconstructing $w(z)$ using supernova data. The Matérn class of kernels have the following general form

$$k(x, \tilde{x}) = \sigma^2 \frac{2^{1-v}}{\Gamma(v)} \left( \frac{2v(x - \tilde{x})^2}{\ell} \right)^v \frac{\Gamma(v + \frac{1}{2})}{\sqrt{\pi} \Gamma(v + 1)} \times K_v \left( \frac{2v(x - \tilde{x})^2}{\ell} \right).$$

(40)

where $\Gamma(v)$ is the gamma function, $K_v$ is a modified Bessel function, and $v$ controls the shape of the covariance function, tending to the Gaussian limit as $v \to \infty$. The hyperparameters $\ell$ and $\sigma$ correspond

reconstruction given by the squared exponential kernel, the simplest kernels can be added or multiplied in almost any combination, we did not test every possibility exhaustively. We therefore present the baseline of zero when it has insufficient information. We therefore conclude that the GP will be better suited to reconstructing a case with many more redshift bins, which we intend to investigate in a future work.

7 COMMENT ON OTHER RESULTS

Finally, we note that there has been an extensive treatment in the literature of a similar interacting vacuum scenario to that studied in this work (Kumar & Nunes 2017; Solà, Gómez-Valent & de Cruz Pérez 2017b; Solà, de Cruz Pérez & Gómez-Valent 2018b; Tsiapi & Basilakos 2018; Kumar, Nunes & Yadav 2019), upon which we would like to comment.

First, all of the aforementioned works appear to use a single bin case, akin to what we call $C_{\text{fix}}$, which implies the interaction parameter $q_v$ has been constant throughout the entire cosmic history. This is sufficient for a basic analysis, but carries some important physical implications. If the interaction remains constant for the entire cosmic history (and is found to favour a decay of CDM into the vacuum) it implies that eventually the energy density of CDM must become negative, as we have pointed out at the end of Section 3.1. While the phenomenology of such a scenario may still be interesting when studying the Universe’s history, the unphysicality of the model is motivation enough to instead consider the effects of a dynamical interaction, as we have done in this work.

Secondly, in Tsiapi & Basilakos (2018), the effect of the interaction on perturbations in the matter energy density are not clearly taken in to account. As we have shown, the interaction enters into the equation for the density contrast ($\nu$) and it is necessary to modify CAMB accordingly. The presence of the coupling in this equation means that the interaction will have some effect on cosmological structure growth, which is also clear from the matter power spectrum for the $C_{\text{fix}}$ case, as shown in Fig. 4. While an analysis of the background cosmology is instructive, we consider our current work an improvement, as we also take into account the effect of the coupling at the level of the perturbations.

Furthermore, Solà et al. (2017b, 2018b) forgo a complete MCMC parameter inference with the full Planck CMB likelihood, choosing instead to use only the compressed likelihood. We believe our full analysis that takes the complete, uncompressed data into account has produced a more reliable result. However, we note that the novel use of the bispectrum as a potential tracer of the dynamics of dark energy was investigated in Solà et al. (2018b) and subsequently expanded on in Solà et al. (2018a) using the well-known XCDM, CPL, and $\phi$CDM parametrizations (in this work the authors also used the full Planck likelihood). Such an idea was also proposed by Borges & Wands (2017), but we emphasize that the original arXiv version of Solà et al. (2018b) preceded Borges & Wands (2017). It was indeed found in Solà et al. (2018a) that the bispectrum enhances the dynamical dark energy signal, so an interesting avenue of future investigation would be to use the bispectrum data when constraining the interacting vacuum scenario. A careful consideration of the effect of the interaction on the bispectrum measurements would be needed, however.

Figure 13. Gaussian process reconstruction of $q_v(z)$ using the squared exponential kernel, with data points as provided by the analysis of the 4bins cosmology. The grey dashed lines indicate the boundaries of each redshift bin and the shaded regions denote the 68 per cent confidence intervals of the GP reconstruction.

Figure 14. Gaussian process reconstruction of $q_v(z)$ using three different kernels, with data points as provided by the analysis of the 4bins cosmology. The grey dashed lines indicate the boundaries of each redshift bin and the shaded regions denote the 68 per cent confidence intervals of the GP reconstruction.

to the approximate length-scale over which the function varies and the magnitude of these variations, respectively.

In the course of our analysis, we investigated the results given by all the basic kernels provided by george, none of which resulted in a function that excludes $\Lambda$CDM at any confidence level, but as kernels can be added or multiplied in almost any combination, we did not test every possibility exhaustively. We therefore present the reconstruction given by the squared exponential kernel, the simplest of the Matérn class kernels, recovered from equation (40) when $\nu \to \infty$,

$$k(x, \tilde{x}) = \sigma^2 \exp \left( -\frac{(x - \tilde{x})^2}{2\ell^2} \right), \quad (41)$$

This reconstruction is shown in Fig. 13. For comparison, we also show the reconstruction using the second- and third-order polynomial kernels provided by george in Fig. 14. The data points in both cases come from the Planck + Low-$\ell$ runs, in which we can clearly see the oscillatory behaviour of the coupling mentioned earlier.

The hyperparameters $\ell$ and $\sigma$ that appear in the kernels described above can be optimized by maximizing the log-likelihood of the functions they produce. However, with this optimization implemented, our GP regressions all collapsed to be exactly equal to zero for all redshifts. This is because we have very little data with which to inform the Gaussian process and the GP always returns to its baseline of zero when it has insufficient information. We therefore conclude that the GP will be better suited to reconstructing a case with many more redshift bins, which we intend to investigate in a future work.
The work of Kumar & Nunes (2017) also examined the same interacting scenario, but in addition to varying the interaction strength along with the six standard cosmological parameters in $\Lambda$CDM, they also varied the sum of the neutrino masses, $\sum m_n$, and the effective number of relativistic degrees of freedom, $N_{\text{eff}}$. It was found in that work that the use of the combination of Planck+BAO+JLA data (exactly equivalent to the Planck+Low-z combination used in this work) resulted in finding no suggestion of an interaction. However, the inclusion of galaxy cluster count data from Planck (Ade et al. 2016b) and CFHTLenS (Heymans et al. 2013) resulted in finding a non-zero interaction at the 99 per cent confidence level.

In Kumar et al. (2019), the authors again tested the same interacting scenario, but with yet another combination of data sets: Planck 2015 with the KiDS weak-lensing survey (Köhlinger et al. 2017) and the 2016 Hubble Space Telescope measurement of $H_0$ (Riess et al. 2016). In this work, the authors found compelling statistical evidence for an interaction and were also able to simultaneously relax the $H_0$ and $\sigma_8$ tensions. This again indicates the strong effects that different data sets can have and demonstrates the need for awareness of possible systematics when choosing and combining data sets. In particular, when using weak-lensing data, it is important to make a conservative cut of the non-linear scales in these data sets, unless the non-linear theory for perturbations is known.

Finally, we would like to address some differences between this work and the previous work of some of the current authors (Salvatelli et al. 2014). The current work was partly designed to make a comparison with the work presented in that Letter, confronting the same interacting scenario with the latest available data sets. In Salvatelli et al. (2014), it was found that a late-time interaction in a single low-redshift bin of $z \leq 0.9$ was favoured over the null interaction case, with $\Lambda$CDM being excluded at 99 per cent confidence level. As described in Section 5.2, we replicated this case, $C_{\text{fix}}$ with $z_{\text{trans}} = 0.9$, albeit using more up-to-date data sets (the Planck 2015 likelihood and newer BAO, RSD, and Type Ia supernovae data), as well as a broader prior on the parameter $q_V$ that includes positive values, but found no significant deviation from $\Lambda$CDM at all.

Similarly, when replicating the 4bin case, also analysed by Salvatelli et al. (2014), we found no significant deviation from $\Lambda$CDM at low redshift, in contrast to the 95 per cent confidence level difference reported in that work. We can possibly attribute this to the simple lack of evidence for an interaction in the newer observational data sets used in the current work. Our finding that the null interaction scenario (i.e. $\Lambda$CDM) is always well within the 95 per cent confidence region for $q_V$ is in agreement with the recent work by Yang et al. (2018b).

8 CONCLUSIONS

In this work, we have considered the possibility of an interaction in the dark sector, represented as a pure energy exchange between vacuum and CDM. We have investigated constraints on this scenario, by making a simple binned parametrisation of the coupling function in redshift, using the latest cosmological data sets to place constraints on the coupling in each bin.

We investigated a number of different cases under the umbrella scenario of the interacting vacuum, namely the cases with a single bin and either a fixed or varying transition redshift ($C_{\text{fix}}$ and $C_{\text{var}}$); a case in which the vacuum energy is zero at early times, only growing after the interaction switches on, and lastly, in a model-independent way, a four bin case to replicate the work of Salvatelli et al. (2014).

In all the cases we studied, we found that the $\Lambda$CDM case, corresponding to no interaction in our scenario, is always well within the 95 per cent confidence regions of our parameter estimation. At the same time, the interacting scenario remains a viable alternative to $\Lambda$CDM, and only future data will be able to settle the case. We also note that our analysis is restricted to linear scales, while it is entirely possible that in extending the interacting vacuum scenario to non-linear scales more stringent constraints will be found, cf. He et al. (2018). Our findings are in contrast to a number of recent works mentioned in the previous section, but we have described the differences in our approach and contest that these are sufficient to explain the different results.

Finally, we note that the observational literature is being continually updated, with ever-larger surveys and telescopes planned for the near future. With these surveys will come an unprecedented level of precision in the measurement of cosmological observables that will in turn demand the utmost rigor from models designed to predict their values. The careful consideration of every implication a model may carry is therefore of paramount importance, and models that take into account the background cosmology only will no longer be satisfactory explanations of our observational data.

ACKNOWLEDGEMENTS

We thank Robert Crittenden and Antony Lewis for helpful comments, and Najla Said and Valentina Salvatelli for useful discussions in the early stages of this work. This paper is based upon work from COST action CA15117 (CANTATA), supported by COST (European Cooperation in Science and Technology). Numerical computations were done on both the Sciama High Performance Compute (HPC) cluster which is supported by the ICG, SEPN net and the University of Portsmouth, and the Marius cluster, which is supported by the Lorentz Institute, Leiden University. MM acknowledges support from the D-ITP consortium, a program of the NWO that is funded by the OCW. NBH is supported by UK STFC studentship ST/N050425/1 and gratefully acknowledges the hospitality of the Lorentz Institute where part of this work was carried out. SP acknowledges support from the NWO and the Dutch Ministry of Education, Culture and Science (OCW), and also from the D-ITP consortium, a program of the NWO that is funded by the OCW. MB and DW are supported by UK STFC Grant No. ST/N000668/1.
