Abstract: Gestational diabetes mellitus (GDM) starts during pregnancy and can increase the risk of adverse pregnancy outcomes, as well as be the cause of a number of diseases in the years after birth in both the mother and the fetus. The aim is to study in the Bulgarian population of pregnant women the relationship between hyperglycemia during pregnancy and some factors – arterial hypertension (AH), previous macrosomic baby weighing 4.5 kg or above, hirsutism. Material: A cross-sectional multicenter population-based study which included 547 pregnant women, with average age 30.49±5.12 years was conducted in 84 settlements in Bulgaria. Methods: A questionnaire was completed, blood pressure was measured (Guideline of ESC/ESH, 2018), BMI was calculated. A two-hour, 75 g oral glucose tolerance test (OGTT) was performed. Glucose was quantitatively determined using enzymatic reference method with hexokinase (Roche reagent) on Cobas e501 analyzer. The statistical analysis was performed using standard SPSS 13.0 for Windows. Results: The incidence of Hyperglycemia for the whole group of pregnant women was 14.4% (79/547), up to 24 gestational week (g.w.) it was 5.3% (29/547) and after 24 g.w. - 9.1% (50/547), P < 0.01. Of all screened pregnant women, 2.4% (13/547) developed AH during the current pregnancy. Hyperglycemia was found in 38.5% (5/13) of the women with AH and in 13.9% (74/534) of the women without AH, P < 0.028. In 3.29% of the pregnant women (18/547) a macrosomic baby weighing 4.5 kg or above was found in a previous pregnancy. Hyperglycemia was present in 38.9% (7/18) of women who gave birth to a large fetus against 13.6% (72/529) of women who gave birth to a fetus under 4 kg, P < 0.008. Hirsutism was reported in 7.9% (43/547) of the studied pregnant women. Hirsutism is twice as common in pregnant women with Hyperglycemia - 13.9% (11/79) versus hirsutism in those with Normoglycemia - 6.8% (32/468), P < 0.049. There was a significant correlation between Hyperglycemia and gestational age (P < 0.006), previous fetal birth over 4 kg (P < 0.03), AH during the current pregnancy (P < 0.01), presence of hirsutism (P < 0.03). Conclusion: A good knowledge of all risk factors associated with the development of glucose intolerance and GDM could play an important role in the early diagnosis of this common disorder during pregnancy.

1. Introduction

Hyperglycemia is one of the most common conditions during pregnancy [1]. According to classification of the International Federation of Gynecology and Obstetrics – FIGO [2] and the World Health Organization – WHO [3], hyperglycemia detected for the first time during pregnancy may be related to: 1) Diabetes in Pregnancy (DIP) – Diabetes diagnosed for the first time during pregnancy according to generally accepted population diagnostic criteria for diabetes (standard oGTT 75 g glucose): fasting plasma glucose ≥ 7.0 mmol / L or 2nd hour plasma glucose ≥ 11.1 mmol / L or HbA1c ≥ 48 mmol / mol or ≥ 6.5% and 2) Gestational diabetes (GDM) – hyperglycemia above the diagnostic threshold for
gestational diabetes (standard oGTT 75 g glucose): fasting plasma glucose 5.1 - 6.9 mmol / L, 1h hour plasma glucose ≥ 10.0 mmol / L, 2h hour plasma glucose 8.5 - 11.0 mmol / L [2, 3]. As early as 2015, the National Institute for Health and Care Excellence-NICE [4] published criteria for diagnosing GDM: plasma fasting blood glucose (FBG) ≥ 5.6 mmol / L or plasma blood glucose at 120 minutes ≥ 7.8 mmol / L. The NICE Recommendations also include instructions for establishing of pregnancy up to 10-16 gestational week (g.w.) to perform oral glucose tolerance test (oGTT) for detection of undiagnosed diabetes. Additionally, in case of normal results, a second oGTT should be performed at the first screening at 24-28 g.w. to open the GDM [4]. GDM started during pregnancy, and it is clear that it did not exist before pregnancy [5].

About half of the women with GDM develop type 2 diabetes mellitus (T2D) 5-10 years after giving birth. It is important for women with Diabetes in pregnancy (DIP) or with GDM to monitor their blood glucose (BG) levels regularly in order to reduce the risk of adverse pregnancy outcomes [1].

Children of mothers with diabetes, especially if they also have CVD or diabetic complications, are at high risk of developing CVD in childhood or adolescence [6]. GDM also increases the risk of diabetes and obesity in the offspring during their childhood and adolescence [7] and for mothers, the risk of T2D increases significantly [8]. Recent publications have shown, that there is a link between failed pregnancies and T2D, and this link becomes stronger as the number of failed pregnancies increases [9]. GDM increases the risk of adverse pregnancy outcomes, such as pre-eclampsia, more frequent maternal cesarean section, neonatal hypoglycemia, large fetus, birth trauma for the fetus [10]. It is believed that GDM increases the risk of developing T2D in the offspring through intrauterine mechanisms [11]. In diabetics, the intrauterine environment can lead to placental dysfunction and hormonal disorders [12, 13]. Various genetic and epigenetic factors, as well as environmental factors through various complex mechanisms contribute to the development of GDM. Physiologically the metabolic activity during pregnancy is high so the maintenance of glucose homeostasis is of great importance. The β-cells of the pancreas fail to compensate for the necessary energy needs, significant insulin resistance (IR) develops and too much glucose goes to the growing fetus. Mild chronic inflammation, impaired gluconeogenesis, oxidative stress, and some placental factors also contribute to the development of GDM. All this requires the introduction of timely and successful strategies for prevention of GDM [14].

That is why the timely diagnosis of this common complication of pregnancy is extremely important. The international recommendations specifically indicate the need for screening of pregnant women in the presence of risk factors for GDM, among which the most frequently mentioned are obesity, previous GDM, family burden with diabetes - first degree relatives [2, 3, 4]. In addition to these major risk factors for the development of hyperglycemia during pregnancy, there are other no less important that influence the manifestation of this frequent complication during pregnancy.

The aim of the present study was to investigate the relationship between Hyperglycemia during pregnancy and the sequence of pregnancy, arterial hypertension, large fetus over 4 kg at birth, hirsutism, reproductive problems or adverse outcome of previous pregnancies among the Bulgarian population of pregnant women.

2. Material

The mean age of the studied 547 pregnant women was 30.49±5.12 years, Median 30.00 (minimum 18 - maximum 47). BMI before pregnancy was 23.36±5.05 kg/m², Median 22.06, and BMI at the time of screening was 25.91±5.11 kg/m², Median 25.25. Distribution of the studied 547 pregnant women by trimesters and gestational week (g.w.) is as follows:

- first - 110 (20.1%) - up to 12 g.w, second - 276 (50.5%) - 13-24 g.w, third - 161 (29.4%) - after 24 g.w.

As can be seen, 84.3% of the pregnant women had first and second pregnancy, and the remaining 15.7% were with sequence pregnancy. Two thirds of them had third consecutive pregnancy (10.4%) and only one third - fourth to sixth (5.3%).

All participants signed informed consent, confirmed by the local Ethics Commission at Sofia University "Saint Kliment Ohridski". It was prepared in accordance with the ethical standards according to the Helsinki Declaration-1964 and later additions [15].

Each pregnant woman filled in a questionnaire with the assistance of a specially designated medical person from the "face to face" team in order to correctly collect data on pregnancy history, past healthy history, family history for diabetes, hypertension, thyroid and chronic kidney disease, current and past medication, smoking. All participants were Caucasian, with no evidence of liver or kidney disease or evidence of malabsorption.

Table 1. Sequence of pregnancies among the surveyed 547 pregnant women.

| Sequence of Pregnancy | first | second | third | four | five | six |
|-----------------------|-------|--------|-------|------|------|-----|
| Number                | 245   | 216    | 57    | 19   | 9    | 1   |
| Percentage            | 44.8  | 39.5   | 10.4  | 3.5  | 1.6  | 0.2 |

3. Methods

3.1. The Weight and Height Resp. BMI – Before and During Pregnancy: Arterial Pressure

After completing the personal Questionnaire, the current weight and height of each pregnant woman were measured and filled in the Questionnaire together with the weight before pregnancy. The body mass index (BMI - kg / m²) before pregnancy and the current one at the time of the study were calculated. Mean weight before pregnancy was 63.68±14.36 kg, Median 60.00 (minimum 40 - maximum 166), and weight at the time of screening was 70.59±14.50 kg, Median 68.00 (minimum 41 - maximum 166). The body mass index (BMI) before pregnancy was 23.36±5.05 kg / m², Median 22.06 (minimum...
15.24 - maximum 63.25), and BMI at the time of screening was 25.91±5.11 kg / m², Median 25.25 (minimum 16.51 - maximum 63.25). At addition Arterial blood pressure was measured in the sitting position after a 5-minute rest according with the last Guideline of European Society of Cardiology (ESC) and the European Society of Hypertension (ESH) [16].

3.2. Laboratory Analysis

A two-hour, 75 g oral glucose tolerance test (OGTT) was performed. Venous blood was drawn at 0, 60 and 120 minutes in plasma tubes, containing Na2EDTA and NaF, as an inhibitor of glycolysis for stability of glucose in the samples. The samples were transported to the laboratory after centrifugation. All of the samples were analysed in one Central laboratory on the day of the blood sampling. Glucose was quantitatively determined using enzymatic reference method with hexokinase (Roche reagent) on Cobas e501 analyzer. The results were in mmol / l. Established precision using human samples and controls:

1) Intra assay: Level 1 (n=6) CV=1.12%; Level 2 (n=6) CV=0.42%
2) Inter assay: Level 1 (n=30) CV=1.25%; Level 2 (n=30) CV=1.58%
3) Two levels Intralaboratory quality control on a daily basis was performed.

The Laboratory participates in two EQA systems – Bulgarian EQAS and INSTAND and has certificates for this parameter.

The statistical analysis was performed using standard SPSS 13.0 for Windows: descriptive statistics (mean, medians, standard deviation), correlation analysis and analysis of variance (ANOVA, post-hoc test - with Bonferroni alpha correction), using parametrical and non-parametrical methods, including - Chi-Square Test, Fisher's Exact Test, Kolmogorov-Smirnov, Shapiro-Wilk Tests, Levene's Test for Equality of Variances, Student's t-test, Kruskal-Wallis test and Mann-Whitney test. All quantitative variables were presented as mean with standard deviation, median or percentage (unless specified otherwise), p values below 0.05 were accepted as statistically significant.

4. Results

4.1. Sequence of Pregnancy

The incidence of Hyperglycemia for the whole group of pregnant women was 14.4% (79/547), and up to 24 g.w. was 5.3% (29/547) and after 24 g.w. - 9.1% (50/547), P < 0.01. It is noteworthy that with each successive pregnancy the percentage of women with Hyperglycemia increases (from 14.3% in the first to 36.8% in the fourth pregnancy), NS. For the period up to 24 g.w. no significant dynamics is observed in this frequency, but after 24 g.w. the incidence of Hyperglycemia increased from 9.4% in the first pregnancy to 31.6% in the fourth (NS), Table 2.

Table 2. Sequence of pregnancy and frequency of Hyperglycemia in total, up to 24 g.w. and after 24 g.w. periods

| Sequence of Pregnancy | Frequency of Hyperglycemia in the whole group (number, percentage) | Frequency of hyperglycemia up to 24 g.w. (number, percentage) | Frequency of hyperglycemia after 24 g.w. (number, percentage) |
|-----------------------|---------------------------------------------------------------|---------------------------------------------------------------|---------------------------------------------------------------|
| First                 | 35 (14.3%)                                                   | 12 (4.9%)                                                   | 23 (9.4%)                                                   |
| Second                | 25 (11.6%)                                                   | 13 (6%)                                                     | 12 (5.6%)                                                   |
| Third                 | 9 (15.8%)                                                    | 2 (3.5%)                                                    | 7 (12.3%)                                                   |
| Fourth                | 7 (36.6%)                                                    | 1 (5.0%)                                                    | 6 (31.6%)                                                   |
| Fifth                 | 2 (22.2%)                                                    | 1 (11.1%)                                                   | 1 (11.1%)                                                   |
| Sixth                 | 1                                                              | 1                                                            | 1                                                            |
| Total                 | 79 (14.4%)                                                   | 29 (5.3%)                                                   | 50 (9.1%)                                                   |

4.2. Arterial Hypertension Before Pregnancy

Previous arterial hypertension (AH) before the current pregnancy was found in 4% (22/547) of all screened pregnant women. In this group of women with previous AH, 18.2% (4/22) had Hyperglycemia versus 14.3% (75/525) in women without AH before the current pregnancy, NS. Hyperglycemia up to 24 g.w. was found in 9.1% (2/22) of women with previous AH versus 5.1% (27/525) of those without previous AH, NS. Hyperglycemia after 24 g.w. proved in 9.1% (2/22) of women with previous AH versus 8.8% (48/525) in those without previous AH, NS. It can be summarized that pre-pregnancy AH is not a significant factor in the occurrence of disturbances in glucose tolerance during pregnancy.

4.3. Arterial Hypertension During Pregnancy

Of all pregnant women screened, 2.4% (13/547) developed AH during the current pregnancy. Hyperglycemia was found in 38.5% (5/13) of women with AH versus 13.9% (74/534) of women without AH, P < 0.028. Hyperglycemia up to 24 g.w. was found in 7.7% (1/13) of pregnant women with AH versus 5.2% (28/534) of pregnant women without AH, NS. Hyperglycemia after 24 g.w. was found in 30.8% (4/13) of pregnant women with AH versus 8.6% (46/534) of pregnant women without AH, P < 0.024.

4.4. Previous Macrosomic Baby Weighing 4.5 kg or Above

In 3.29% of the pregnant women (18/547) a fetus over 4 kg was found in a previous pregnancy, Hyperglycemia was present in 38.9% (7/18) of the women who gave birth to a large fetus over 4 kg versus 13.6% (72/529) of the women who gave birth to a fetus less than 4 kg in a previous pregnancy, P < 0.008. Hyperglycemia up to 24 g.w. was found in 22.2% (4/18) of the women who gave birth to a fetus over 4 kg against 4.7% (25/529) of the women who gave birth to a fetus under 4 kg in a previous pregnancy, P < 0.012. Hyperglycemia after 24 g.w.
was registered in 16.7% (3/18) of the women who gave birth to a fetus over 4 kg in a previous pregnancy against 8.6% (47/547) of the women who gave birth to a fetus under 4 kg, NS.

4.5. Hirsutism

Hirsutism was found in 7.9% (43/547) of the screened pregnant women, while in 92.1% (504/547) of them there wasn’t any. It turned out that hirsutism was twice as common in pregnant women with Hyperglycemia - 13.9% (11/79) against hirsutism in pregnant women with Normoglycemia - 6.8% (32/468), P < 0.049. In pregnant women up to 24 g.w. Hyperglycemia is twice as common in the presence of hirsutism 17.2% (5/29) versus 7.3% (38/518) in its absence, NS. Pregnant women after 24 g.w. have Hyperglycemia 62% more often in the presence of hirsutism - 12% (6/50) compared to pregnant women without hirsutism - 7.4% (37/497), NS (Table 3).

### Table 3. Distribution of cases of Hyperglycemia during pregnancy in total, before and after 24 g.w. among women with and without hirsutism

| Hirsutism | Yes | No |
|----------|-----|----|
| 468 pregnants with Normoglycemia Number (%) | 32/468 (6.8)* | 436/468 (93.2) |
| 79 pregnants with Hyperglycemia Number (%) | 11/79 (13.9)* | 68/79 (86.1%) |
| 518 pregnants with Normoglycemia up to 24 g.w. Number (%) | 38/518 (7.3) | 480/518 (92.7%) |
| 29 pregnants with Hyperglycemia up to 24 g.w. Number (%) | 5/29 (17.2) | 24/29 (82.8) |
| 497 pregnants with Normoglycemia after 24 g.w. Number (%) | 37/497 (7.4) | 460/497 (92.6) |
| 50 pregnants with Hyperglycemia after 24 g.w. Number (%) | 6/50 (12.0) | 45/50 (88.0) |

4.6. Polycystic Ovary Syndrome

Anamnestic data for previous polycystic ovary syndrome (PCOS) were obtained in 11.2% (61/547) of the studied pregnant women. It turned out that in these 61 pregnant women with previous PCOS, Hyperglycemia was present in 14.8% (9/61) - in the subgroup up to 24 g.w. - in 11.5% (7/61) and after 24 g.w. - in 3.3% (2/61). Table 4 presents the distribution of pregnant women with and without previous PCOS in the groups with Hyperglycemia resp. Normoglycemia - total, before and after 24 g.w. No significant difference was found between the groups mainly due to the very small number of pregnant women with Hyperglycemia on the background of previous PCOS - only 9.

### Table 4. Incidence of Hyperglycemia in pregnant women with and without previous PCOS - total, before and after 24 g.w.

| Polycystic ovary syndrome | Yes (61/547, 11.2%) | No (486/468, 88.8%) |
|---------------------------|---------------------|---------------------|
| 468 pregnants with Normoglycemia Number (%) | 52/468 (11.1) | 416/468 (88.9) |
| 79 pregnants with Hyperglycemia Number (%) | 9/79 (11.4) | 70/79 (88.6) |
| 518 pregnants with Normoglycemia up to 24 g.w. Number (%) | 54/518 (10.4) | 464/518 (89.6) |
| 29 pregnants with Hyperglycemia up to 24 g.w. Number (%) | 7/29 (24.1) | 22/29 (75.9) |
| 497 pregnants with Normoglycemia after 24 g.w. Number (%) | 59/497 (11.8) | 438/497 (88.2) |
| 50 pregnants with Hyperglycemia after 24 g.w. Number (%) | 2/50 (4.0) | 48/50 (96.0) |

4.7. Reproductive Problems

Reproductive problems were found in 21.8% (119/547) of pregnant women. Hyperglycemia was present in 19.3% (23/119) of pregnant women with reproductive problems versus 13.1% (56/428) of women without reproductive problems. Hyperglycemia up to 24 g.w. was present in 7.6% (9/119) in pregnant women with reproductive problems against 4.7% (20/428) in those without reproductive problems, and Hyperglycemia after 24 g.w. resp. in 11.8% (14/119) against 8.4% (36/428). In all three cases, the differences are not significant.

4.8. Adverse Outcome in Previous Pregnancy

An adverse outcome of a previous pregnancy was found in 23.7% (130/547) of the examined pregnant women. Hyperglycemia was present in 17.7% (23/130) of pregnant women with an unfavorable outcome from a previous pregnancy against 13.4% (56/417) without an unfavorable outcome. Hyperglycemia up to 24 g.w. was present in 6.2% (8/130) of pregnant women with a previous unfavorable outcome of their pregnancy against 5.0% (21/417) in pregnant women without similar problems. The incidence of Hyperglycemia after 24 g.w. in the two compared groups with and without unfavorable outcome of previous pregnancy was 11.5% (15/130) resp. 8.4% (35/417). In all three cases the differences are not significant.

5. Discussion

All international guidelines focus in detail on the risk factors for the development of GDM [1, 2, 4]. There are several main factors, such as advanced maternal age, weight, preceding GDM and family history. In addition to these risk factors, there are others which also play a significant role in the development of glucose intolerance and GDM. They are subject of the present analyses.

It is noteworthy that the incidence of Hyperglycemia increases with each subsequent pregnancy and only the small number of cases in each subgroup is the reason why the importance of this factor is difficult to prove (from 14.3% in the first to 36.8% in the fourth pregnancy, NS). It should be noted that each subsequent pregnancy occurs at an older age of the woman when her weight usually increases. Therefore, in the fourth consecutive pregnancy, women are already older
and heavier than those in the first pregnancy. These two main factors - age and obesity - are well known reasons for "diabetes epidemic" in the world [1], and we have proven their importance in our population survey from 2012 [17]. In recent months, in our previous study on the same group of 547 Bulgarian pregnant women, we proved a significant relationship between Hyperglycemia, weight and age. It was in the group with Hyperglycemia that pregnant women had a higher BMI (Mean Rank 262.48 vs. 342.26 - Mann-Whitney Test, P < 0.001), and were older (Mean Rank 320.84 vs 266.09 - Mann-Whitney Test, P < 0.005) compared with the corresponding groups with Normoglycemia [18].

The close link between arterial hypertension (AH) and diabetes is well-known. In 2.4% (13/547) of the studied pregnant women in this project, AH was found during pregnancy. Hyperglycemia was found in 38.5% (5/13) pregnant women with AH versus 13.9% (74/534) in pregnant women. Hyperglycemia was found during a previous pregnancy means that there have been similar pancreas fail to compensate for the chronic excess of fuel, which leads to an increase in IR, hyperglycemia and increased glucose flow to the growing fetus. The level of physiological IR during pregnancy increases significantly and studies have shown a decrease in glucose uptake by 54% in pregnant women with GDM compared to those with normal pregnancy [21]. A macrosomic baby weighing 4.5 kg or above in a previous pregnancy means that there have been similar metabolic disorders, and apparently this woman has glucose intolerance, or that the present unstable compensation could be quickly and easily disrupted by the next pregnancy.

In our material, this phenomenon is rarely observed in Bulgarian pregnant women - only 3.29% (18/547). In women who gave birth to a macrosomic baby weighing 4.5 kg or above in 38.9% (7/18) there was Hyperglycemia against 13.6% (72/529) in women who gave birth to a fetus under 4 kg in a previous pregnancy, P < 0.008. It should also be noted that previous macrosomia is significant up to 24 g.w. - 22.2% (4/18) against 4.7% (25/529), P < 0.012, while after 24 g.w. it has no clinical significance - 16.7% (3/18) against 8.6% (47/547), NS. Therefore, we will conclude that the birth of a large fetus is a significant risk factor for the development of Hyperglycemia mainly up to 24 g.w. in the next pregnancy. It may also be risky for the development of disorders in glucose tolerance during the next pregnancy.

It is known that IR develops physiologically during pregnancy. Androgens generally play a very significant adverse role in the realization of insulin action in tissues, which impairs glucose homeostasis. Four separate phenotypes of Polycystic Ovary Syndrome (PCOS) have been identified, according to the Rotterdam criteria [22], as in ¾ of them there is hyperandrogenism. It is on this basis that each phenotype has a different severity of risk in terms of metabolic and reproductive effects. It turned out that almost 60% of our population has phenotype which includes hyperandrogenism, chronic anovulation, ultrasound data for polycystic ovaries [23]. It is hyperandrogenism that causes more severe IR. It is believed that IR and subsequent compensatory hyperinsulinemia may directly induce the flow of cellular androgen production. In turn, under the conditions of hyperandrogenization, the insulin receptor is suppressed and the expression of glucose transporters is reduced, which increases IR, i.e. a vicious circle is formed. PCOS is common and affects about 12-21% of women at reproductive age [24]. In the studied 547 pregnant women data for PCOS were obtained in 11.2% (61/547) of them. It was found that 11.4% (9/79) of the pregnant women with PCOS had Hyperglycemia, while 11.1% (52/468) of the rest with PCOS had Normoglycemia, NS. Therefore, the frequency is identical, but we have only anamnestic data for PCOS, and no data on the current androgen level in the studied 547 pregnant women.

Regarding hirsutism, it was registered in 7.9% (43/547) of the studied pregnant women and it turned out that it was twice as common in pregnant women with Hyperglycemia - 13.9% (11/79) in comparison with pregnant women with Normoglycemia - 6.8% (32/468), P < 0.049. As already noted, androgens play a very significant adverse role in the realization of insulin action in tissues. This effect is added to the physiological development of IR during pregnancy, which further impairs glucose homeostasis. This develops glucose intolerance and leads to Hyperglycemia in the pregnant women complicated by hirsutism.

Applying the nonparametric correlation coefficients of C. E. Spearman found that in the studied pregnant women there was a significant correlation between Hyperglycemia and gestational age (P < 0.006), with a previous birth of a fetus over 4 kg (P < 0.03), with AH during the current pregnancy (P < 0.01), with the presence of hirsutism (P < 0.03). Hyperglycemia up to 24 g.w. there was a significant correlation with previous fetal birth over 4 kg (P < 0.001) and with the presence of PCOS (P < 0.02), and Hyperglycemia after 24 g.w. there was a significant correlation only with AH...
during the current pregnancy (P < 0.006).

6. Conclusion

It may be concluded that good knowledge of all risk factors associated with the development of glucose intolerance and GDM has an important role in the early diagnosis of this common disorder during pregnancy. In addition to the main factors, such as advanced maternal age, obesity, family history with diabetes, there are other factors which can also be important - AH during pregnancy, birth of a large fetus in a previous pregnancy and hirsutism. The proven significant correlation between Hyperglycemia and the listed additional factors gives them impaired glucose tolerance could be taken on time.

Conduct additional studies in order to prove possible already initial screening of pregnant women so that a correct decision to serious weight and requires that they should be included in the screening of pregnant women so that a correct decision to conduct additional studies in order to prove possible already impaired glucose tolerance could be taken on time.
