Received March 2005; accepted February 2006

Abstract. CCD BVI photometry of the faint open clusters Berkeley 73, Berkeley 75 and Berkeley 25 are presented. The two latter are previously unstudied clusters to our knowledge. While Berkeley 73 is found to be of intermediate-age (about 1.5 Gyr old), Berkeley 75 and Berkeley 25 are two old clusters, with ages larger than 3.0 Gyr. We provide also estimates of the clusters size. Very interestingly, all these clusters turn out to lie far away from the Galactic Center, at $R_{\odot} \geq 16$ kpc, and quite high onto the Galactic plane, at $|Z_\odot| \geq 1.5$ kpc. They are therefore important targets to probe the properties of the structure of the Galaxy in this direction, where the Canis Major over-density has been recently discovered to be located.

1. Introduction

The paper belongs to a series aimed at providing homogeneous photometry of open clusters located in the third Galactic Quadrant. The main motivations of the survey are discussed in Moitinho (2001) and Giorgi et al. (2005). Briefly, we want to i) better trace the spiral structure and ii) probe the history of star formation in this part of the Galaxy. For these purposes open
clusters of different ages are very useful. While the youngest clusters are very well known spiral arm tracers, the older ones are routinely used to probe the chemical evolution and star formation history of the disk (Carraro et al. 1998, de la Fuente Marcos & de la Fuente Marcos 2004). Moreover very distant open clusters in the Third Galactic Quadrant might help to probe the stellar population of the recently discovered Canis Major over-density, or to better understand the warp structure of the Galactic disk (Momany et al. 2004, Bellazzini et al. 2004). In this paper we discuss BVI photometry of three old open clusters, namely Berkeley 73, Berkeley 75 and Berkeley 25 (= Ruprecht 3) with the aim to derive their fundamental parameters, in particular age and distance, which are the basic input for the derivation of the star formation history in the Galactic disk. These clusters until now were unstudied except for Berkeley 73, whose first Color Magnitude Diagram (CMD) is discussed in Ortolani et al. (2005). The coordinates of these three clusters are listed in Table 1, and have been redetermined by one of us (G.C.) based on inspection of Digital Sky Survey (DSS and XDSS) images. In fact these clusters are very loose and faint, and in many cases the reported coordinates are not very precise. We notice that the coordinates reported by Ortolani et al. (2005) for Berkeley 73 are wrong, and refer instead to the cluster vdB-Hagen 73.

The plan of this paper is as follows. In Sect. 2 we briefly illustrate observations and data reduction and in Sect. 3 we describe how we obtain astrometry. In Sect. 4 we derive an estimate of the clusters diameters, and in Sect. 5 we describe the CMDs. Sect. 6 is then dedicated to derive clusters’ fundamental parameters. Finally, in Sect. 7 we draw some conclusions and suggest further lines of research.

### 2. Observations and Data Reduction

CCD BVI observations were carried out with the CCD camera on-board the 1.0m telescope at Cerro Tololo Interamerican Observatory (CTIO, Chile), on the nights of December 13 and 15, 2004. With a pixel size of 0.469, and a CCD size of 512 × 512 pixels, this samples a 4′.1 × 4′.1 field on the sky.

The details of the observations are listed in Table 2 where the observed fields are reported together with the exposure times, the average seeing values and the range of air-masses during the

Fig. 2. A DSS red map of the covered region in the field of Berkeley 75. North is up, East on the left.

observations. Figs. 1 to 3 show DSS finding charts in the area of Berkeley 73, Berkeley 75 and Berkeley 25, respectively, and here one can easily recognize that these clusters are faint objects. The data have been reduced with the IRAF\(^1\) packages CCDRED, DAOPHOT, ALLSTAR and PHOTCAL using the point spread function (PSF) method (Stetson 1987). The two nights turned

\(^1\) IRAF is distributed by NOAO, which are operated by AURA under cooperative agreement with the NSF.
out to be photometric and very stable, and therefore we derived calibration equations for all the 130 standard stars observed during the two nights in the Landolt (1992) fields SA 95-41, PG 0231+051, Rubin 149, Rubin 152, T phe and SA 98-670 (see Table 2 for details). Together with the clusters, we observed three control fields 20 arcmins apart from the nominal cluster centers to deal with field star contamination. Exposure of 600 secs in V and I were secured for these fields.

The calibration equations turned out of be of the form:

\[
\begin{align*}
 b &= B + b_1 + b_2 \times X + b_3 (B - V) \\
 v &= V + v_1 + v_2 \times X + v_3 (B - V) \\
 i &= I + i_1 + i_2 \times X + i_3 (V - I),
\end{align*}
\]

where BVI are standard magnitudes, bvi are the instrumental ones and X is the airmass; all the coefficient values are reported in Table 3. The standard stars in these fields provide a very good color coverage. The final r.m.s. of the calibration are 0.039, 0.034 and 0.033 for the B, V and I filters, respectively. We generally used the third equation to calibrate the V magnitude in order to get the same magnitude depth both in the cluster and in the field. It turns out that the limiting magnitudes are B = 21.9, V = 22.5 and I =21.8. Moreover we performed a completeness analysis following the method described in Carraro et al. (2005). It turns out that our sample has completeness level larger than 50% down to B = 20.0, V = 21.0 and I = 20.5.

The final photometric catalogs for Berkeley 73, Berkeley 75 and Berkeley 25 (coordinates, B, V and I magnitudes and errors) consist of 941, 1035 and 1039 stars, respectively, and are
Table 2. Journal of observations of Berkeley 73, Berkeley 75 and Berkeley 25 and standard star fields (December 13 and 15, 2004).

| Field       | Filter | Exposure time [sec.] | Seeing [′′] | Airmass |

3. Astrometry

We derived the astrometric solution to provide for all the stars in the three clusters the J2000.0 coordinates. This is a basic step for any further follow-up study in the area of the cluster. In order to obtain an astrometric solution we use the SkyCat tool and the Guide Star Catalogue v2 (GSC-2) at ESO. This way we find about 80 stars per field for which we have both the celestial coordinates on the GSC-2 and the corresponding pixel coordinates. Then, by using the IRAF tasks CCXYMATCH, CCMAP and CCTRAN, we find the corresponding transformations between the two coordinate systems compute the individual celestial coordinates for all the detected stars. The transformations have an r.m.s. value of 0\'\,37 both in RA and in DEC, in broad agreement with other studies (Momany et al. 2001, Carraro et al. 2005).

4. Star counts and cluster size

Since our photometry covers entirely each cluster’s area we performed star counts to obtain the first quantitative estimate of the clusters size. We derived the surface stellar density by performing star counts in concentric rings around the clusters nominal centers (see Table 1) and then dividing by their respective area. Poisson errors have also been derived and normalized to the corresponding area. The field star contribution has been derived from the control field which we secured for each cluster. We selected the magnitude interval 12 \leq V \leq 20 both in the cluster and in the field to minimize incompleteness effects.

Berkeley 73. The final radial density profile for Berkeley 73 is shown in the lower panel of Fig. 4. The profile is smooth and reaches the level of the field at about 1.5 arcmin, which we are going to adopt as Berkeley 73 radius throughout this paper. This estimate is a bit larger than the value of 2.0 arcmin reported by Dias et al. (2002) for the cluster diameter.

Berkeley 75. The final radial density profile for Berkeley 75 is shown in the middle panel of Fig. 4. The cluster clearly emerges from the background up to about 1.0 arcmin, a value that we are going to adopt as Berkeley 75 radius throughout this paper.

Berkeley 25. The final radial density profile for Berkeley 25 is shown in the upper panel of Fig. 4. The cluster seems to be faint and dense, with a probable radius of less than 1 arcmin. This estimate is much smaller than the value of 5.0 arcmin reported by Dias et al. (2002) for the cluster diameter.

The estimates we provide for the radius, although reasonable, must be taken as preliminary. In fact the size of the CCD is probably too small to derive conclusive estimates of the cluster sizes. This is particularly true in the case Berkeley 73, for which the cluster radius we derived must be considered as a lower limit to the real cluster radius. In fact, while for Berkeley 75 and 25 the
Fig. 4. Star counts in the area of the three open clusters under study as a function of radius. The dashed lines represent the level of the control field counts estimated from the accompanying control field.

The cluster density profile converges toward the field level within the region covered by the CCD, in the case of Berkeley 73 the cluster dominates the star counts up to almost the border of the region we covered. Larger field coverage is necessary in this case to derive a firm estimate of the cluster radius.

5. Colour-Magnitude Diagrams

In Fig. 5 we present the CMDs we obtained for the three clusters under investigation. In this figure the open cluster Berkeley 73 is shown together with the corresponding control field in the lower panels, whereas Berkeley 75 and Berkeley 25 are presented in the middle and upper panels, respectively. The control fields help us to better interpret these CMDs, which are clearly dominated by foreground star contamination.

Berkeley 73. It exhibits a Main Sequence (MS) extending from $V=17$, where the Turn Off Point (TO) is located, down to $V=21$. This MS is significantly wide, a fact that we ascribe to the increasing photometric error at increasing magnitude, the field star contamination, and to the possible presence of a sizeable binary star population, which mainly enlarges the MS toward red colors. However, the reality of this cluster seems to be secured by the shape and density of the MS compared to the control field MS, whose population sharply decreases at $V \leq 18$. In addition, the cluster MS is significantly bluer and more tilted than the field MS, which derives from the superposition of stars of different reddening located at all distances. Another interesting evidence is the possible presence of a clump of stars at $V=15.5-16.0$, which does not have a
clear counterpart in the field, and which makes the cluster an intermediate-age one. In fact if we use the age calibration from Carraro & Chiosi (2004), for a $\Delta V$ (the magnitude difference between the red clump and the TO) of 1.5 mag, we infer an age around 1.2 billion year. This estimate does not take into account the cluster metallicity, and therefore is a simple guess. In the

Fig. 5. $V$ vs $(B-V)$ (left panels) and $V$ vs $(V-I)$ (middle panels) CMDs of Berkeley 73 (lower panels), Berkeley 75 (middle panels) and Berkeley 25 (upper panels) and corresponding control fields (right panels). We include all stars in each field.
Fig. 6. $B - V$ vs $V - I$ diagram for the four clusters. The solid line is the normal reddening law, whereas dashed and dotted lines are the intrinsic colors for luminosity class III and V, respectively. See text for details.

following we shall provide a more robust estimate of the age through a detailed comparison with theoretical isochrones.

**Berkeley 75.** The TO is located at $V \approx 18$, and the clump at $V \approx 16.0$, thus implying a rough estimate for the age around 3 billion year. The overall morphology of the CMDs is less different from the field than the previous cluster. A significant binary population seems to affect the TO shape, which appears at first glance confused (see for comparison the CMDs in the middle and upper panels).

Moreover, the field star contamination seems to be important for this cluster, but it does not prevent us from recognizing a probable clump of stars located at $V = 16$, $B-V = 1.2$, $(V-I) = 1.4$. The field in the right panel also exhibits a clump, but it lies along the MS at $(V-I) = 1.0$. If the Berkeley 75 clump mean magnitude is actually around $V = 16$, this would imply a distance modulus ($m-M$) of about 16 mag, according to Salaris & Girardi (2002).

**Berkeley 25.** The TO is located at $V \approx 18.5$, and the clump at $V \approx 16.5$, thus implying a rough estimate for the age around 3.0 Gyr year. The overall morphology of the CMDs is also in this case very different from the field CMD so this is a bona-fide cluster. The same kind of argument applied to Berkeley 75 clump holds for Berkeley 25, since also in this case the field exhibits a star condensation at about the cluster clump position.
6. Clusters fundamental parameters

In this section we perform a detailed comparison of the star distribution in the clusters CMDs with theoretical isochrones. We adopt in this study the Padova library from Girardi et al. (2000). This comparison is clearly not an easy exercise. In fact the detailed shape and position of the various features in the CMD (MS, TO and clump basically) depends mostly on age and metallicity, and then also on reddening and distance. The complex interplay between the various parameters is well known, and we refer to Chiosi et al. (1992) and Carraro (2005) as nice examples of the underlying technique.

Our basic strategy is to survey different age and metallicity isochrones attempting to provide the best fit of all the CMD features both in the $V$ vs $(B - V)$ and in the $V$ vs $(V - I)$ CMD.

Besides, to further facilitate the fitting procedure we shall consider only the stars which lie within the cluster radius as derived in Sect. 3. Therefore, in the series of Figs. 7 to 9 we shall present the best fit we were able to achieve. Together with the best fit, we could make estimates of uncertainties in the basic parameters derivation. These uncertainties simply reflect the range in the basic parameter which allow a reasonable fit to the clusters CMDs. In particular in the left panel of Figs. 7 to 9, we overlaid another isochrone to show the effect of assuming different combinations of age and metallicity. Error estimates are reported in Table 4.

To derive clusters’ distances from reddening and apparent distance modulus, a reddening law must be specified. In Fig. 6 we show that the normal extinction law is valid for all the clusters, and therefore we shall use the relation $A_V = 3.1 \times E(B-V)$ to derive clusters’ distances. In details, the solid line in Fig. 10 is the normal extinction $E(V-I) = 1.245 \times E(B-V)$ law, whereas the dashed and dotted lines are the luminosity class $III$ and $V$ ZAMS from Cousin (1978). Finally to limit in some ways the degrees of freedom of the whole fit technique, we derived from FIRB maps (Schlegel et al. 1998) the reddening in the direction of the clusters. We got $E(B-V) = 0.18, 0.12$ and $0.10$ for Berkeley 73, Berkeley 75 and Berkeley 25, respectively. Due to the clusters Galactic latitude, these values can be considered very reasonable.

**Berkeley 73.** The isochrone solution for this cluster is discussed in Fig. 7. We consider here only the stars located within 1.5 arcmin from the cluster center (see Sect. 2). We obtained the best fit for an age of 1.5 Gyr and a metallicity $Z=0.008$. The inferred reddening and apparent distance modulus are $E(B-V)=0.12$ ($E(V-I)=0.18$) and $(m-M)=15.3$, respectively. As a consequence the cluster possesses a heliocentric distance of 9.7 kpc, and is located at a Galactocentric distance of 16.4 kpc, assuming 8.5 kpc as the distance of the Sun to the Galactic Center. The overall fit is very good, the detailed shape of the MS and TO are nicely reproduced, and the color of the clump as well. With respect to Ortolani et al. (2005) we find a significantly younger age, and this is due to our interpretation of the group of stars at $V \approx 16$, $(B-V) \approx 1.0$ as a clump He-burning stars. This choice is supported by the fact that we are selecting only stars located well within the
cluster radius, and actually this group of stars lie very close to the cluster center, as expected for more massive stars after the mass segregation mechanism. Looking carefully at the isochrone fitting in Ortolani et al. (2005, Fig. 9), one can note that the isochrone poorly matches the low MS, below V ≈ 19, and is in general too red with respect to the mean locus of Berkeley 73 stars. Also the color of the TO point is poorly matched. To achieve a better fitting a bluer (say younger) isochrone is necessary.

To address the effect of a possible variation of the clusters parameters due to a different metallicity, in the left panel of Fig. 7 we superposed the best fit Z=0.019 isochrone, which provides an age of 2 Gyr and a distance modulus (m-M)=14.8. The fit is rather good in the MS, but the RGB is too blue, like in Ortolani et al (2005). A lower metallicity isochrone would solve this problem. Moreover the reddening value we get in this case is E(B-V)=0.00±0.03. This value of the reddening is reasonable indeed for this combination of age and metallicity. If the Ortolani et al. (2005) fit matched the TO color, it would imply exactly such a reddening, and not the value they report.

Therefore we favor a low metal content and a younger age (see Table 4). Moreover the set of Galactic coordinates that Ortolani et al. (2005) report are in error, due to the wrong Galactic l and b they assign to this cluster. Therefore the cluster does not lie in the fourth Galactic quadrant, but below the plane in the third quadrant.

Interestingly, a considerable binary fraction seems to be present in the form of a parallel sequence red-ward the cluster MS.

**Berkeley 75** The isochrone solution for this cluster is discussed in Fig. 8. We obtained the best fit for an age of 3 Gyr and a metallicity Z=0.004. The inferred reddening and apparent distance modulus are E(B-V)=0.08 (E(V-I)=0.13) and (m-M)=15.2, respectively. As a consequence the cluster lies at 9.8 kpc from the Sun, and is located at a Galactocentric distance of 16.2 kpc toward the anti-center direction in the third Galactic quadrant. The overall fit is very good also in this case, the detailed shape of the MS and TO are nicely reproduced, and the color of the clump as well.

The reddening we derived by the way is in close agreement with FIRB maps, which at the Galactic latitude of Berkeley 75 are surely reliable.

Also in this case we check the age-metallicity effect. Superposed in the left panel of Fig. 8 is a Z=0.008 isochrone for the age of 3.5 Gyr, which produces the best fit to the bulk of Berkeley 75 stars. By assuming this combination of age and metallicity, the derived distance modulus is (m-M)=14.9, and the reddening E(B-V) = 0.00. By increasing more the metallicity an untenable negative reddening would be necessary to get a good fit. We therefore conclude that the best fit metallicity is Z=0.004, which yields the parameters set reported in Table 4.

**Berkeley 25** The isochrone solution for this cluster is shown in Fig.9. We obtained the best fit for an age of 4 Gyr and a metallicity Z=0.008. The inferred reddening and apparent distance
Fig. 7. Isochrone solution for Berkeley 73. The solid lines are isochrones for the age of 1500 million year and metallicity $Z=0.008$. The apparent distance modulus is $(m-M)=15.3$, and the reddening $E(B-V)=0.12$ and $E(V-I)=0.18$. Only stars within the derived radius are shown. The dashed line in the left panel is a $Z=0.019$ isochrone for the age of 2 Gyr. See text for more details.

Fig. 8. Isochrone solution for Berkeley 75. The isochrones (solid lines) are for the age of 3 Gyr and metallicity $Z=0.004$. The apparent distance modulus is $(m-M)=15.2$, and the reddening $E(B-V)=0.08$ and $E(V-I)=0.13$. Only stars within the derived radius are shown. The dashed line is a 3.5 Gyr, $Z=0.008$ isochrone. See text for more details.
Fig. 9. Isochrone solution for Berkeley 25. The isochrones (solid lines) are for the age of 4 Gyrs year and metallicity $Z=0.008$. The apparent distance modulus is $(m-M)=15.8$, and the reddening $E(B-V)=0.17$ and $E(V-I)=0.24$. Only stars within the derived radius are shown. The dashed line is a 3.5 Gyr, $Z=0.004$ isochrone. See text for more details.

modulus are $E(B-V)=0.17$ ($E(V-I)=0.24$) and $(m-M)=15.8$, respectively. Therefore the cluster has a heliocentric distance of 11.3 kpc, and is located at a Galactocentric distance of 16.8 kpc. The overall fit is very good also in this case, the detailed shape of the MS and TO are nicely reproduced, and the color of the clump as well. The reddening we derived by the way is in close agreement with FIRB maps.

In the left panel of the same figure we overlaid a metal poorer ($Z=0.004$) isochrone for the age of 3.5 Gyrs. This isochrone provides a good fit as well, with a distance modulus $(m-M)=16.2$, and a reddening $E(B-V)=0.35$. However, since FIRB maps support a much lower reddening, we tend to favour here the higher metallicity solution, which provides a more reasonable reddening value.

All these clusters are very interesting because of their position so far away from the Galactic center. We only known in fact a few clusters located so distant from the center of the Galaxy (Villanova et al. 2005), and therefore they are crucial targets for spectroscopic follow-up. Besides, Berkeley 25 is one of the old open clusters located at highest Galactic latitude (see Table 4, and Friel 1995).
Table 4. Fundamental parameters of the studied clusters. The coordinates system is such that the Y axis connects the Sun to the Galactic Center, while the X axis is perpendicular to that. Y is positive toward the Galactic anti-center, and X is positive in the first and second Galactic quadrants (Lynga 1982).

| Name       | Radius | \(E(B-V)\) | \(E(V-I)\) | \((m-M)\) | \(d_0\) | \(X_0\) | \(Y_0\) | \(Z_0\) | \(R_{GC}\) | Age | Metallicity |

7. Conclusions

We have presented CCD \(BVI\) photometric study of the star clusters Berkeley 73, Berkeley 75 and Berkeley 25. The CMDs we derive allow us to infer estimates of the clusters’ basic parameters, which are summarized in Table 4.

In detail, the fundamental findings of this paper are:

- the best fit reddening estimates support within the errors a normal extinction law toward the three clusters;
- all the clusters are very distant from the Galactic center and quite high onto the Galactic plane.
  They might be very interesting object for further investigation to clarify whether they might belong to the recently discovered Canis Major-Monoceros over-density;
- Berkeley 73 is found to be of intermediate age.

All these clusters are very interesting in the context of the chemical evolution of the Galactic disk (Geisler et al. 1992, Carraro et al. 1998, Friel et al 2002).

They may be very useful to trace the slope of the Galactic disk radial abundance gradient and to probe the chemical properties and the structure of the disk in its outskirts, in a region which is dominated by the Galactic warp and/or the recently discovered Canis Major over-density.

If we make use of the provisional photometric estimates presented in this paper, we obtain that all the clusters are basically consistent with the most recent slope of the gradient in the 3-4 Gyrs and \(\leq 2\) Gyr bins, as derived by Friel et al. (2002).

Further studies therefore should concentrate on the confirmation of the clusters’ metal content by means of a detailed abundance analysis of the clump stars.

Finally, Berkeley 75 and Berkeley 25 are very interesting clusters because they fall in an age range where only a few clusters are known (see the discussion in Ortolani et al. 2005).

The authors show the age distribution of 103 old open clusters. The ages they use are highly inhomogeneous, since they come from a variety of different sources. This fact however does not seem to change significantly the overall conclusions on the possible existence of a peak at 5 Gyrs with respect to the previous analysis on the same subject conducted by Friel (1995) using
a smaller but homogeneous sample. This might mean that the level of inhomogeneity in the ages is not very important.

If we include the new two clusters Berkeley 75 and Berkeley 25, Berkeley 22 and Berkeley 66 (around 3-4 Gyrs old, Villanova et al. 2005), and Berkeley 29 (4 Gyrs, Carraro et al. 2004), for which we report new estimates of the age, the dip Ortolani et al. (2005) report in the old open clusters age distribution (their Fig. 11) becomes less prominent, and the reality of a peak at 5 Gyrs less significant. The new age distribution is shown in Fig. 10, where we consider all the clusters reported by Ortolani et al. (2005, solid line) and add a few more clusters, (dashed line).

It is by the way quite probable that more clusters are to be discovered in this age range.

In our opinion, this is simply suggesting that the completeness of the sample and homogeneity of the ages are crucial issues which have to be carefully taken into account before drawing conclusions on the star formation history of the Galactic disk using old open clusters.

Acknowledgements. We thank the anonymous referee for important suggestions, that led to a better presentation of the paper. The observations presented in this paper have been carried out at Cerro Tololo Interamerican Observatory CTIO (Chile). CTIO is operated by the Association of Universities for Research in Astronomy, Inc. (AURA), under a cooperative agreement with the National Science Foundation as part of the National Optical Astronomy Observatory (NOAO). The work of G.C. is supported by Fundación Andes.
