Abstract

Document-level information extraction is a flexible framework compatible with applications where information is not necessarily localized in a single sentence. For example, key features of a diagnosis in radiology a report may not be explicitly stated, but nevertheless can be inferred from the report’s text. However, document-level neural models can easily learn spurious correlations from irrelevant information. This work studies how to ensure that these models make correct inferences from complex text and make those inferences in an auditable way: beyond just being right, are these models “right for the right reasons?” We experiment with post-hoc evidence extraction in a predict-select-verify framework using feature attribution techniques. While this basic approach can extract reasonable evidence, it can be regularized with small amounts of evidence supervision during training, which substantially improves the quality of extracted evidence. We evaluate on two domains: a small-scale labeled dataset of brain MRI reports and a large-scale modified version of DocRED (Yao et al., 2019) and show that models’ plausibility can be improved with no loss in accuracy.

1 Introduction

Document-level information extraction (Yao et al., 2019; Christopoulou et al., 2019; Xiao et al., 2020; Guoshun et al., 2020) has seen great strides due to the rise of pre-trained models (Devlin et al., 2019). But in high-stakes domains like medical information extraction (Irvin et al., 2019; McDermott et al., 2020; Smit et al., 2020), machine learning models are still too error-prone to use broadly. Since they are not perfect, they typically play the role of assisting users in tasks like building cohorts (Pons et al., 2016) or in providing clinical decision support (Demner-Fushman et al., 2009). To be most usable in conjunction with users, these systems should not just produce a decision, but a correctly-sourced justification that can be checked (Rudie et al., 2019).

Our goal is to study document-level information extraction systems that are both accurate and which make predictions based on the correct information (Doshi-Velez and Kim, 2017). This process involves identifying what evidence the model actually used, verifying the model’s prediction based on that evidence, and checking whether that evidence aligns with what humans would use, which would allow a user to more quickly see if the system is correct. For example, in Figure 1, localizing the prediction of mass effect (a feature expressing whether there is evidence of brain displacement by a mass like a tumor) to the first two sentences allows a trained user in a clinical decision support setting to easily verify what was extracted here.

Our evidence extraction hews to principles of both
rather than use complex approaches with intermediate latent variables for extraction (Lei et al., 2016), we focus on what can be done with off-the-shelf pre-trained models (Liu et al., 2019) using post-hoc interpretation. We explore various techniques for attribution but primarily use DeepLIFT (Shrikumar et al., 2019) to find key parts of each document that were used by the model. We ask two questions: first, can we identify the document sentences that truly contributed to the prediction (faithfulness)? Using the ranking of sentences provided by DeepLIFT, we extract a set of sentences where the model returns nearly the same prediction as before, thus verifying that these sentences are a sufficient explanation for the model. Second, do these document sentences align with what users annotated (plausibility)? Unsurprisingly, we find that this alignment is low in a basic Transformer model.

To further improve the alignment with human annotation, we consider injecting small amounts of token-level labeled data. Critically, in the brain MRI extraction setting we consider (see Table 1), large-scale token-level annotation is not available; most instances in the dataset only have document-level labels from existing clinical decision support systems, making it a weakly-supervised setting (Pruthi et al., 2020a; Patel et al., 2020). We explore two methods for using this small amount of annotation, chiefly based around supervising or regularizing the model’s behavior. One notion is entropy maximization that the model should be uncertain when it isn’t exposed to sufficient evidence (Feng et al., 2019). Another is attention regularization where the model’s attentions should focus on the key pieces of evidence; while not a perfect cue (Jain and Wallace, 2019), we can investigate whether this then leads to a model whose explanations leverage this information more heavily.

We validate our methods first on a small dataset of radiologists’ observations from brain MRIs. These reports are annotated with document-level key features related to different aspects of the report, which we want to extract in a faithful way. We see positive results here even in a small-data condition, but to understand how this method would scale with larger amounts of data, we adapt the DocRED relation extraction task to be a document-level classification task. The question of which sentence in the document describes the relation between the two entities, if there even is one, is still quite challenging, and we show our techniques can lead to improvements in a weakly-labeled setting here as well.

Our contributions are (1) We apply evidence extraction methods to document-level IE, emphasizing a new brain MRI dataset that we annotate. (2) We explore using weak sentence-level supervision in two techniques adapted from prior work; (3) We evaluate pre-trained models and evidence extraction through DeepLIFT for plausibility compared to human annotation, while ensuring faithfulness of the evidence.

| mass_effect | side: bilateral | contrast_enhancement | evid. | label |
|------------|----------------|----------------------|-------|-------|
| negative   | evid: [0, 1]    | implicit             | [0]   |
| increased  | evid: [0]       | explicit             | [1]   |
| No         | evid: [2]       | explicit             | [0]   |

Table 1: Example from annotated brain MRI reports. Labels and supporting evidence for 4 key features are annotated for this example report presented. “Explicit” means the label of given key feature can be directly inferred by the highlighted terms; “implicit” indicates that it requires domain knowledge and potential reasoning skills to label. We want the model to identify implicit features while not leveraging dataset biases or reasoning incorrectly about explicit ones.
The finding section of a brain MRI radiology report often describes these key features in both explicit and implicit ways. For instance, contrast enhancement, one of our key features, is mentioned explicitly much of the time; see no abnormal enhancement in the third sentence. A rule-based system can detect this type of evidence easily. But some key features are harder to identify and require reasoning over context and draw on implicit cues. For example, severe encephalomalacia in the first sentence and enlargement of the ventricular system in the following sentence are both implicit signs of positive mass effect and either is sufficient to infer the label. It is significantly harder to build a rule-based extractor for this case. Learning-based systems have the potential to do much better here, but lack of understanding about their behavior can lead to hard-to-predict failure modes, such as acausal prediction of key features (e.g., inferring evidence about mass effect from a hypothesized diagnosis somewhere in the report, where the causality is backwards).

Our work aims to leverage the ability of learning-based systems to capture implicit features while improving their ability to make correctly-sourced predictions.

2.2 Problem Setting

The problem we tackle in this work is document-level information extraction. Let $D = \{x_1, \ldots, x_n\}$ be a document consisting of $n$ sentences. The document is annotated with a set of labels $(t_i, y_i)$ where $t_i$ is an auxiliary input specifying a particular task for this document (e.g., mass effect) and $y_i$ is the label associated with that task from a discrete label space. In our adaptation of the DocRED task, we consider $t = (e_1, e_2)$ to classify the relationship (if any) between a pair of entities $(e_1, e_2)$ in a document, defined in Section 4.1.2.

Our method takes a pair $(D, t)$ and then computes the label $y_t$ from a predictor $y_t = f(D, t)$. We can then extract evidence post-hoc using a separate procedure $g$ such as a feature attribution method: $E_t = g(f, D, t)$.

**Supervision** In addition to the labels $y_t$, we assume access to a small number of examples with additional supervision in each domain. That is, for a $(D, t, y_t)$ triple, we also assume we are given a set $E = \{x_{i1}, \ldots, x_{im}\}$ of ground-truth evidence with sentence indices $\{i_1, \ldots, i_m\}$. This evidence should be sufficient to compute the label, but not always necessary; for example, if multiple sentences can contribute to the prediction, they might all be listed as supporting evidence here. See Section 3.3 for more details.

2.3 Related Work

Our work fits into a broader thread of relation extraction (Han et al., 2020). Due to the cost of collecting large-scale data with good quality, distant supervision (DS) (Mintz et al., 2009) and ways to denoise auto-labeled data from DS (Surdeanu et al., 2012; Wang et al., 2018) have been widely explored. However, the sentence-level setting typically features much less ambiguity about evidence needed to predict a relation compared to the document-level setting we explore. Several document-level RE datasets (Li et al., 2016a; Peng et al., 2017) have been proposed as well as efforts to tackle these tasks (Christopolou et al., 2019; Xiao et al., 2020; Guoshun et al., 2020), which we explicitly build off of.

**Explanation techniques** To identify the sentences that the model considers as evidence, we draw on a recent body of work in explainable NLP focused on identifying salient features of the input. These primarily consist of input attribution techniques, such as LIME (Ribeiro et al., 2016), input reductions (Li et al., 2016b; Feng et al., 2018), attention-based explanations (Bahdanau et al., 2015) and gradient-based methods (Simonyan et al., 2014; Selvaraju et al., 2017; Sundararajan et al., 2017; Shrikumar et al., 2017). In present work, we extract rationales using the DeepLIFT (DL) method (Sundararajan et al., 2017). Rather than focus on comparing techniques, we instead focus on doing a thorough evaluation of the capabilities of DL.

**Frameworks for interpretable pipelines** Our goal of building a system grounded in evidence draws heavily on recent work on attribution techniques and model explanations, particularly notions of faithfulness and plausibility. *Faithfulness* refers to how accurately the explanation provided by the model truly reflects the information it used in the reasoning process (Jain et al., 2020). On the other hand, *plausibility* indicates to what extent the interpretation provided by the model makes sense to a

---

1We found our qualitative conclusions to be the same with integrated gradients (Sundararajan et al., 2017), but DeepLIFT overall performed better.
person.  

“Select-then-predict” approaches are one way to enforce faithfulness in pipelines (Jain et al., 2020): important snippets from inputs are extracted and passed through a classifier to make predictions. Past work has used hard (Lei et al., 2016) or soft (Zhang et al., 2016) rationales, and other work has explicitly looked at tradeoffs in the amount of text extracted (Paranjape et al., 2020).

Jacovi and Goldberg (2020) note several problems with this setup. Our work aims to align model behavior with what cues we expect a model to use (plausibility), but uses the predict-select-verify paradigm (Jacovi and Goldberg, 2020) to ensure that these are actually sufficient cues for the model. Like our work, Pruthi et al. (2020a) simultaneously trained a BERT-based model (Devlin et al., 2019) for the prediction task and a linear-CRF (Lafferty et al., 2001) module on top of it for the evidence extraction task with shared parameters. Compared to their work, we focus explicitly on what can be done with pre-trained models alone, not augmenting the model for evidence extraction.

3 Methods
The systems we devise take \((D, t)\) pairs as input and return (a) predicted labels \(y_t\) for each \(t\); (b) sets of extracted evidence sentences \(E_t\) from an interpretation method. Figure 1 shows the basic setting.

3.1 Transformer Classification Model

We use RoBERTa (Liu et al., 2019) as our document classifier due to its strong performance in classification, training to minimize log loss in a standard way. For each of our two domains, we use different pre-trained weights, as described in the training details in Appendix A.1. The task inputs are described in Section 4.1.

3.2 Interpretation for Evidence Extraction

Our base technique for evidence extraction uses the DeepLIFT method (Shrikumar et al., 2019) to identify key input tokens. From our model \(y_t = f(D, t)\), we compute attribution scores with respect to the predicted class \(y_t\) for each token in

\[\text{Transformer} \quad [CLS] \quad [0] \quad \text{Severe encephalomalacia} \quad \ldots \quad [1] \quad \text{Moderate enlargement} \quad \ldots \quad [2] \quad \text{No abnormal} \quad \ldots \quad [3] \quad \text{Near complete} \ldots\]

Figure 2: An illustration of attention regularization and entropy maximization using the example in Table 1. The model is predicting the label for key feature \(t_2\).

the RoBERTa input representation. DeepLIFT attributes the change in the output from a reference output in terms of the difference in input from the reference input.  

We average over the absolute value of attribution score for each token in that sentence to give sentence-level scores \(\{s_1, \ldots, s_n\}\). These give us a ranking of the sentences. Given a fixed number of evidence sentences \(k\) to extract, we can extract the top \(k\) sentences by these scores.

To verify the extracted evidence (Jacovi and Goldberg, 2020), our main technique (SUFFICIENT) feeds the model increasingly large subsets of the document ranked by attribution scores (e.g., first \(\{s_{\text{max}}\}\), then \(\{s_{\text{max}}, s_{\text{2nd-max}}\}\), etc.) until it (a) makes the same prediction as when taking the whole document as input and (b) assigns that prediction at least \(\alpha\) times the probability when the whole document is taken as input. We consider this attribution faithful: it is a subset of the input supporting the model’s decision judged as important by the attribution method.

3.3 Improving Evidence Extraction

While many document-level extraction settings do not have token-level attributions labeled for every decision, one can in practice annotate a small fraction of a dataset with such ground-truth rationales. This is indeed the case for our brain MRI case study. Past work has shown significant benefits from inte-
grating this supervision into learning (Strout et al., 2019; Dua et al., 2020; Pruthi et al., 2020b). 

Assume that a subset of our labeled data consists of \((D, t, y_t, E_t)\) tuples with ground truth evidence sentence indices \(E_t = \{i_1, \ldots, i_m\}\). We consider two modifications to our model training, namely attention regularization (Pruthi et al., 2020b), entropy maximization (Feng et al., 2018), and their combination. An illustration of both methods is shown in Figure 2.

Attention regularization Attention regularization encourages our model \(f(D, t)\) to leverage more information from \(E_t\). Specifically, let \(A = \{\alpha_1, \ldots, \alpha_n\}\) be a set of attentions from the [CLS] token in the final layer to all tokens in \(D\), where \(\alpha_i\) is a vector of attentions for each token in sentence \(x_i\). During learning, we add the following loss over all evidence sentences \(x_i\) to the training objective: 
\[
\ell_{\text{attn}} = -\log \sum_{i,j} \alpha_{ij},
\]
encouraging the model to attend to the labeled evidence sentences.

Entropy maximization When there is no sufficient information contained in the text to infer any predictions, entropy maximization encourages a model to be uncertain, represented by a uniform probability distribution across all classes (DeYoung et al., 2020; Feng et al., 2019). Doing so should encourage the model to not make predictions based on irrelevant sentences. We can achieve this by taking a reduced document \(D' = D \setminus E\) as input by removing evidence \(E\) from original document \(D\). We treat \((D', t)\) pairs as extra training examples where we aim to maximize the entropy 
\[
-\sum_y P(y|D') \log P(y|D')
\]
over all possible \(y\).

4 Experiments

4.1 Datasets and Evaluation Metrics

We investigate our methods on (a) a small collection of brain MRI reports from radiologists’ observations; and (b) a modified version of the DocRED dataset. The statistics for both datasets are included in Appendix B. For both datasets, we evaluate on task accuracy (captured by either accuracy or prediction macro-F1) as well as evidence selection accuracy (macro-F1) or precision, measuring how well the model’s evidence selection aligns with human annotations. We will use the SUFFICIENT method defined in Section 3.2 to select evidence sentences which guarantee that our predictions on the given evidence subsets will match the model’s predictions on the full document. For the brain MRI report dataset, we evaluate evidence extraction by precision since human annotators typically only need to refer to one sentence to reach the conclusion but our model and baselines may extract more than one sentence.

4.1.1 Brain MRI Reports

We present a new dataset of radiology reports from brain MRIs. It consists of the “findings” sections of reports, which present observations about the image, with labels for pre-selected key features by attending physicians and fellows. Crucially, these features are labeled based on the original radiology image, not the report. The document-level labels are therefore noisy because the radiologists’ labels may disagree with the findings written in the report.

A key feature is an observable variable \(t\), which can take on \(n_t\) emission values. We focus on the evaluation of two key features, namely contrast enhancement and mass effect, since they appear in most of manually annotated reports. For our RoBERTa classification model, we only feed the document and train separate classifiers for each key feature, with no shared parameters between these.

Annotation We have a moderate number (327) of reports that have noisy labels from the process above. We treat these as our training set. However, all of these labels are document-level.

To evaluate models’ performance on more fine-grained evidence labels, we randomly select 86 unlabeled reports (not overlapping with the 327 for training) and asked four radiology residents to (1) assign key feature labels and reach consensus, while (2) highlighting sentences that support their decision making. We use Prodigy\(^5\) as our annotation interface. See Appendix C for more details about our annotation instructions.

Pseudo sentence-level supervision Since we have limited number of annotated reports for evaluation, we need a way to prepare weak sentence-level supervision while training. To achieve this, we use sentences selected by a rule-based system as pseudo evidence to supervise models’ behavior. We use 10\% of this as supervision while training for consistency with the DocRED setting.

Rule-based system Our rule-based system uses keyword matching to identify instances of mass

\(^{5}\)https://prodi.gy
effect and contrast enhancement in the reports, and negspacy to detect negations of these key features.

**Data split** For the results in Section 5, we evaluate on reports that contain ground truth fine-grained annotations for either contrast enhancement or mass effect, respectively. There are 64 and 68 out of 86 documents total in each of these categories. We call this the BRAINMRI set. When we restrict to this set for evaluation, all of the documents we study where the annotators labeled something related to contrast enhancement end up having an explicit mention of it. However, for mass effect, this is not always the case; Table 6 shows an example where mass effect is discussed implicitly in the first sentence.

### 4.1.2 Adapted DocRED

DocRED (Yao et al., 2019) is a document-level relation extraction (RE) dataset with large scale human annotation of relevant evidence sentences. Unlike sentence-level RE tasks (Qin et al., 2018; Alt et al., 2020), it requires reading multiple sentences and reasoning about complex interactions between entities. We adapt this to a document-level relation classification task: a document \( D \) and two entity mentions \( e_1, e_2 \) within the document are provided and the task is to predict the relation \( r \) between \( e_1 \) and \( e_2 \). We synthesize these examples from the original dataset and sample random entity pairs from documents to which we assign an NA class to construct negative pairs exhibiting no relation.

The model input is represented as:

\[
[CLS]<ent-1>[SEP]<ent-2>[SEP]<doc>[SEP].
\]

To make the setting more realistic, we do not use the large-scale evidence annotation and assume there is limited sentence-level supervision available. To be specific, we include 10% fine-grained annotations in our adapted DocRED dataset.

### 4.2 Models

Due to richer and higher-quality supervisions in the DocRED setting, we conduct a larger set of ablations and comparisons there. We compare against a subset of these models in the radiology setting.

#### Baselines

We consider a number of baselines for adapted DocRED which return both predicted labels and evidence. (1) DIRECT predicts the relation directly from the entity pairs without any sentences as input, using a model trained with just these inputs. (2) FULLDOC takes the full document as selected evidence and uses the base RoBERTa model.

| Model Names | Input Text |
|-------------|------------|
| DIRECT      | None       |
| FULLDOC     | Full document |
| ENT         | Sentences containing at least one of the two query entities |
| FIRST2      | First two sentences |
| FIRST3      | First three sentences |
| BESTPAIR    | Two sentences yielding highest prediction prob. (incl. variants using regularization) |
| SUFFICIENT  | Sufficient sentences selected by DL (incl. variants using regularization) |

Table 2: Model names used in the experiments and their associated evidence given as inputs.

(3) ENT takes all sentences with entity mentions \( e_1 \) and \( e_2 \) as input; (4) FIRST2, FIRST3 retrieve the first 2 and 3 sentences, respectively; and (5) BESTPAIR chooses the best sentence pair by first taking each individual sentence as input to the model and then picking top two sentences having highest probabilities on their predictions. This approximates an erasure-based method like LIME (Ribeiro et al., 2016) in contrast to our DeepLIFT method.

SUFFICIENT is our main method for both datasets, which we then augment with additional supervision as described in Section 3.3. We use subscripts \( \text{attn} \), \( \text{entropy} \), \( \text{both} \) and \( \text{none} \) to represent attention regularization, entropy maximization, the combination of two, and neither.

Table 2 summarizes the abbreviated names of models and their inputs. Training details are described in Appendix A.1.

#### Metrics

We report both the accuracy and F1 for the model as well as the evidence selection F1 comparing to human judgments. We also report results in the reduced setting, where only the selected evidence sentences are fed to the RoBERTa model (trained over whole documents) as input. For our SUFFICIENT method, this accuracy is the same as the full method by construction, but note that it can differ for other methods. This reduced setting serves as a sanity check for the faithfulness of our explanation techniques.

### 5 Results

#### 5.1 Results on Brain MRI

Table 3 shows the performance of our models and baselines in terms of label prediction and evidence extraction. In the mass effect setting, our SUFFICIENT model achieves the highest evidence extraction precision of the learning-based models.
and nearly matches that of the rule-based system. It is difficult to be more reliable than a rule-based system, which will nearly always make correctly-sourced predictions. But this model is able to combine that reliability with the higher F\textsubscript{1} of a learned model. Note that due to the high base rates of certain findings, we focus on F\textsubscript{1} instead of accuracy. We see a similar pattern on contrast enhancement as well, although the evidence precision is lower in that case.

These results show that learning-based systems make accurate predictions in this domain, and that their evidence extraction can be improved with better training, even in spite of the small size of the training set. In section 5.2, we focus on the adapted DocRED setting, which allows us to examine our model’s performance in a higher-data regime.

### Attribution scores are more peaked at the occurrence of key terms

We conduct analysis on how the attribution scores from SUFFICIENT\textsubscript{both} are peaked around the correct evidence compare to that from SUFFICIENT\textsubscript{none} using our manually annotated set BRAINMRI. To quantify this analysis, we take the mean of instance-wise average and maximum of the normalized attribution mass falling into a few explicit tokens. In particular, we consider enhancement for contrast enhancement and effect for mass effect, which are common explicit indicators in the context of specified key features. The results in Table 5 show attribution scores being peaked around the correct terms, highlighting that these models can be guided to not only make correct predictions but attend to the right information.

Table 6 shows visualizations of attribution scores for an example in BRAINMRI using DeepLIFT. Notice that even though baseline models make correct predictions, their attribution mass is diffused over the document. With the help of regularization, our model is capable of capturing implicit cues such as downward displacement of the brain stem, although it is trained on an extremely small training set with only explicit cues like mass effect in a weak sentence-level supervision framework.

#### 5.2 Results on Adapted DocRED

**Comparison to baselines** We see that the ENT baseline is quite strong at DocRED evidence extraction. However, our best method still exceeds this method on both label accuracy as well as evidence extraction while extracting more succinct explanations. We see that the ability to extract a

Table 6: An illustration of models’ attribution scores over a report from BRAINMRI using DeepLift with and w/o regularization techniques. SUFFICIENT\text{\textsuperscript{both}} appears to leverage more information from right sentences.

variable-length explanation is key, with FIRST\text{\textsuperscript{2}}, FIRST\text{\textsuperscript{3}} and BESTPAIR performing poorly. Notably, these methods exhibit a drop in accuracy in the reduced doc setting for each method compared to the full doc setting, showing that the explanations extracted are not faithful.

Learning-based models with appropriate regularization perform relatively better in this larger-data setting. From Table 3 and Table 4, we can observe that various regularization techniques applied to SUFFICIENT models maintain or improve overall model performance on both key feature and relation classification. We see that our SUFFICIENT methods do not compromise on accuracy but make predictions based on plausible evidence sets, which is more evident when we have richer training data. We perform further error analysis in Appendix D.

Faithfulness of techniques One may be concerned that, like attention values (Jain and Wallace, 2019), our feature attribution methods may not faithfully reflect the computation of the model. We emphasize again that the SUFFICIENT paradigm on top of the DeepLIFT method is faithful by our definition. For a model $f$, we measure the faithfulness by checking the agreement between $y = f(D, t)$ and $y' = f(E_t, t)$, where $E_t$ is the extracted evidence we feed into the same model under the reduced document setting. This is shown for all methods in the “Reduced doc” columns in Tables 3 and 4. We see a drop in performance from techniques such as BESTPAIR: the full model does not make the same judgment on these evidence subsets, but by definition it does in the SUFFICIENT setting.

As further evidence of faithfulness, we note that only a relatively small number of evidence sentences, in line with human annotations, are extracted in the SUFFICIENT method. These small subsets are indicated by feature attribution methods and sufficient to reproduce the original model predictions with high confidence. We believe this constitutes strong evidence that these explanations are faithful.

6 Conclusion

In this work, we develop techniques to employ small amount of token-annotated data to improve reliability of document-level IE systems in two domains. We systematically evaluate our model from perspectives of faithfulness and plausibility and show that we can substantially improve models’ capability in focusing on supporting evidence while maintaining their prediction performance, leading to models that are “right for the right reasons” and avoid learning spurious patterns.

A Reproducibility

A.1 Implementation Details

We train all RoBERTa models for 15 epochs with early stopping using 1 TITAN-Xp GPU. We use AdamW (Loshchilov and Hutter, 2019) as our optimizer and initialize the model with roberta-base for DocRED and biomed-roberta-base (Gururangan et al., 2020) for brain MRI data, both with 125M parameters. The batch size is set to 16, and the learning rate is 1e-5 with linear schedule warmup.

The maximum number of tokens in each document is capped at 296 for modified DocRED and 360 for radiology reports. These numbers are chosen such that the number of tokens for around 95% of the documents is within these limits. We do not perform extensive hyperparameter tuning in this work. The hidden state of the [CLS] token from the final layer is fed as input to a linear projection head to make predictions.

B Dataset statistics

We provide the statistics for both adapted DocRED and brain MRI reports dataset in Table 7. Both datasets are in English and the DocRED dataset is publicly available at https://github.com/thunlp/DocRED.

C Annotation Instructions

The annotation instructions are provided in Figure 3. These were developed jointly with the annotators. In particular, decisions to exclude normal brain activity and confounders such as SVID were made to increase interannotator agreement after an initial round of annotation, making it easier for the labeling to focus on a single core disease or diagnosis per report.

D Error Analysis

The first example in Table 8 shows a representative case where our model predicts the correct relation and extracts reasonable supporting evidence. Unsurprisingly, this happens most often in simple cases when reasoning over the interaction of sentences is not required.

We observe a few common types of errors. First, are potential alternatives for relations or evidence extraction. From around 60% of our randomly selected error cases, our model either predicts debatably correct relations or picks up sentences that are related but not perfectly aligned with human annotations. The second row in Table 8 illustrates an example where the two entities exhibit multiple relationships; the model’s prediction is correct (Vienna is place where Martinelli was both born and died), but differs from the annotated ground truth and supporting evidence. Such relations are relatively frequent in this dataset; a more complex multi-label prediction format is necessary to fully support these.

Another type of error is complex logical reasoning. Even if our model can extract right evidence, it still fails in around 10% of random error cases requiring high-level reasoning capability. For example, to correctly predict the relation between Theobald Tiger and 21 December 1935 in the third example in Table 8, a model needs to recognize that Theobald Tiger and Kurt Tucholsky are in fact the same entity by referring to pseudonym, which is a challenging relation to recognize.

Finally, the model sometimes selects more sentences than we truly need. Interestingly, this is an error in terms of evidence plausibility but not in terms of prediction. The number of extracted sentences is very high in around 25% of the random error cases. The last row from Table 8 is one of representative examples with this kind of error. Although our model possibly has already successfully extracted right evidence in the first two steps, it continues selecting unnecessary sentences because the prediction confidence is not high enough, a drawback in our way of selecting evidence mentioned in Section 4.2. Moreover, our model extracts one more sentence on average when predicting incorrect relations, suggesting that in these cases it does not cleanly focus on the correct information.
| Dataset         | Setting    | # doc. | # inst. | # word/inst. | # sent./inst. | # relation | NA% |
|-----------------|------------|--------|---------|--------------|---------------|------------|-----|
| Adapted DocRED  | train      | 3053   | 38180   | 203          | 8.1           | 96+1       | 33  |
|                 | val        | 1000   | 12323   | 203          | 8.1           | 96+1       | 33  |
| Brain MRI       | train      | 327    | 327     | 177          | 11.6          | –          | –   |
|                 | val        | 86     | 86      | 132          | 10.1          | –          | –   |

Table 7: Statistics of the two document-level IE datasets. Each document may have multiple entity pairs of interest, giving rise to multiple instances in the adapted DocRED setting. For adapted DocRED, we have 96 relations from the data plus an NA relation that we introduce for 1/3 of the data.

Instructions

For each finding, please highlight clues (if any) in the text for each key feature listed below using the provided web interface and provide one label listed below for each key feature. Some key features are explicitly mentioned in the findings, but some are not and are tricky to identify.

Key Features and labels:

- flair/t2: decreased, flair/t2: normal, flair/t2: increased
- t1: decreased, t1: normal, t1: increased
- diffusion/ADC: decreased, diffusion/ADC: normal, diffusion/ADC: increased
- susceptibility: increased, susceptibility: normal
- contrast Enhancement: yes, contrast Enhancement: no
- signal pattern: homogeneous, signal pattern: heterogeneous, signal pattern: ring
- lesion: single, lesion: multiple
- side: lesion(s) symmetric, side: lesion(s) asymmetric
- mass effect: positive, mass effect: no, mass effect: negative

Note:
side: lesion(s) symmetric, side: lesion(s) asymmetric: 'symmetric about the midline'.
If one lesion, most responses would be 'asymmetric', with lesion right or left. Single lesion 'symmetric' would be midline lesion.

General guidelines
- You should choose the minimal, most informative spans for each finding. For example, highlight "high T1 signal" instead of "there is high T1 signal".
- Prefer a single most informative span if possible; otherwise, you may choose two spans (as in an example below, under "Mass Effect") .
- Within each category (flair, mass effect, etc.), please carefully consider whether there is any evidence for one of those findings or not. Not annotating a category will be taken as a sign that there is no evidence for it.
- Often the span will be a noun phrase like "acute intracranial hemorrhage", or "no [noun phrase]".
- Ignore extra-axial lesions, small vessel ischemic disease, and all other minor diseases.
- In cases of "There is no X, Y, or Z", you should select just the span containing Z to indicate "no Z" -- the tool doesn't support overlapping annotations or those with a "gap".
- Do not annotate normal brain and non-brain chunks of the report (in addition to confounders such as SVID).
- If the same information shows up in multiple places, do try to annotate all of them.

Figure 3: Annotation instructions.
| Type                                                                 | Example                                                                                                                                                                                                 |
