Abstract

We consider the scalar-tensor theories of gravity extended by the pseudoscalar couplings to matter and gauge fields and derive constraints on the $CP$-odd combinations of scalar and pseudoscalar couplings from laboratory spin precession experiments and from the evolution of photon polarization over cosmological distances. We show the complimentary character of local and cosmological constraints, and derive novel bounds on the pseudoscalar couplings to photons from the laboratory experiments. It is also shown that the more accurate treatment of the spin content of nuclei used in the spin precession experiments allows to tighten bounds on Lorentz-violating backgrounds coupled to the proton spin.
1 Introduction

The discovery of dark energy [1] instigated many developments in cosmology and particle physics during the last decade. To date all observational data are consistent with the most economic possibility: the dark energy is just a cosmological constant, and as such does not evolve over the cosmological time scales. On the other hand, it is intriguing to think about the alternative explanations related to a drastic change of the infrared physics. In parallel to the attempts of modifying gravity on large scales [2], there is a renewed interest in the cosmological scalar fields that are nearly massless, and manifest themselves as a ”dark energy” component over large cosmological distances [3].

An interesting twist to the well-known story of cosmological scalars comes from the possibility of their interaction with matter and gauge fields (For purely cosmological signatures of ”interacting” quintessence, see e.g. [4]). In fact such theories exhibit a rich plethora of phenomena that go beyond pure cosmological effects, which we would like to illustrate on the following toy example. Let us consider a Lagrangian for the scalar field $\phi$ interacting with a Standard Model fermion $\psi$ (e.g. electron) and a gauge field $A_\mu$ (e.g. photon),

$$\mathcal{L} = \frac{1}{2} \partial_\mu \phi \partial^\mu \phi - V(\phi) + \bar{\psi}(iD_\mu \gamma^\mu - m)\psi - \frac{1}{4} F_{\mu\nu} F^{\mu\nu} \quad (1.1)$$

$$- c_{S\psi} \phi \bar{\psi} \psi - c_{P\psi} \phi \bar{\psi} i\gamma_5 \psi - c_{S\gamma} \phi F_{\mu\nu} F^{\mu\nu} - c_{P\gamma} \phi \tilde{F}_{\mu\nu} \tilde{F}^{\mu\nu}.$$ 

Here $c_{Si}$ and $c_{Pi}$ parametrize the strengths of the scalar and pseudoscalar couplings to photons and fermions, while $F_{\mu\nu}$ and $\tilde{F}_{\mu\nu}$ denote the usual and dual field strengths, and $D_\mu$ is the covariant derivative. Written in flat space, Lagrangian (1.1) can be trivially generalized to curved backgrounds, and to nonlinear couplings to matter. Starting from (1.1), one can immediately infer a number of interesting consequences, a partial list of which is given below.

1. **The existence of a new long-range force distinguishable from spin-two gravity.** The scalar field contributes to the gravitational force, adding $\sim c_s^2$ on top of the familiar Newton constant mediated by gravitons. Such a force leaves distinguishable imprints via relativistic corrections and/or composition dependence (effective violation of the equivalence principle).

2. **The existence of a preferred Lorentz frame associated with $\partial_\mu \phi$.** If $\phi$ is a very light quintessence-like field, then there is a preferred frame where cosmologically $\partial_\mu \phi = (\dot{\phi}, 0, 0, 0)$. For most of the models this frame coincides with the frame of the cosmic microwave background (CMB), and $|\dot{\phi}|$ is limited by $(\rho_{d.e.}(1 + w))^{1/2}$, where $w$ is the dark energy equation of state parameter.

3. **Variation of masses and couplings in time and space.** Effective values of masses and
coupling constants vary in space and time, \( m_{\text{phys}}(t, \mathbf{x}) = m + c_{S\psi} \phi(t, \mathbf{x}) \), following the \( \phi \)-profile.

4. **Coupling of polarization to velocity relative to the CMB frame.** A particle moving relative to the CMB frame acquires a helicity-dependent interaction, \( H_{\text{int}} \sim (\mathbf{S}n) \dot{\phi} \), where \( n \) is the direction of propagation. This way, the \( C_{P\gamma} \)-proportional interaction would result in the rotation of polarization for photons propagating over varying \( \phi \)-background.

5. **Photon-scalar conversion.** In the presence of an external electromagnetic field a photon can ”oscillate” to a quantum of the scalar field thereby e.g. reducing the luminosity of distant objects or providing additional channels for star cooling.

6. **Coupling of spin to the local gravitational force.** Scalar coupling \( g_{S\psi} \) will lead to the local field gradient \( \nabla \phi \) generated by massive bodies, which is closely parallel to the vector of local free-fall acceleration. The pseudoscalar couplings then create a Zeeman-like splitting for the spin of \( \psi \)-particles in the direction of the local gravitational acceleration, \( H_{\text{int}} \sim (\mathbf{S}g) \).

It is remarkable that such a simple Lagrangian leads to a number of quite different phenomena. Unfortunately, at this stage the exciting phenomenology of ”interacting dark energy” lives in a pure theoretical realm: there is no confirmed experimental evidence for any of the effects on our list\(^1\). Consequently, there are only upper limits on the combinations of the couplings in Lagrangian (1.1) that can be quoted. Nevertheless, many of the effects on our list have found an extensive coverage in the theoretical works. Most notably, the changing couplings were discussed, for example, in Refs. [9, 10, 12], the photon-scalar conversion considered in Refs. [13], and the fixed frame effects versus the cosmological evolution of photon polarization were addressed in a series of papers [14, 15, 16, 7, 8]. For the limits on scalar-induced corrections to gravitational interactions we refer the reader to recent reviews [17] and references therein. In contrast, the last item on our list, the spin coupling to the local gradient of the scalar field received far less attention (see e.g. [18]).

The purpose of this paper is to show that the pseudoscalar couplings of the Brans-Dicke type scalar can indeed be subjected to stringent laboratory constraints that are complementary to the cosmological limits. The high-precision spin precession experiments constrain pseudoscalar interactions both in the fermion and photon sectors. In the rest of this paper we present the set-up for our model, briefly review the effects created by the cosmological evolution of \( \phi(t) \), investigate the local spin effects created by the gradient of \( \phi \), and set the limits on the admissible size of the pseudoscalar couplings.

\(^1\)A tantalizing hint on the redshift evolution of the fine structure constant was reported in Ref. [5], which so far has not been corroborated by other searches [6]. Also, an earlier claim of the non-zero pseudoscalar-induced anisotropy in polarization signal [7] was disputed in the literature [8].
Before we delve into studying the physical effects induced by the pseudoscalar couplings, we would like to add a word of caution addressed to all models of "interacting quintessence". The models of light scalar fields represent a formidable challenge at the quantum level, as there are no fundamental reasons for a scalar to remain massless or nearly massless. The scalar interaction of such field makes the whole problem even more difficult, if not impossible, from the point of view of "technical naturalness"; the loops of Standard Model (SM) fields tend to generate big corrections to $V(\phi)$ even with a relatively small ultraviolet cutoff parameter, which would be in conflict with requirements $m_\phi \sim H$ [10, 15, 19]. There is no clear resolution to this problem, which essentially prevents the fully consistent study of $\phi$ dynamics. Instead, one has to rely, perhaps too optimistically, that the problem of near-masslessness of the scalar field could be cured by the same mechanisms that make the cosmological constant small and meanwhile keep $V(\phi)$ fixed by hand. To finish this "disclaimer" on an optimistic note, we would like to remark that the pseudoscalar couplings do not make this problem worse. Indeed, in essence the pseudoscalar couplings give only derivative interactions, and therefore do not affect the potential $V(\phi)$ at perturbative level.

2 Adding spin couplings to scalar-tensor theories

We would like to formulate our reference Lagrangian at the normalization scale just below the QCD scale, so that the effective matter degrees of freedom are electrons, photons, nucleons and neutrinos. Splitting the $\phi$-field Lagrangian into the scalar and pseudoscalar parts,

$$L = \mathcal{L}_S + \mathcal{L}_P,$$

we choose the following parametrization,

$$\mathcal{L}_S = \frac{1}{2} \partial_\mu \phi \partial^\mu \phi - V(\phi) - \sum_{j=e,p,n} \frac{\phi}{M_{Sj}} m_j \bar{\psi}_j \gamma_{5} \psi_j - \frac{\phi}{M_{S\gamma}} F_{\mu\nu} F^{\mu\nu},$$

and

$$\mathcal{L}_P = \sum_{j=e,p,n,\nu} \frac{\partial_\mu \phi}{M_{Pj}} \bar{\psi}_j \gamma_\mu \gamma_5 \psi_j - \frac{\phi}{M_{P\gamma}} F_{\mu\nu} \tilde{F}^{\mu\nu}.$$  

Lagrangian (2.4) includes all possible pseudoscalar interaction at mass dimension five level. Notice that the pseudoscalar interactions can be chosen in a slightly different form, $\bar{\psi} \gamma_5 \psi$, as in (1.1). This does not mean, however, that the set of our operators should be enlarged. The two type of operators, pseudoscalar and axial vector, are related on the equations of motion. These equations are in general anomalous, but since we include the interaction with $F \tilde{F}$ explicitly, we can assert that Lagrangian (2.4) is indeed complete in a given dimension of the operators.
The scalar part of the Lagrangian (2.3) leads to new contribution to gravitational force, and to change of masses and couplings. Since in this paper our main interest is in spin effects, we are going to make simplifying assumptions of approximate universality of the $\phi$-mediated attractive force,

$$M_{Se} = M_{Sp} = M_{Sn} \equiv M_S, \quad \text{and} \quad M_{S\gamma} \gg M_S. \quad (2.5)$$

At distances shorter than the Compton wavelength of $\phi$-quanta the Newton constant receives contributions from both spin-two and spin-zero exchanges,

$$G_N = G_0^N \left( 1 + \frac{2M_{Pl}^2}{M_S^2} \right), \quad (2.6)$$

where $G_0^N$ is the unperturbed Newton constant due to graviton exchange, and Planck mass is defined as $M_{Pl} = \left( \frac{8\pi G_0^N}{3} \right)^{-1/2} = 2.4 \times 10^{18}\text{GeV}$.

If needed, the pseudoscalar couplings could be ”lifted” from the nucleon level to the level of individual quarks. Using the experimental results for the spin content of the nucleon combined with $SU(3)$-flavour relations [20] one gets

$$M_{Pp}^{-1} \simeq 0.8M_{Pu}^{-1} - 0.4M_{Pd}^{-1} - 0.1M_{Ps}^{-1}, \quad M_{Pn}^{-1} \simeq 0.8M_{Pd}^{-1} - 0.4M_{Pu}^{-1} - 0.1M_{Ps}^{-1}, \quad (2.7)$$

where the light quark couplings are normalized at the scale of 1 GeV.

Using the appropriate field content, one can determine the renormalization group evolution of the pseudoscalar couplings. In general the equations governing this evolution takes the following form,

$$\frac{dM_{P_i}^{-1}}{d\log(\Lambda/\mu)} = a_{ij}M_{P_j}^{-1} + b_{i\alpha}M_{P_\alpha}^{-1},$$

$$\frac{dM_{P_\alpha}^{-1}}{d\log(\Lambda/\mu)} = c_{\alpha i}M_{P_i}^{-1} + d_{\alpha\beta}M_{P_\beta}^{-1}, \quad (2.8)$$

where the logarithm is taken between the ultraviolet scale $\Lambda$ and the infrared scale $\mu$, Latin indices indicate fermionic fields and Greek indices indicate the gauge bosons of the SM group. The renormalization group coefficients $a_{ij}, b_{i\alpha}, c_{\alpha i},$ and $d_{\alpha\beta}$ depend on charge assignments and coupling constants of field running inside the loops. The precise form of these coefficients is not of immediate interesting to us, but we would like to emphasize the following important observation: at any loop level the derivative couplings to fermions do not generate couplings to $F_{\mu\nu}F^{\mu\nu}$. In other words,

$$c_{\alpha i} \equiv 0. \quad (2.9)$$

Whatever size of the pseudoscalar couplings between photons and $\phi$ is generated by some (perhaps anomalous) ultraviolet scale physics at energies order $\Lambda$, it is preserved by the
subsequent evolution to the lower scales. In fact, this refers both to the logarithmic running and to the threshold corrections. This observation delineates two important classes of models: there are models where both fermion and photon pseudoscalar couplings present in the Lagrangian, and there are models where only couplings to fermions are present. The models where $\phi$ couples only to gauge bosons would necessarily be fine-tuned, as quantum effects in (2.8) would definitely generate induced couplings to fermions.

Existing constraints on the model can be divided into pseudoscalar and scalar constraints. The constraints on the universal scalar coupling $M_S$ can be derived from the constraint imposed by the Cassini satellite data on the post-Newtonian parameter $\bar{\gamma}$ [21],

$$|\bar{\gamma}| < 4 \times 10^{-5} \implies M_S > 400 M_{Pl}. \quad (2.10)$$

The constraints on the non-universal part of the scalar coupling are several orders of magnitude stronger. The scalar coupling to photons is constrained via the limits on the time variation of the coupling constant, and less directly via the composition-dependent contribution to local acceleration. Typically, one has $M_{S\gamma} > 10^3 M_{Pl}$. In contrast, the pseudoscalar couplings are far less constrained. The leading source of constraints are the energy loss mechanisms in stars [22], and for electrons, photons and nucleons all constraints are in the ballpark of

$$|M_P| \gtrsim (10^{10} - 10^{12}) \text{ GeV} \sim (10^{-8} - 10^{-6}) \times M_{Pl}. \quad (2.11)$$

In the next section, we are going to show that if both pseudoscalar and scalar couplings are present, some constraints on $M_P$ can be significantly improved.

3 Cosmological constraints on the model

To derive cosmological constraints on pseudoscalar couplings we remind the reader that the presence of a time-evolving scalar field with a pseudoscalar coupling to photons leads to a rotation of polarization for photons. The resulting angular change in the linear polarization for a photon propagating from point 1 to point 2 is simply related to the change of $\phi$ between the two points,

$$\Delta \theta = \frac{2\Delta \phi}{M_{P\gamma}}. \quad (3.1)$$

Following the work of Carroll [15] and the original analysis of Ref. [24], we use the limit on the extra rotation of polarization from distant source (3C 9) at redshift $z = 2.012$ as $|\Delta \theta| < 6^\circ$,

$$\frac{|\phi(z = 2) - \phi(z = 0)|}{M_{P\gamma}} < 0.052. \quad (3.2)$$

Even more distant sources of polarization are available in the studies of the cosmic microwave background. The $E$-mode polarization map of the sky has been produced [23],
which agrees well with the expectation based on the temperature map. This constrains the amount of extra rotation of polarization introduced by $\phi F \tilde{F}$ interaction between the surface of last scattering and $z = 0$. Recent numerical analyses of the CMB data provide a constraint on the amount of extra rotation at the level of $|\Delta \theta| < 6^\circ$ [16] (the same limit of $6^\circ$ is purely coincidental), which allows to extend (3.2) to the redshifts of photon decoupling, $z_{\text{dec}} \simeq 1100$, 

$$\frac{|\phi(z_{\text{dec}}) - \phi(z = 0)|}{M_{\text{Pl}}^2} < 0.052. \quad (3.3)$$

Finally, we would like to point out that the CMB polarization signal is generated in the narrow window of redshifts that correspond to the "last scattering" surface, and therefore the existing measurements constrain the amount of extra rotation within the thickness of this surface, 

$$\frac{2}{M_{\text{Pl}}} |\Delta \phi(z_{\text{dec}} \pm \Delta z_{\text{dec}}/2)| < O(1), \quad (3.4)$$

where $\Delta z_{\text{dec}} \simeq 200$ correspond to the thickness of the last scattering surface. The violation of this bound would suppress the strength of polarization signal, which is well measured.

With these bounds at hand, we are ready to translate them into the constraints on the parameters of our model. However, the cosmological constraints depend very sensitively on what we assume about the scalar couplings of $\phi$ to dark matter and even more so on the choice of the potential $V(\phi)$. Since the number of options is infinite, we would like to consider in detail two well-motivated cases.

**Case 1.** The simplest case is when the potential for $\phi$ is nearly flat and the evolution of $\phi$ is slow. In this case one can linearize $V(\phi)$, 

$$V(\phi) \simeq \rho_{\Lambda} \left(1 + \frac{\phi}{M_{\Lambda}}\right), \quad (3.5)$$

where $\rho_{\Lambda}$ is approximately equal to the measured value of dark energy density, and $M_{\Lambda}$ is a new parameter on the order of the Planck scale and/or $M_S$. In the limit when the back-reaction of $\rho_{\phi}$ on Friedmann’s equations is neglected one can find an analytic expression for the evolution of $\phi$ in the flat Universe [10]. In this approximation the time evolution of the scale factor can be expressed via the scale factor and the Hubble parameter today ($t_{\text{now}} \equiv t_0$): $H_0 = H(t = t_0) = \dot{a}/a|_{t = t_0}$ and $a(t = t_0) \equiv a_0$, as well as the current energy densities of matter and cosmological constant relative to the critical density, $\Omega_m = \rho_m/\rho_c$ and $\Omega_{\Lambda} = \rho_{\Lambda}/\rho_c$:

$$a(t)^3 = a_0^3 \Omega_m \Omega_{\Lambda} \left[\sinh\left(\frac{3}{2} \Omega_{\Lambda}^{1/2} H_0 t\right)\right]^2. \quad (3.6)$$

The equation of motion for the scalar field receives forcing terms directly related to dark energy and matter densities:

$$\ddot{\phi} + 3H \dot{\phi} = -\frac{\rho_m}{M_S} - \frac{\rho_{\Lambda}}{M_{\Lambda}} = -\rho_c \left[\Omega_m \left(\frac{a_0}{a}\right)^3 + \Omega_{\Lambda} \right], \quad (3.7)$$
where we made an assumption of the universal strength of $\phi$ coupling to matter, including the dark matter. This equation can be integrated out explicitly [10] to give

$$\phi(t) = \frac{4}{3} M_{\text{Pl}}^2 \left[ \left( \frac{1}{2M_\Lambda} - \frac{1}{M_\phi} \right) (bt_0 \coth(bt_0) - bt \coth(b)) - \frac{1}{M_\phi} \ln \frac{\sinh(b)}{\sinh(bt)} \right], \quad (3.8)$$

where the following notation has been introduced:

$$b = \frac{3}{2} \Omega_\Lambda^\frac{4}{3} H_0. \quad (3.9)$$

This solution implies boundary conditions $\dot{\phi}|_{t \to 0} \sim$ not too large and $\phi(t_0) = 0$. The first condition is automatically satisfied as $\phi$ does not evolve rapidly during the radiation domination, and the second condition is simply a choice, possible since $\phi$ enters linearly in the Lagrangian. It is easy to see that in the limit of $t \ll t_0$ the dependence of $\phi$ on redshift is logarithmic,

$$\phi(a) \simeq \text{const} - \frac{2M_{\text{Pl}}^2}{M_\phi} \ln(a/a_0) \quad \text{at} \quad t_{\text{eq}} \ll t \ll t_0. \quad (3.10)$$

Now we can use the evolution (3.8) to impose limits on the combination of $M_P$ and $M_{\phi(\Lambda)}$ parameters using observational constraint (3.2). We do it for three separate representative cases: for the equal couplings to the matter and dark energy density, and for couplings to dark energy and matter only:

$$M_\Lambda = M_\phi \quad \Rightarrow \quad |M_{P,\gamma}M_\phi| > 36 M_{\text{Pl}}^2; \quad (3.11)$$

$$|M_\Lambda| \to \infty \quad |M_{P,\gamma}M_\phi| > 30 M_{\text{Pl}}^2; \quad (3.12)$$

$$|M_\phi| \to \infty \quad |M_{P,\gamma}M_\Lambda| > 6.1 M_{\text{Pl}}^2. \quad (3.13)$$

These limits generalize the analysis of Ref. [15] where only the $V(\phi)$-induced optical rotation was considered. We also notice that both (3.11) and (3.12) are about one order of magnitude stronger than (3.13), which is the consequence of $(a_0/a)^3 \sim 8$ enhancement of matter density over the cosmological constant at redshifts $\sim 2$.

Due to logarithmic dependence on redshifts at $t \ll t_0$ (3.10) there is about one order of magnitude gain in the strength of the constraint when using the CMB limit (3.3) for the case of finite $M_\phi$,

$$M_\Lambda = M_\phi \quad \text{or} \quad |M_\Lambda| \to \infty \quad \Rightarrow \quad |M_{P,\gamma}M_\phi| > 255 M_{\text{Pl}}^2. \quad (3.14)$$

In order to see the maximal sensitivity to $M_P$, we can saturate the constraint on $M_\phi$ (2.10), which results in $M_{P,\gamma} \gtrsim O(M_{\text{Pl}})$ at maximally allowed $M_\phi$.

**Case 2.** Going away from the linearized case, we consider the cosmological evolution of $\phi$-field approaching some local minimum of $V(\phi)$,

$$V(\phi) = \rho_\Lambda + \frac{m_\phi^2}{2}(\phi - \phi_0)^2. \quad (3.15)$$
If the mass of the field is well above the current Hubble parameter, \( m_\phi \gg H_0 \), then the evolution of \( \phi \) starts long before the present epoch. A well-known solution for \( \phi \) in this case are the oscillations around the minimum with the amplitude that red-shifts as \( a^{-3/2} \). If the initial deviation of \( \phi \) from equilibrium was \( \phi_{in} \) at the time \( t_{in} \) when oscillations began, \( H(t_{in}) \approx m_\phi \), then the subsequent evolution in the radiation domination will be given by

\[
\phi(t) \simeq \phi_0 + \phi_{in} \left( \frac{a_{in}}{a(t)} \right)^{3/2} \cos[m_\phi(t - t_{in}) + \alpha],
\]

(3.16)

where \( \alpha \) is some phase factor. Because of the red-shifted amplitude in (3.16), the constraints provided by the CMB are clearly more advantageous than the low \( z \) constraints. However, the oscillations of \( \phi \) (3.16) make it difficult to define \( \phi(z_{dec}) \), and consequently the analyses of [16] with limits (3.3) are not directly applicable and instead one should resort to limits (3.4). Still, if the initial deviation of \( \phi \) field from its minimum is on the order or less than the pseudoscalar coupling \( M_{P\gamma} \), and oscillations begin earlier than the decoupling, then the cosmological evolution of polarization provides no constraints on the size of the pseudoscalar coupling,

\[
|\phi_{in}| < |M_{P\gamma}|; \quad t_{in} \ll t_{dec} \implies \text{no constraints on } M_{P\gamma}.
\]

(3.17)

This is an important observation, since the first condition \( |\phi_{in}| < |M_{P\gamma}| \) is quite natural if \( \phi \) field has a phase-like origin similar to e.g. QCD axion, and \( t_{in} \ll t_{dec} \) is satisfied for all masses of \( \phi \) in excess of \( 10^{-28} \) eV.

4 Local spin precession constraints

As we have shown in the two previous sections, the cosmological constraints on pseudoscalar couplings apply only to \( M_{P\gamma} \), and not to fermionic couplings. Moreover, all cosmological constraints will be eliminated if the field starts oscillating much earlier than the decoupling of the CMB photons (3.17). This leaves a large domain of parameter space where only the local experiments are going to be sensitive to the pseudoscalar couplings. We wish to consider them in this section. Before we do that, we would like to note that the couplings of spins to the local gravitational (spin-two) field has been extensively studied in the literature [25, 26, 27]. Of main interest for us is the conclusion reached in these works that \( g \cdot S \) coupling does not arise in general relativity. Therefore, if detected, it can be thought of as a distinct signature of the scalar exchange.

Since most of the experiments deal with non-relativistic atoms and nuclei, it is convenient to use the non-relativistic Hamiltonian,

\[
H_{int} = -\sum_{j=n,p,e} \frac{(\sigma_j \cdot \nabla \phi)}{M_{Pj}} + \int d^3x \frac{4(E \cdot B)\phi}{M_{P\gamma}},
\]

(4.18)
where $\vec{\sigma} = S/|S| = 2S$. The local gradient of $\phi$ is one-to-one related to the gravitational acceleration,

$$\nabla \phi = g \frac{2M_{Pl}^2}{M_S}$$

so that the strength of interaction of each spin to the gravitational field is given by $g \times 2M_{Pl}^2/(M_SM_P)$. Gravitational acceleration has dimension of energy in particle physics units of $c = \hbar = 1$, and corresponds to the frequency splitting of spin up and spin down states $\nu_g = 2 \times 9.8 \times 10^2 \text{cm/s}^2/(2\pi \times 3 \times 10^{10} \text{cm/s}) = 10.4 \text{ nHz}$. Unlike most problems in quantum mechanics where "up" and "down" are usually a matter of convention, in this theory these words should be used literally. Only a handful of spin precession experiments ever reached the sensitivity lower than 10 nHz, among them the experiments searching for the permanent electric dipole moments of diamagnetic atoms [28], where the statistical sensitivity is comparable or better than 10 nHz. Unfortunately, this sensitivity is related to the energy difference of spins in parallel and anti-parallel electric and magnetic fields and does not translate into the limits on spin interaction with the vertical direction.

Dedicated search for $g \cdot S$ interaction was pursued in [29] (and earlier in [30]), where a $\sim \mu$Hz accuracy was achieved. In particular, experiment [29] compared the precession frequencies of two mercury isotope spins, $^{199}$Hg and $^{201}$Hg for different orientations of magnetic field and set a limit of $2.2 \times 10^{-30}$ GeV for the spin-dependent component of gravitational energy. Another group of measurements that can be used to limit the pseudoscalar couplings are the spin precession experiments that searched for the effects of Lorentz violation [31, 32] and the experiment with spin-polarized pendulum [33]. The absence of sidereal modulation of spin precession, confirmed by these experiments, sets the limit on the coupling of spins to any direction in space that does not change as the Earth rotates around its axis. Besides useful limits on Lorentz-violating theories [34], such effects will constrain the pseudoscalar couplings in combination with $\nabla \phi$ created by astronomical bodies other than the Earth. The solar contribution to $\nabla \phi$ is smaller than $\nabla \phi_{Earth}$ by a factor of $\sim 6 \times 10^{-4}$, thereby reducing the strength of the constraints extracted from sidereal variations by the same amount. Putting different results together, and assuming that the range of the force is comparable to or larger than the solar system, we arrive at the following set of constraints,

$$|M_{Pn}M_S| > 5 \times 10^{-4} M_{Pl}^2 \quad \text{Ref. [29]}$$

$$|M_{Pn}M_S| > 1 \times 10^{-4} M_{Pl}^2 \quad \text{Ref. [31, 32]}$$

$$|M_{Pe}M_S| > 2 \times 10^{-5} M_{Pl}^2 \quad \text{Ref. [33]}$$

Bounds (4.20) and (4.21) are derived in the assumption of Ref. [35] that the spin of the nucleus is given by the angular momentum of the of the outside nucleon, which happens to be a neutron for all nuclei used in the most sensitive searches ($^3$He, $^{129}$Xe, $^{199}$Hg, $^{201}$Hg). Consequently, the limits are formulated on the pseudoscalar coupling to neutrons, as it is also the case for the limits on the external Lorentz-violating axial-vector backgrounds [35].
In fact, one can refine these bounds and impose separate constraints on the strength of the pseudoscalar coupling for protons and neutrons. Although most of the nuclei in atoms used in experiments [29]-[32] have a valence neutron outside of closed shells, one can use the information on the magnetic moments of these nuclei together with simple theoretical model of nuclear structure to deduce the proton contribution to the total nuclear spin. To be specific we shall assume that the magnetic moment of the nucleus is composed entirely from the spin magnetic moment of the valence neutron and spin magnetism of polarized nuclear core,

\[ \mu = \mu_n \langle \sigma_z^{(n)} \rangle + \mu_p \langle \sigma_z^{(p)} \rangle \]
\[ \langle \sigma_z^{(n)} \rangle + \langle \sigma_z^{(p)} \rangle = \langle \sigma_z^{(0)} \rangle. \] (4.23)

In these equations, \( \mu, \mu_p, \mu_n \) are the magnetic moment of the nucleus, proton and neutron. Numerical estimates show that the orbital contribution to the magnetic moment \( \mu \) in the nuclei of interest is less important than the spin contribution since the neutron orbital contribution is zero and the proton orbital contribution is small in comparison with the proton spin contribution. The latter is enhanced by the large value of the proton magnetic moment \( \mu_p = 2.8 \), which justifies the neglection of proton orbital magnetism for low \( l \) orbitals. Neglection of spin-orbit interaction makes total spin conserved and its total value equal to the average spin of the neutron above the unpolarized core, \( \langle \sigma_z^{(0)} \rangle \). The latter is equal to 1 for \( j = l + 1/2 \) and \( -j/(j+1) \) for \( j = l - 1/2 \), where \( j \) is the value of the nuclear angular momentum, and \( l \) is the orbital quantum number of the valence neutron. Using these simple formulae (4.23), we determine \( \langle \sigma_z^{(n)} \rangle \) and \( \langle \sigma_z^{(p)} \rangle \) for observationally relevant cases of \(^{199}\text{Hg}, \ ^{201}\text{Hg}, \ ^{129}\text{Xe}, \) and \(^3\text{He} \) as shown in Table 1.

| nucleus | \( \mu \) | \( j, l \) | \( \langle \sigma_z^{(0)} \rangle \) | \( \langle \sigma_z^{(n)} \rangle \) | \( \langle \sigma_z^{(p)} \rangle \) |
|--------|--------|--------|----------------|----------------|----------------|
| \(^3\text{He}\) | -2.13  | 1/2, 0 | 1.04           | -0.04          |                |
| \(^{129}\text{Xe}\) | -0.78  | 1/2, 0 | 0.76           | 0.24           |                |
| \(^{199}\text{Hg}\) | 0.50   | 1/2, 1 | -0.31          | -0.03          |                |
| \(^{201}\text{Hg}\) | -0.56  | 3/2, 1 | 0.71           | 0.29           |                |

Table 1: Composition of the nuclear spin

One can see that the contribution of the proton spin into the total spin of these nuclei, especially \(^{129}\text{Xe} \) and \(^{201}\text{Hg} \), can be as high as 30%, and therefore the proton pseudoscalar coupling is also limited in these experiments. For example, experiment [29] limits the following combination of the proton and neutron couplings:

\[ |M_{P_{\text{eff}}} M_S| > 1.5 \times 10^{-4} M^2_{P_{\text{I}}} \], \text{ where } M_{P_{\text{eff}}}^1 = -0.5M_{P_{\text{n}}}^1 + 0.7M_{P_{\text{p}}}^1. \] (4.24)
The relative enhancement of the proton contribution is due to a rather close cancellation of neutron contribution to the differential frequency of spin precession for $^{199}\text{Hg}$ and $^{201}\text{Hg}$.

As a bi-product of our analysis, we can improve the bounds on the Lorentz-violating axial-vector couplings in the Colladay-Kostelecky parametrization [34]. Indeed, the spatial components of the axial vector background to protons, $b_\mu$, is constrained in the same experiments, Refs. [31, 32], in particular because of the substantial contribution of proton spin to the spin of $^{129}\text{Xe}$. For example, the interpretation of the null result of the most sensitive experiment [32] with the use of the analysis [35] that assumes $\langle \sigma_z^{(n)} \rangle = -\langle \sigma_z^{(p)} \rangle$, and our work differ in the following way:

$$2\pi\nu_{LV} = 2b_i^{(n)} \left(1 - \frac{\mu_{\text{He}}}{\mu_{\text{Xe}}}\right) = -3.5b_i^{(n)}, \text{ Ref.}[35]$$

$$2\pi\nu_{LV} = 2(0.76b_i^{(n)} + 0.24b_i^{(p)}) - \frac{\mu_{\text{He}}}{\mu_{\text{Xe}}}(1.04b_i^{(n)} - 0.04b_i^{(p)}) = -4.2b_i^{(n)} + 0.7b_i^{(p)} \text{ this work},$$

where $\nu_{LV} = 53\pm45 \text{ nHz}$ is the experimentally measured (and consistent with zero) Lorentz-violating frequency shift [32]. Obviously, the contribution of $b_i^{(p)}$ to $\nu_{LV}$ is non-negligible, and implies that $|b_i^{(p)}| < \text{few} \times O(10^{-31}) \text{ GeV}$, which is far better than the results of dedicated searches of Lorentz violation in the proton sector with e.g. hydrogen maser [36].

Besides the constraints on nucleon and electron couplings, the same clock comparison experiments allow to set limits on $M_{P\gamma}$. For example, for an atom (or nucleus) with the total angular momentum $J$, the matrix element of $\phi \hat{F} \hat{F}$ interaction is not zero,

$$\langle J | \int d^3x \frac{4(\mathbf{E} \cdot \mathbf{B})}{M_{P\gamma}} | J \rangle = \frac{\kappa}{M_{P\gamma}} \left( \frac{J}{|J|} \cdot \nabla \phi \right), \quad (4.25)$$

where $\kappa$ is a dimensionless matrix element that can be calculated explicitly. For the ground state of the hydrogen atom, $\kappa$ is given by

$$\kappa = \frac{8\epsilon \mu_B}{3a_0} = \frac{4\alpha^2}{3}, \quad (4.26)$$

where $a_0$ and $\mu_B$ are Bohr radius and magneton, and $\alpha$ is the fine structure constant. This calculation take into account the magnetic field generated by the electron magnetic moment, and the electric field of the proton. If we consider both E and B created by the electron, we discover that the result has a logarithmic divergence in the ultraviolet regime that has the interpretation of $1/M_{P\epsilon}$, being generated by $1/M_{P\gamma}$. Even with a modestly low choice of the cutoff, the coefficient is going to be on the order of $\alpha/\pi \sim O(10^{-3})$ and thus parametrically larger than (4.26).

What happens if instead of an atomic electron we consider a nucleus where the electric field is considerably stronger? To understand the scaling of the effect with Z, we consider a simplified case of a single s-wave neutron above the closed nuclear shells with "uniform"
distribution of its wave function inside the nucleus, which also has uniform charge distribution within a sphere of radius $R_N \simeq 1.2 \text{ fm} \, (A)^{1/3}$. The resulting $\kappa$ can be expressed in terms of the neutron magnetic moment,

$$\kappa = \frac{8}{5} \frac{2\mu_n Z e}{R_N} = \frac{4}{5} \frac{g_n Z \alpha}{m_p R_N} = 0.05 - 0.07 \quad \text{for} \quad Z \sim 80,$$

(4.27)

where the overall numerical coefficient follows from the approximation of the radial matrix element, $\langle r^2/(2R_N^2) - 3/2 \rangle_{r<R_N} = -6/5$. Although an overall numerical coefficient in estimate (4.27) cannot be taken very seriously, the parametric dependence on $Z$, $\mu_n$ and $R_N$ is certainly expected to hold for large nuclei. For mercury this effect is larger than the loop-induced admixture of the photon coupling into the nucleon coupling. Thus we can deduce the sensitivity of spin precession experiments to the pseudoscalar couplings to photons at 5% level from the coupling to neutrons:

$$|M_{P\gamma}M_S| \gtrsim O(10^{-5}) \, M_{Pl}^2 \quad \text{Ref. [29]}$$

(4.28)

One can see that the combined bounds from the clock comparison experiments are comparable to or better than the product of separate bounds (2.10) and (2.11). Unfortunately, these bounds do not allow to probe the pseudoscalar coupling to fermions all the way to the "natural" scale $M_P \sim M_{Pl}$.

5  Conclusions

Our paper considers the constraints on the combination of scalar and pseudoscalar couplings in the scalar-tensor theories of gravity. The strongest constraints come from the considerations of cosmological evolution of polarized light, and in the best case scenario of the maximal scalar coupling, consistent with constraints on Brans-Dicke theories, the sensitivity to the pseudoscalar coupling to photons can be as large as the Planck scale. However, the cosmological constraints are not sensitive to the derivative pseudoscalar couplings to fermions as they do not induce corresponding photon couplings even at the loop level. We also point out that for a wide range of pseudoscalar masses, one can avoid cosmological constraints due to the red-shifting of $\phi$-oscillations. Therefore, the laboratory constraints on spin precession from locally generated gradient of $\phi$ are complimentary to cosmological bounds. We revisited lab bounds to find that the most sensitive experiments are still few orders of magnitude below the sensitivity to Planck-scale-suppressed couplings. We also note that the local spin precession experiments provide sensitivity to the pseudoscalar coupling to photons, through the relatively large matrix element of $\phi \mathbf{B} \cdot \mathbf{E}$ interaction inside atomic nuclei. As a separate remark, we have shown that nuclei of atoms used in the high-precision clock comparison experiments have significant proton contribution to their spins.
This allows to set separate constraints on pseudoscalar couplings to neutrons and protons, and improve the limit on Lorentz-violating axial-vector backgrounds in the proton sector. Further progress in experiments searching for a preferred Lorentz frame would also provide better sensitivity to the scalar-tensor theories extended by pseudoscalar couplings.

Acknowledgements. The authors would like to express their gratitude to W. Israel, who took an active part in the initial discussions that led to this project. M.P. would like to acknowledge useful conversations with M. Romalis. V.F. and S.L. thank Perimeter Institute for hospitality.
