A Case of Synchronous Lung Adenocarcinoma and Extranodal Marginal Zone B-Cell Lymphoma of Mucosa-Associated Lymphoid Tissue (MALT) Type

Chi Young Jung, M.D.¹, Kun Young Kwon, M.D.²
Departments of ¹Internal Medicine and ²Pathology, Keimyung University School of Medicine, Daegu, Korea

Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue type (extranodal MZL) is a distinct subgroup of non-Hodgkin's lymphoma. Pulmonary extranodal MZL is a rare entity and accounts for less than 0.5% of primary pulmonary malignancies. Only a few cases of simultaneous occurrence of lung cancer and pulmonary extranodal MZL have been reported. A 60-year-old woman was referred to our hospital with a pulmonary nodule. She was diagnosed with lung adenocarcinoma by percutaneous needle biopsy. The protrusions into the left main bronchus were found by accident while performing bronchoscopy during lung cancer evaluation. The bronchial lesions were diagnosed as extranodal MZL. Although the patient underwent surgical resection for the lung adenocarcinoma, the pulmonary extranodal MZL was left untreated; it was monitored during follow-up visits. To our knowledge, this is the first report of synchronous lung adenocarcinoma and primary extranodal MZL of the main bronchus.

Key Words: Lymphoma, B-Cell, Marginal Zone; Adenocarcinoma of Lung; Lung Neoplasms

Introduction

Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT) type (extranodal MZL), also called MALT lymphoma, is a distinct subgroup of non-Hodgkin's lymphoma (NHL) that constitutes about 5% of all NHLs. Although the stomach is involved most frequently, the lung is one of the most common sites among non-gastrointestinal sites in extranodal MZL. More than two thirds of primary pulmonary NHLs are extranodal MZLs but they account for less than 0.5% of all primary lung neoplasms.

The simultaneous occurrence of gastric adenocarcinoma and gastric extranodal MZL has often been documented. However, only a few cases of simultaneous lung cancer and pulmonary extranodal MZL have been reported. Also, it is extremely rare that primary extranodal MZL occurs in the large airways. To our knowledge, only one case of lung cancer coexisting with extranodal MZL of the large airway has been reported. We report a case of synchronous lung adenocarcinoma and primary extranodal MZL of the left main bronchus.

Case Report

A 60-year-old woman was referred to our hospital with a pulmonary nodule in the right upper lung seen on chest radiograph during a routine health checkup. She had been treated curatively with surgical resection for papillary thyroid carcinoma 3 years ago. She had never smoked. There was no history of respiratory illness such as tuberculosis. Her vital signs were normal, and physical examination revealed no abnormalities,
Laboratory data were within the normal range except a tumor marker, carcinoembryonic antigen, which had a level of 6.07 ng/mL. Pulmonary function testing revealed no ventilatory defect.

A chest radiograph showed a nodule in the right upper lung (Figure 1A). A chest computed tomographic (CT) scan showed a peripherally located 2.4 × 1.8 cm sized solid nodule in the anterior segment of the right upper lobe (Figure 1B). Fluorine 18-labeled fluorodeoxyglucose (FDG)-positron emission tomography-CT scan revealed abnormal FDG uptake in the right upper lobe lung nodule and in the right hilar lymph node (Figure 2). She underwent CT image-guided percutaneous core needle biopsy of the nodule in the right upper lobe. Additionally, a flexible bronchoscopic examination was performed to identify the endobronchial lesion. At bronchoscopy, a few small variable-sized protrusions were observed in the proximal left main bronchus and a biopsy was performed (Figure 3).

The needle biopsy specimens of the right lung nodule showed non-mucinous adenocarcinoma with a lepidic and acinar growth pattern (Figure 4A). Immunohistochemical stains were positive for cytokeratin (CK) 7 and thyroid transcription factor-1, and negative for CK20 (Figure 4B–D). Histopathology of the bronchoscopic biopsy specimens of the left main bronchus lesions showed diffuse proliferation of atypical lymphoid cells beneath the mucosal epithelium (Figure 5A). Immuno-
Figure 4. The computed tomography-guided percutaneous needle biopsy specimens of the right lung nodule. (A) Lung tumor tissue shows non-mucinous adenocarcinoma with a lepidic and acinar growth pattern and stromal infiltration. Immunohistochemical stains were positive for (B) cytokeratin (CK) 7 and (C) thyroid transcription factor-1, and negative for (D) CK20 (A–D, ×200).

histochemical stains showed diffuse strong positive for CD20, and were negative for pan cytokeratin and CD10 (Figure 5B–D). The proliferation fraction (Ki67) was very low (<5%). The bronchial lesion was diagnosed as extranodal MZL. A bone scan and a brain magnetic resonance imaging study found no other abnormal lesion. A gastroduodenoscopy revealed no mucosal abnormality.

She underwent right upper lobectomy and lymph node dissection for the lung adenocarcinoma. However, she did not receive specialized therapy for extranodal MZL of the left main bronchus. Since then she has been observed regularly.

Discussion

In 1983, Isaacson and Wright first described two cases of MALT lymphoma arising in the gastrointestinal tract. Recently, it has been reclassified as extranodal marginal zone B-cell lymphoma of MALT type in the revised European-American classification of lymphoid neoplasms and the World Health Organization classification.

Extranodal MZL is an extranodal lymphoma with 'low grade' features that infiltrates the marginal zone of reactive B-cell follicles. Extranodal MZL arises from the MALT of the stomach most frequently and also from lung, salivary gland, and thyroid gland.
Pulmonary extranodal MZL is a rare entity and accounts for less than 0.5% of primary pulmonary malignancies, and less than 1% of all lymphomas\(^5\). Lung adenocarcinoma usually arises from peripheral small bronchi or alveolar epithelial cells and is increasing in incidence globally.

Synchronous primary malignancy and extranodal MZL in the same anatomical sites, such as stomach and lung is very unusual\(^8\). To our knowledge, there is only one other report showing the coexistence of lung cancer and pulmonary extranodal MZL of the large airway\(^9\). However, in that case, the histology of lung cancer was squamous cell carcinoma\(^9\). The present case is the first report of the simultaneous occurrence of lung adenocarcinoma and pulmonary extranodal MZL of the large airway.

The pathogenesis of extranodal MZL may be associated with chronic immune stimulation driven by infection or autoimmune disorder. The strong association between *Helicobacter pylori* and gastric extranodal MZL is known\(^2,4\). However, the etiology of pulmonary extranodal MZL is unclear\(^7\).

The simultaneous occurrence of adenocarcinoma and extranodal MZL in the stomach is well established. *H. pylori* seems to be one of the common causes of both diseases\(^8\).

The cause of the synchronous lesions in our case is uncertain. We postulate that a pulmonary extranodal MZL may coincide with a lung adenocarcinoma by accident. Little is known about the mechanism of the
simultaneous occurrence of these different tumors. Moreover, the two different malignancies were located in different lungs in this case. However, other possible causes may include common etiologic factors and genetic or epigenetic alterations participating in the development of both the lung adenocarcinoma and extranodal MZL. One case report speculated that smoking could lead to both lung cancer and extranodal MZL. Another report suggested that the API2-MALT1 fusion gene or factors associated with the gene may play a role in the development of both diseases. In the current case, the patient had never smoked, and no examination for genetic change was performed. Further studies will be required to clarify the relationship between lung adenocarcinoma and pulmonary extranodal MZL. It is necessary to accumulate more cases with both malignancies.

Approximately half of the patients are asymptomatic at presentation, with abnormal radiologic findings being discovered on chest radiograph. Symptomatic patients present with nonspecific pulmonary symptoms, including cough, dyspnea, chest pain and hemoptysis. B symptoms are uncommon and observed in only a few patients. In this current case, the patient with lung cancer was asymptomatic and the protrusions into the left main bronchus were found by accident while performing bronchoscopy during lung cancer evaluation.

The major radiographic patterns of pulmonary extranodal MZL have been reported as nodules, consolidation, ground-glass opacity, and centrilobular nodules with linear branching opacities (tree-in-bud sign). In the one published report on CT findings, single or multiple nodules or areas of consolidation were the main patterns, while none exhibited involvement of the main bronchus. In the most recent Korean study, of the 61 enrolled patients, only two had masses in the main bronchus. Therefore, our case is unusual because the patient presented with endobronchial protrusions without lung parenchymal lesions on bronchoscopy.

Although diagnosis can be achieved by bronchoscopic or transbronchial biopsy or by percutaneous needle biopsy, surgical lung biopsy is required in many cases. Extranodal MZL is characterized by an infiltrate of small to medium-sized lymphocytes with irregular nuclei and abundant cytoplasm. Reactive follicles are usually observed. Lymphoepithelial lesions, in which tumor cells infiltrate the bronchial, bronchiolar, and alveolar epithelium, are characteristic but not pathognomonic.

The tumor cells are positive for B cell markers (CD19, CD20, CD22, CD79a) and complement receptors (CD21 and CD35), and are usually negative for CD5, CD10, and CD23. The proliferation fraction (Ki67) is usually very low (<10%). Immunophenotyping studies are useful in confirming diagnosis, particularly when done on small biopsy specimens, and in differentiating this malignancy from diffuse large B cell lymphoma, small lymphocytic lymphoma, mantle cell lymphoma and follicular lymphoma.

There is controversy about the optimal treatment of extranodal MZL; treatment ranges from observation only to surgery, radiotherapy or chemotherapy alone or in combination. Surgical resection and radiotherapy are preferred for localized cases and chemotherapy may be considered for bulky or disseminated cases. However, treatment protocols have not yet been established. If the patient is asymptomatic, the treatment may be a watch-and-wait policy instead of attempting immediate curative treatment.

Pulmonary extranodal MZL is an indolent disease and has a favorable prognosis. The five-year survival rate is about 90%. Extrapulmonary lesions and lymph node involvement are poor prognostic factors.

In the present case, although the patient underwent surgical resection for the lung adenocarcinoma, the pulmonary extranodal MZL was left untreated, and monitored during follow-up visits.

Here, we report a unique case of pulmonary extranodal MZL of main bronchus coexisting with lung adenocarcinoma. The patient was asymptomatic and was diagnosed with pulmonary extranodal MZL by chance during investigation of an endobronchial lesion.
